In the constant concentration technique, the tracer gas injection rate is adjusted to maintain a constant concentration within the building. If the concentration is truly constant, then Equation (16) reduces to

$$Q(\theta) = F(\theta)/C \quad (19)$$

There is less experience with this technique than with the decay procedure, but an increasing number of applications exist (Bohac et al. 1985; Collet 1981; Fortmann et al. 1990; Kumar et al. 1979; Walker and Forest 1995; Walker and Wilson 1998; Wilson and Walker 1993).

Because tracer gas injection is continuous, no initial mixing period is required. Another advantage is that tracer gas injection into each zone of the building can be separately controlled; thus, the amount of outdoor air flowing into each zone can be determined. This procedure is best suited for longer-term continuous monitoring of fluctuating infiltration rates. One disadvantage is that it requires measurement of absolute tracer concentrations and injection rates. Also, imperfect mixing of the tracer and interior air causes a delay in the response of the concentration to changes in the injection rate.

Constant Injection

In the constant-injection procedure, the tracer is injected at a constant rate, and the solution to Equation (16) becomes

$$C(\theta) = (F/Q)(1 - e^{-I\theta}) \quad (20)$$

After sufficient time, the transient term reduces to zero, the concentration attains equilibrium, and Equation (20) reduces to

$$Q = F/C \quad (21)$$

Equation (21) is valid only when air exchange rate I and airflow rate Q are constant; thus, this technique is only appropriate for systems at or near equilibrium. It is particularly useful in spaces with mechanical ventilation or with high air exchange rates. Constant injection requires measurement of absolute concentrations and injection rates.

Dietz et al. (1986) used a special case of the constant-injection technique, using permeation tubes as a tracer gas source. The tubes release the tracer at an ideally constant rate into the building being tested, and a sampling tube packed with an adsorbent collects the tracer from the interior air at a constant rate by diffusion. After a sampling period of one week or more, the sampler is removed and analyzed to determine the average tracer gas concentration within the building during the sampling period.

Solving Equation (16) for C and taking the time average gives

$$\langle C \rangle = \langle F/Q \rangle = F \langle 1/Q \rangle \quad (22)$$

where $\langle \dots \rangle$ denotes time average. Note that the time average of dC/dt is assumed to equal zero.

Equation (22) shows that the average tracer concentration $\langle C \rangle$ and injection rate F can be used to calculate the average of the inverse airflow rate. The average of the inverse is less than the inverse of the actual average, with the magnitude of this difference depending on the distribution of airflow rates during the measurement period. Sherman and Wilson (1986) calculated these differences to be about 20% for one-month averaging periods. Differences greater than 30% have been measured when occupant airing of houses caused large changes in air exchange rate; errors from 5 to 30% were measured when the variation was caused by weather effects (Bohac et al. 1987). Longer averaging periods and large changes in air exchange rates during the measurement periods generally lead to larger differences between the average inverse exchange rate and the inverse of the actual average rate.

Multizone Air Exchange Measurement

Equation (16) is based on the assumption of a single, well-mixed enclosure, and the techniques described are for single-zone measurements. Airflow between internal zones and between the exterior and individual internal zones has led to the development of multizone measurement techniques (Fortmann et al. 1990; Harje et al. 1985; Harje et al. 1990; Sherman and Dickerhoff 1989). These techniques are important when considering the transport of pollutants from one room of a building to another. A theoretical development is provided by Sinden (1978a). Multizone measurements typically use either multiple tracer gases for the different zones or the constant-concentration technique. A proper error analysis is essential in all multizone flow determination (Charlesworth 1988; D'Ottavio et al. 1988).

DRIVING MECHANISMS FOR VENTILATION AND INFILTRATION

Natural ventilation and infiltration are driven by pressure differences across the building envelope caused by wind and air density differences because of temperature differences between indoor and outdoor air (buoyancy, or the stack effect). Mechanical air-moving systems also induce pressure differences across the envelope through operation of appliances, such as combustion devices, leaky forced-air thermal distribution systems, and mechanical ventilation systems. The indoor/outdoor pressure difference at a location depends on the magnitude of these driving mechanisms as well as on the characteristics of the openings in the building envelope (i.e., their locations and the relationship between pressure difference and airflow for each opening).

Stack Pressure

Stack pressure is the hydrostatic pressure caused by the weight of a column of air located inside or outside a building. It can also occur within a flow element, such as a duct or chimney that has vertical separation between its inlet and outlet. The hydrostatic pressure in the air depends on density and the height of interest above a reference point.

Air density is a function of local barometric pressure, temperature, and humidity ratio, as described in Chapter 1. As a result, standard conditions should not be used to calculate the density. For example, a building site at 5000 ft has air density that is about 20% less than if the building were at sea level. An air temperature increase from -20 to 70°F causes a similar air density difference. Combined, these elevation and temperature effects reduce air density about 45%. Moisture effects on density are generally negligible, so dry air density can be used instead, except in hot, humid climates when air is hot and close to saturation. For example, saturated air at 105°F has density about 5% less than that of dry air.

Assuming temperature and barometric pressure are constant over the height of interest, the stack pressure decreases linearly as the separation above the reference point increases. For a single column of air, the stack pressure can be calculated as

$$p_s = p_r - 0.00598\rho gH \quad (23)$$

where

- p_s = stack pressure, in. of water
- p_r = stack pressure at reference height, in. of water
- g = gravitational acceleration, 32.2 ft/s²
- ρ = indoor or outdoor air density, lb_m/ft³
- H = height above reference plane, ft
- 0.00598 = unit conversion factor, (in. of water) · ft · s²/lb_m

For tall buildings or when significant temperature stratification occurs indoors, Equation (23) should be modified to include the density gradient over the height of the building.

Temperature differences between indoors and outdoors cause stack pressure differences that drive airflows across the building envelope; the **stack effect** is this buoyancy phenomenon. Sherman (1991) showed that any single-zone building can be treated as an equivalent box from the point of view of stack effect, if its leaks follow the power law as described in the section on Residential Air Leakage. The building is then characterized by an effective stack height and neutral pressure level (NPL) or leakage distribution, as described in the section on Neutral Pressure Level. Once calculated, these parameters can be used in physical, single-zone models to estimate infiltration.

Neglecting vertical density gradients, the stack pressure difference for a horizontal leak at any vertical location is given by

$$\begin{aligned} \Delta p_s &= 0.00598(\rho_o - \rho_i)g(H_{NPL} - H) \\ &= 0.00598\rho_o \left(\frac{T_i - T_o}{T_i} \right) g(H_{NPL} - H) \end{aligned} \quad (24)$$

where

- T_o = outdoor temperature, °R
- T_i = indoor temperature, °R
- ρ_o = outdoor air density, lb/ft³
- ρ_i = indoor air density, lb/ft³
- H_{NPL} = height of neutral pressure level above reference plane without any other driving forces, ft

Chastain and Colliver (1989) showed that, when there is stratification, the average of the vertical distribution of temperature differences is more appropriate to use in Equation (24) than the localized temperature difference near the opening of interest.

By convention, stack pressure differences are positive when the building is pressurized relative to outdoors, which causes flow out of the building. Therefore, absent other driving forces and assuming no stack effect within the flow elements themselves, when indoor air is warmer than outdoors, the base of the building is depressurized and the top is pressurized relative to outdoors; when indoor air is cooler than outdoors, the reverse is true.

Absent other driving forces, the location of the NPL is influenced by leakage distribution over the building exterior and by interior compartmentation. As a result, the NPL is not necessarily located at the mid-height of the building; with effective horizontal barriers in tall buildings, it is also possible to have more than one NPL. NPL location and leakage distribution are described later in the section on Combining Driving Forces.

For a penetration through the building envelope for which (1) there is vertical separation between its inlet and outlet and (2) air inside the flow element is not at the indoor or outdoor temperature, such as in a chimney, more complex analyses than Equation (24) are required to determine the stack effect at any location on the building envelope.

Wind Pressure

When wind impinges on a building, it creates a distribution of static pressures on the building's exterior surface that depends on the wind direction, wind speed, air density, surface orientation, and surrounding conditions. Wind pressures are generally positive with respect to the static pressure in the undisturbed airstream on the windward side of a building and negative on the leeward sides. However, pressures on these sides can be negative or positive, depending on wind angle and building shape. Static pressures over building surfaces are almost proportional to the velocity head of the undisturbed airstream. The wind pressure or velocity head is given by the Bernoulli equation, assuming no height change or pressure losses:

$$p_w = 0.0129C_p\rho\frac{U^2}{2} \quad (25)$$

where

- p_w = wind surface pressure relative to outdoor static pressure in undisturbed flow, in. of water
- ρ = outside air density, lb_m/ft³ (about 0.075 at or near sea level)
- U = wind speed, mph
- C_p = wind surface pressure coefficient, dimensionless
- 0.0129 = unit conversion factor, (in. of water) · ft³/lb_m · mph²

C_p is a function of location on the building envelope and wind direction. Chapter 24 provides additional information on values of C_p .

Most pressure coefficient data are for winds normal to building surfaces. Unfortunately, for a real building, this fixed wind direction rarely occurs, and when the wind is not normal to the upwind wall, these pressure coefficients do not apply. Walker and Wilson (1994) developed a harmonic trigonometric function to interpolate between the surface average pressure coefficients on a wall that were measured with the wind normal to each of the four building surfaces. This function was developed for low-rise buildings three stories or less in height. For each wall of the building, C_p is given by

$$\begin{aligned} C_p(\phi) &= 1/2 \{ [C_p(1) + C_p(2)](\cos^2 \phi)^{1/4} \\ &\quad + [C_p(1) - C_p(2)](\cos \phi)^{3/4} \\ &\quad + [C_p(3) - C_p(4)](\sin^2 \phi)^2 \\ &\quad + [C_p(3) - C_p(4)]\sin \phi \} \end{aligned} \quad (26)$$

where

- $C_p(1)$ = pressure coefficient when wind is at 0°
- $C_p(2)$ = pressure coefficient when wind is at 180°
- $C_p(3)$ = pressure coefficient when wind is at 90°
- $C_p(4)$ = pressure coefficient when wind is at 270°
- ϕ = wind angle measured clockwise from the normal to wall 1

Because the cosine term in Equation (26) can be negative, its sign must be tracked. When $\cos(\phi)$ is negative, subtract the value of the absolute of $\cos(\phi)$ to the 3/4 power.

The measured data used to develop the harmonic function from Akins et al. (1979) and Wiren (1985) show that typical values for the pressure coefficients are $C_p(1) = 0.6$, $C_p(2) = -0.3$, $C_p(3) = C_p(4) = -0.65$. Because of geometry effects on flow around a building, application of this interpolation function is limited to low-rise buildings of rectangular plan form (i.e., not L-shaped) with the longest wall less than three times the length of the shortest wall. For less regular buildings, simple correlations are inadequate and building-specific pressure coefficients are required. Chapter 24 discusses wind pressures for complex building shapes and for high-rise buildings in more detail.

The wind speed most commonly available for infiltration calculations is that measured at the local weather station, typically the nearest airport. This wind speed needs to be corrected for reductions caused by the difference between the height where the wind speed

is measured and the height of the building, and reductions caused by shelter effects.

The reference wind speed used to determine pressure coefficients is usually the wind speed at the eaves height for low-rise buildings and the building height for high-rise buildings. However, meteorological wind speed measurements are made at a different height (typically 33 ft) and at a different location. The difference in terrain between the measurement station and the building under study must also be accounted for. Chapter 24 shows how to calculate the effective wind speed U_H from the reference wind speed U_{met} using boundary layer theory and estimates of terrain effects.

In addition to the reduction in wind pressures caused by reduced wind speed, the effects of local shelter also act to reduce wind pressures. The shielding effects of trees, shrubbery, and other buildings within several building heights of a particular building produce large-scale turbulence eddies that not only reduce effective wind speed but also alter wind direction. Thus, meteorological wind speed data must be reduced carefully when applied to low buildings.

Ventilation rates measured by Wilson and Walker (1991) for a row of houses showed reductions in ventilation rates of up to a factor of three when the wind changed direction from perpendicular to parallel to the row. They recommended estimating wind shelter for winds perpendicular to each side of the building and then using the interpolation function in Equation (27) to find the wind shelter for intermediate wind angles:

$$s = \frac{1}{2} \left\{ \begin{array}{l} [s(1) + s(2)] \cos^2 \phi + [s(1) - s(2)] \cos \phi \\ + [s(3) + s(4)] \sin^2 \phi + [s(3) - s(4)] \sin \phi \end{array} \right\} \quad (27)$$

where

- s = shelter factor for the particular wind direction ϕ
- $s(i)$ = shelter factor when wind is normal to wall i ($i = 1$ to 4, for four sides of a building)

Although this method gives a realistic variation of wind shelter effects with wind direction, estimates for numerical values of wind shelter factor s for each of the four cardinal directions must be provided. Table 8 in the section on Residential Calculation Examples lists typical shelter factors. The wind speed used in Equation (25) is then given by

$$U = sU_H \quad (28)$$

The magnitude of pressure differences found on the surfaces of buildings varies rapidly with time because of turbulent fluctuations in the wind (Etheridge and Nolan 1979; Grimsrud et al. 1979). However, using average wind pressures to calculate pressure differences is usually sufficient to calculate average infiltration values.

Mechanical Systems

Operation of mechanical equipment, such as supply or exhaust systems and vented combustion devices, affects pressure differences across the building envelope. Interior static pressure adjusts such that the sum of all airflows through openings in the building envelope plus equipment-induced airflows balance to zero. To predict these changes in pressure differences and airflow rates caused by mechanical equipment, the location of each opening in the envelope and the relationship between pressure difference and airflow rate for each opening must be known. The interaction between mechanical ventilation system operation and envelope airtightness has been discussed for low-rise buildings (Nylund 1980) and for office buildings (Persily and Grot 1985a; Tamura and Wilson 1966, 1967a).

Air exhausted from a building by a whole-building exhaust system must be balanced by increasing airflow into the building through other openings. As a result, airflow at some locations changes from outflow to inflow. For supply fans, the situation is

reversed and envelope inflows become outflows. Thus, the effects of a mechanical system on a building must be considered. Depressurization caused by an improperly designed exhaust system can increase the rate of radon entry into a building and interfere with proper operation of combustion device venting or other exhaust systems. Depressurization can also force moist outdoor air through the building envelope; for example, during the cooling season in hot, humid climates, moisture may condense within the building envelope and cause rust, rot, or mold. A similar phenomenon, but in reverse, can occur during the heating (and potentially humidifying) season in cold climates if the building is pressurized.

The interaction between mechanical systems and the building envelope also pertains to systems serving zones of buildings. Performance of zone-specific exhaust or pressurization systems is affected by leakage in zone partitions as well as in exterior walls.

Mechanical systems can also create infiltration-driving forces in single-zone buildings. Specifically, some single-family houses with central forced-air duct systems have multiple supply registers, yet only a central return grille. When internal doors are closed in these houses, large positive indoor/outdoor pressure differentials are created for rooms with only supply registers, whereas the room or hallway with the return grille tends to depressurize relative to outside. This is caused by the resistance of internal door undercuts, often partially blocked by carpeting, to flow from the supply register to the return (Modera et al. 1991). The magnitudes of the indoor/outdoor pressure differentials created have been measured to average 0.012 to 0.024 in. of water (Modera et al. 1991). Balanced airflow systems, with ducted air return and distributed grilles, or adequately sized transfer grilles (where allowed by fire code) reduce this significantly.

Building envelope airtightness and interzonal airflow resistance can also affect performance of mechanical systems. The actual airflow rate delivered by these systems, particularly ventilation systems, depends on the pressure they work against. This effect is the same as the interaction of a fan with its associated ductwork, which is discussed in Chapter 21 of this volume and Chapter 20 of the 2008 *ASHRAE Handbook—HVAC Systems and Equipment*. The building envelope and its leakage must be considered part of the ductwork in determining the pressure drop of the system.

Duct leakage can cause similar problems. Supply leaks to the outside tend to depressurize the building; return leaks to the outside tend to pressurize it. Keeping ducts within the conditioned buildings, and sealing ducts well with durable materials and high-quality construction methods, significantly reduces this problem.

Combining Driving Forces

Pressure differences caused by wind, stack effect, and mechanical systems are considered in combination by adding them together and then determining the resulting airflow rate through each building envelope. The airflows must be determined in this manner, as opposed to adding the airflow rates due to the separate driving forces, because the airflow rate through each opening is not linearly related to pressure difference.

For uniform indoor air temperatures, the total pressure difference across each leak can be written in terms of a reference wind parameter P_U and stack effect parameter P_T common to all leaks:

$$P_U = \rho_o \frac{U_H^2}{2} \quad (29)$$

$$P_T = g\rho_o[(T_i - T_o)/T_i] \quad (30)$$

where T is air temperature, in °R.

The pressure difference across each leak, with positive pressures for flow into the building, is then given by

$$\Delta p = 0.0129s^2C_pP_U + HP_T + \Delta p_I \quad (31)$$

where Δp_i is the pressure that acts to balance inflows and outflows, including mechanical system flows. Equation (31) can then be applied to every leak for the building with appropriate values of C_p , s , and H . Thus, each leak is defined by its pressure coefficient, shelter, and height. Where indoor pressures are not uniform, more complex analyses are required.

Neutral Pressure Level

The neutral pressure level (NPL) is that location or locations in the building envelope where there is no indoor-to-outdoor pressure difference. Internal partitions, stairwells, elevator shafts, utility ducts, chimneys, vents, operable windows, and mechanical supply and exhaust systems complicate the prediction of NPL location. An opening with a large area relative to the total building leakage causes the NPL to shift toward the opening. In particular, chimneys and openings at or above roof height raise the NPL in small buildings. Exhaust systems increase the height of the NPL; outdoor air supply systems lower it.

Figure 6 qualitatively shows the addition of driving forces for a building with uniform openings above and below mid-height and without significant internal resistance to airflow. The slopes of the pressure lines are a function of the densities of the indoor and outdoor air. In Figure 6A, with inside air warmer than outside and pressure differences caused solely by thermal forces, the NPL is at mid-height, with inflow through lower openings and outflow through higher openings. Direction of flow is always from the higher to the lower pressure region.

Figure 6B presents qualitative uniform pressure differences caused by wind alone, with opposing effects on the windward and leeward sides. When temperature difference and wind effects both exist, the pressures caused by each are added together to determine the total pressure difference across the building envelope. In Figure 6B, there is no NPL because no locations on the building envelope have zero pressure difference. Figure 6C shows the combination, where the wind force of Figure 6B has just balanced the thermal force of Figure 6A, causing no pressure difference at the top windward or bottom leeward side.

The relative importance of wind and stack pressures in a building depends on building height, internal resistance to vertical airflow, location and flow resistance characteristics of envelope openings, local terrain, and the immediate shielding of the building. The taller the building and the smaller its internal resistance to airflow, the

stronger the stack effect. The more exposed a building is, the more susceptible it is to wind. For any building, there are ranges of wind speed and temperature difference for which the building's infiltration is dominated by stack effect, wind, or the driving pressures of both (Sinden 1978b). These building and terrain factors determine, for specific values of temperature difference and wind speed, in which regime the building's infiltration lies.

The effect of mechanical ventilation on envelope pressure differences is more complex and depends on both the direction of ventilation flow (exhaust or supply) and the differences in these ventilation flows among the zones of the building. If mechanically supplied outdoor air is provided uniformly to each story, the change in the exterior wall pressure difference pattern is uniform. With a nonuniform supply of outdoor air (for example, to one story only), the extent of pressurization varies from story to story and depends on internal airflow resistance. Pressurizing all levels uniformly has little effect on pressure differences across floors and vertical shaft enclosures, but pressurizing individual stories increases the pressure drop across these internal separations. Pressurizing the ground level is often used in tall buildings in winter to reduce negative air pressures across entries.

Available data on the NPL in various kinds of buildings are limited. The NPL in tall buildings varies from 0.3 to 0.7 of total building height (Tamura and Wilson 1966, 1967b). For houses, especially houses with chimneys, the NPL is usually above mid-height. Operating a combustion heat source with a flue raises the NPL further, sometimes above the ceiling (Shaw and Brown 1982).

Thermal Draft Coefficient

Compartmentation of a building also affects the NPL location. Equation (24) provides a maximum stack pressure difference, given no internal airflow resistance. The sum of pressure differences across the exterior wall at the bottom and top of the building, as calculated by these equations, equals the total theoretical draft for the building. The sum of actual top and bottom pressure differences, divided by the total theoretical draft pressure difference, equals the **thermal draft coefficient**. The value of the thermal draft coefficient depends on the airflow resistance of exterior walls relative to the airflow resistance between floors. For a building without internal partitions, the total theoretical draft is achieved across the exterior walls (Figure 7A), and the thermal draft coefficient equals 1. In a building with airtight separations at each floor, each story acts

Fig. 6 Distribution of Inside and Outside Pressures over Height of Building

independently, its own stack effect being unaffected by that of any other floor (Figure 7B). The theoretical draft is minimized in this case, and each story has an NPL.

Real multistory buildings are neither open inside (Figure 7A), nor airtight between stories (Figure 7B). Vertical air passages, stairwells, elevators, and other service shafts allow airflow between floors. Figure 7C represents a heated building with uniform openings in the exterior wall, through each floor, and into the vertical shaft at each story. Between floors, the slope of the line representing the inside pressure is the same as that shown in Figure 7A, and the discontinuity at each floor (Figure 7B) represents the pressure difference across it. Some of the pressure difference maintains flow through openings in the floors and vertical shafts. As a result, the pressure difference across the exterior wall at any level is less than it would be with no internal flow resistance.

Maintaining airtightness between floors and from floors to vertical shafts is a way to control indoor/outdoor pressure differences because of the stack effect and, therefore, infiltration. Good separation is also conducive to proper operation of mechanical ventilation and smoke management systems. However, care is needed

Fig. 7 Compartmentation Effect in Buildings

to avoid pressure differences that could prevent door opening in an emergency. Tamura and Wilson (1967a) showed that when vertical shaft leakage is at least two times envelope leakage, the thermal draft coefficient is almost one and the effect of compartmentation is negligible. Measurements of pressure differences in three tall office buildings by Tamura and Wilson (1967b) indicated that the thermal draft coefficient ranged from 0.8 to 0.9 with ventilation systems off.

INDOOR AIR QUALITY

Outdoor air requirements for acceptable indoor air quality (IAQ) have long been debated, and different rationales have produced radically different ventilation standards (Grimsrud and Teichman 1989; Janssen 1989; Klauss et al. 1970; Yaglou et al. 1936; Yaglou and Witheridge 1937). Historically, the major considerations have included the amount of outdoor air required to control moisture, carbon dioxide (CO₂), odors, and tobacco smoke generated by occupants. These considerations have led to prescriptions of a minimum rate of outdoor air supply per occupant. More recently, a major concern has been maintaining acceptable indoor concentrations of various additional pollutants that are not generated primarily by occupants. Engineering experience and field studies indicate that an outdoor air supply of about 20 cfm per person is very likely to provide acceptable perceived indoor air quality in office spaces, whereas lower rates may lead to increased sick building syndrome symptoms (Apte et al. 2000; Mendell 1993; Seppanen et al. 1999). Information on contaminants can be found in Chapter 11, and odors are covered in Chapter 12.

Indoor pollutant concentrations depend on the strength of pollutant sources and the total rate of pollutant removal. Pollutant sources include outdoor air; indoor sources such as occupants, furnishings, and appliances; dirty ventilation system ducts and filters; soil adjacent to the building; and building materials themselves, especially when new. Pollutant removal processes include dilution with outside air, local exhaust ventilation, deposition on surfaces, chemical reactions, and air-cleaning processes. If (1) general building ventilation is the only significant pollutant removal process, (2) indoor air is thoroughly mixed, and (3) pollutant source strength and ventilation rate have been stable for a sufficient period, then the steady-state indoor pollutant concentration is given by

$$C_i = C_o + 10^6 S / Q_{oa} \quad (32)$$

where

C_i = steady-state indoor concentration, ppm

C_o = outdoor concentration, ppm

S = total pollutant source strength, cfm

Q_{oa} = ventilation rate, cfm

Variation in pollutant source strengths (rather than variation in ventilation rate) is considered the largest cause of building-to-building variation in concentrations of pollutants that are not generated by occupants. Turk et al. (1989) found that a lack of correlation between average indoor respirable particle concentrations and whole-building outdoor ventilation rate indicated that source strength, high outdoor concentrations, building volume, and removal processes are important. Because pollutant source strengths are highly variable, maintaining minimum ventilation rates does not ensure acceptable indoor air quality in all situations. The lack of health-based concentration standards for many indoor air pollutants, primarily because of the lack of health data, makes the specification of minimum ventilation rates difficult.

In cases of high contaminant source strengths, such as with indoor sanding, spray painting, or smoking, impractically high rates of dilution ventilation are required to control contaminant levels, and other methods of control are more effective. Removal or reduction of contaminant sources is the most effective means of control. Controlling a localized source by means of local exhaust, such as

range hoods or bathroom exhaust fans, as well as filtration and absorption, may also be effective [e.g., Rock (2006)].

Particles can be removed with various types of air filters. Gaseous contaminants with higher molecular weight can be controlled with activated carbon or alumina pellets impregnated with a substance such as potassium permanganate. Chapter 28 of the 2008 *ASHRAE Handbook—HVAC Systems and Equipment* has information on air cleaning.

Protection from Extraordinary Events

The design, operation and maintenance of a building's ventilation system, envelope, and other factors can significantly affect the building's potential vulnerability to extraordinary threats, which range from intentional releases of chemical or biological agents inside or outside a building, to releases of chemicals in industrial or transportation accidents, to natural disasters. ASHRAE (2003) addresses several key steps to manage risk from extraordinary incidents, including the following:

- Evaluate the risk to a facility of an extraordinary incident.
- Assess the building's vulnerability.
- Determine the degree of acceptable vulnerability.
- Consider protective measures or options in relation to new, renovated, and existing buildings.

Persily (2004) details how ventilation affects buildings' vulnerability to airborne chemical and biological releases, as well as some strategies for using ventilation (particularly involving airtightness and pressurizing the building interior to protect against outdoor releases) to increase the level of building protection against such incidents. Persily et al. (2007) evaluate retrofit options for building protection from airborne threats; approaches considered include enhanced particle filtration, sorbent-based gaseous air cleaning, ventilation system recommissioning, building envelope airtightening, building pressurization, relocation of outdoor air intakes, shelter-in-place (SIP), isolation of vulnerable spaces such as lobbies, and system shutdown and purge cycles. The filtration and air cleaning options have the advantage of always being operational as long as the systems are properly designed, installed, and maintained. However, the lack of standard test methods is a critical issue in application of some air-cleaning technologies. Building envelope air sealing and pressurization can be quite effective in protecting against outdoor releases as long as effective filtration against the contaminant of concern is also in place. The protection provided by operational changes such as system shutdown and purging depends heavily on timing; if timing is inappropriate, occupant exposure may increase. Isolating vulnerable zones and other system-related modifications depend on building layout and system design, and careful implementation is necessary for effectiveness under the range of conditions that exist in buildings. Finally, many retrofits also increase energy efficiency and improve indoor air quality, which should be included in a life-cycle cost comparison of different options to the degree possible. Chapter 58 of the 2007 *ASHRAE Handbook—HVAC Applications* addresses this topic of extraordinary events further.

THERMAL LOADS

Outdoor air introduced into a building constitutes a large part of the total space-conditioning (heating, cooling, humidification, and dehumidification) load, which is one reason to limit air exchange rates in buildings to the minimum required. Air exchange typically represents 20 to 50% of a building's thermal load. Chapters 17 and 18 cover thermal loads in more detail.

Air exchange increases a building's thermal load in several ways. First, incoming air must be heated or cooled from the outdoor air temperature to the indoor or supply air temperature. The rate of energy consumption by this sensible heating or cooling is given by

$$q_s = 60Q\rho c_p \Delta t \quad (33)$$

where

- q_s = sensible heat load, Btu/h
- Q = airflow rate, cfm
- ρ = air density, lb/ft³ (about 0.075 at or near sea level)
- c_p = specific heat of air, Btu/lb·°F (about 0.24)
- Δt = temperature difference between indoors and outdoors, °F

and at or near sea-level air density, with an adjustment for typical room air humidity, this equation is commonly presented for design use as

$$q_s = 1.1Q\Delta t \quad (34)$$

Equation (33) is known as the **sensible heat equation**. HVAC designers typically assume sea-level air pressure for locations with altitudes of 2000 ft or lower. A method to adjust for elevation is provided in Chapter 18.

Air exchange also modifies the moisture content of the air in a building. The rate of energy consumption associated with these latent loads (neglecting the energy associated with any condensate) is given by

$$q_l = 60Q\rho\Delta W(1061 + 0.444t) \quad (35)$$

where

- q_l = latent heat load, Btu/h
- ΔW = humidity ratio difference between indoors and outdoors, lb_m water/lb_m dry air
- t = average of indoor and outdoor temperatures, °F

Equation (35) is known as the **latent heat equation**. When at or near sea level, and for common comfort air temperatures, the right-hand side of Equation (35) is approximately $4840Q\Delta W$.

Example 1. A makeup air unit (MAU) is to condition 5000 cfm of outdoor air in the winter for a building in Atlanta, Georgia. If the air is to be delivered directly to the occupied spaces at 75°F and 30% rh, how much sensible and latent heat must be added to this ventilation air at winter design conditions?

Solution: From the weather data tables provided on the CD included with this volume, Atlanta is at an elevation of about 1000 ft. Because this is below the rule-of-thumb cutoff of 2000 ft for assuming sea-level conditions, air density is assumed to be 0.075 lb_m/ft³. Also from the Atlanta data table, the winter 99% design dry-bulb (db) temperature is 23.9°F, but a mean coincident wet bulb is not provided. However, for humidification design, a dew-point temperature of 1.9°F is given along with its 24.9°F mean coincident dry bulb (MCDB). Using these data, a 1°F dew point is assumed as the 99% mean coincident dew point.

From ASHRAE's sea-level psychrometric chart and the winter design conditions, the desired humidity ratio W of the 75°F, 30% rh makeup air is about 0.0056 lb_mw/lb_mda. For the very dry outside air, with a dew point of 1°F, a problem occurs: the standard sea-level psychrometric chart does not extend below 32°F. Designers often assume that air below this temperature has $W = 0$, and this assumption gives conservative results. However, both high- and low-temperature psychrometric charts are available from ASHRAE, as is a table of moist air properties at standard conditions in Chapter 1. From this table, saturated air at 1°F, which is also its dew point, has a humidity ratio of 0.0008298 lb_mw/lb_mda. With 5000 cfm of outdoor air to be conditioned, and using the sensible and latent heat equations for sea level, the energy needed to condition this outdoor air is

$$q_s = 1.1Q\Delta T = 1.1 \times 5000 \text{ cfm}(75 - 23.9^\circ\text{F}) \\ = 281,050 \text{ Btu/h} \approx 282,000 \text{ Btu/h}$$

and

$$q_l = 4840Q\Delta W = 4840 \times 5000 \text{ cfm}(0.0056 - 0.0008298 \text{ lb}_m\text{w/lb}_m\text{da}) \\ = 115,439 \text{ Btu/h} \approx 115,000 \text{ Btu/h}$$

Thus, the MAU's heating coil and humidifier, neglecting fan heat, need to be sized to provide at least a net 282,000 Btu/h of sensible heat, and 115,000 Btu/h of latent heat. Humidification can be provided by

cold water, warm water, or steam, so a more precise psychrometric analysis is needed to size the heating coil correctly after the humidification method is selected and it is decided whether the humidifier will be placed before or after the heating coil.

As Example 1 shows, ventilation loads are substantial. They are often 50% or more of the total space conditioning loads in modern, well-insulated commercial buildings in less temperate climates. When cooling outdoor air, substantial moisture usually must be removed from the ventilation air; reheat or regenerative heat recovery may be required in all but dry climates.

Effect on Envelope Insulation

Air exchange also can affect a building's thermal load by altering performance of the envelope insulation system. Airflow through insulation can decrease thermal load through heat exchange between infiltrating or exfiltrating air and the insulation. Conversely, air moving in and out of the insulation from outside can increase the thermal load. Experimental and numerical studies have demonstrated that significant thermal coupling can occur between air leakage and insulation layers, thereby modifying the heat transmission in building envelopes. In particular, research (Bankvall 1987; Berlad et al. 1978; Lecompte 1987; Wolf 1966) has shown that convective airflow through air-permeable insulation in an envelope assembly may degrade its effective thermal resistance. This R-value degradation occurs when outside air moves through and/or around the insulation within the wall cavity and returns to the outdoors without reaching the conditioned space. A literature review by Powell et al. (1989) summarized the findings about air movement effects on the effective thermal resistance of porous insulation under various conditions. The effect of such airflow on insulation system performance is difficult to quantify, but should be considered. Airflow within the insulation system can also decrease the system's performance because of moisture condensation in and on the insulation.

Even if air flows only through cracks instead of through the insulation, the actual heating/cooling load from the combined effect of conduction and airflow heat transfer can be lower than the heating/cooling load calculated by Equation (33). This reduction in total heating/cooling load is a consequence of the thermal coupling between conduction and convection heat transfer and is called **infiltration heat recovery (IHR)**. Using a computer simulation, Kohonen et al. (1987) found that the conduction/infiltration thermal interaction reduced total heating load by 15%. Several experimental studies (e.g., Claridge and Bhattacharyya 1990; Claridge et al. 1988; Liu and Claridge 1992a, 1992b, 1992c, 1995; Timusk et al. 1992), using a test cell under both steady-state and dynamic conditions, found that the actual energy attributed to air infiltration can be 20 to 80% of the values given by Equation (35). Judkoff et al. (1997) measured heat recovery in a mobile home under steady-state conditions, and found that up to 40% heat recovery occurs during exfiltration through the envelope. Buchanan and Sherman (2000) performed two- and three-dimensional computational fluid dynamics (CFD) simulations to study the fundamental physics of the IHR process and developed a simple macro-scale mathematical model based on the steady-state one-dimensional convection-diffusion equation to predict a heat recovery factor. Their results show that the traditional method may overpredict the infiltration energy load. Using physical experiments, ASHRAE research project RP-1169 (Ackerman et al. 2006) showed that thermal resistances are affected by infiltration and exfiltration, but, on a net basis, the IHR effect can be neglected.

Infiltration Degree-Days

Heating and cooling degree-days are a simple way to characterize the severity of a particular climate. Heating and cooling degree-day values are based on sensible temperature data, but infiltration loads are both sensible and latent. **Infiltration degree days (IDDs)** more

fully describe a climate and can be used to estimate heat loss or gain from infiltration in residences (Sherman 1986). Total infiltration degree-days is the sum of the heating and cooling infiltration degree-days and is calculated from hour-by-hour weather data and base conditions using weather weighted by infiltration rate. The selection of base conditions is an important part of the calculation of the IDD. ASHRAE *Standard* 119 lists IDDs for many locations with a particular set of base conditions.

NATURAL VENTILATION

Natural ventilation is the flow of outdoor air caused by wind and thermal pressures through intentional openings in the building's shell. Under some circumstances, it can effectively control both temperature and contaminants in mild climates, but it is not considered practical in hot and humid climates or in cold climates. Temperature control by natural ventilation is often the only means of providing cooling when mechanical air conditioning is not available. The arrangement, location, and control of ventilation openings should combine the driving forces of wind and temperature to achieve a desired ventilation rate and good distribution of ventilation air through the building. However, intentional openings cannot always guarantee adequate temperature and humidity control or indoor air quality because of the dependence on natural (wind and stack) effects to drive the flow (Wilson and Walker 1992). Using night ventilation and the building's thermal mass effect may be effective for reducing conventional cooling energy consumption in some buildings and climates if moisture condensation can be controlled. Axley (2001a) and the Chartered Institute of Building Services Engineers (CIBSE 2005) review natural ventilation in commercial buildings, including potential advantages and problems, natural ventilation components and system designs, and recommended design and analysis approaches.

Natural Ventilation Openings

Natural ventilation openings include (1) windows, doors, dormer (monitor) openings, and skylights; (2) roof ventilators; (3) stacks; and (4) specially designed inlet or outlet openings.

Windows transmit light and provide ventilation when open. They may open by sliding vertically or horizontally; by tilting on horizontal pivots at or near the center; or by swinging on pivots at the top, bottom, or side. The type of pivoting used is important for weather protection and affects airflow rate.

Roof ventilators provide a weather-resistant air outlet. Capacity is determined by the ventilator's location on the roof; the resistance to airflow of the ventilator and its ductwork; the ventilator's ability to use kinetic wind energy to induce flow by centrifugal or ejector action; and the height of the draft.

Natural-draft or gravity roof ventilators can be stationary, pivoting, oscillating, or rotating. Selection criteria include ruggedness, corrosion resistance, stormproofing features, dampers and operating mechanisms, noise, cost, and maintenance. Natural ventilators can be supplemented with power-driven supply fans; the motors need only be energized when the natural exhaust capacity is too low. Gravity ventilator dampers can be manual or controlled by thermostat or wind velocity.

A natural-draft roof ventilator should be positioned so that it receives full, unrestricted wind. Turbulence created by surrounding obstructions, including higher adjacent buildings, impairs a ventilator's ejector action. Inlets can be conical or bell-mouthed to increase their flow coefficients. The opening area at any inlet should be increased if screens, grilles, or other structural members cause flow resistance. Building air inlets at lower levels should be larger than the combined throat areas of all roof ventilators.

Stacks or vertical flues should be located where wind can act on them from any direction. Without wind, stack effect alone removes air from the room with the inlets.

Ceiling Heights

In buildings that rely on natural ventilation for cooling, floor-to-ceiling heights are often increased well beyond the normal 8 to 10 ft. Higher ceilings, as seen in buildings constructed before air conditioning was available, allow warm air and contaminants to rise above the occupied portions of rooms. Air is then exhausted from the ceiling zones, and cooler outside air is provided near the floors; a degree of floor-to-ceiling displacement airflow is thus desirable when using natural ventilation for cooling.

Required Flow for Indoor Temperature Control

The ventilation airflow rate required to remove a given amount of heat from a building can be calculated from Equations (33) and (35) if the quantity of heat to be removed and the indoor/outdoor temperature difference are known.

Airflow Through Large Intentional Openings

The relationship describing the airflow through a large intentional opening is based on the Bernoulli equation with steady, incompressible flow. The general form that includes stack, wind, and mechanical ventilation pressures across the opening is

$$Q = 776C_D A \sqrt{2\Delta p / \rho} \tag{36}$$

where

- Q = airflow rate, cfm
- C_D = discharge coefficient for opening, dimensionless
- A = cross-sectional area of opening, ft²
- ρ = air density, lb_m/ft³
- Δp = pressure difference across opening, in. of water
- 776 = unit conversion factor

The discharge coefficient C_D is a dimensionless number that depends on the geometry of the opening and the Reynolds number of the flow.

Flow Caused by Wind Only

Aspects of wind that affect the ventilation rate include average speed, prevailing direction, seasonal and daily variation in speed and direction, and local obstructions such as nearby buildings, hills, trees, and shrubbery. Liddament (1988) reviewed the relevance of wind pressure as a driving mechanism. A multifold path simulation model was developed and used to illustrate the effects of wind on air exchange rate.

Wind speeds may be lower in summer than in winter; directional frequency is also a function of season. Natural ventilation systems are often designed for wind speeds of one-half the seasonal average. Equation (37) shows the rate of air forced through ventilation inlet openings by wind or determines the proper size of openings to produce given airflow rates:

$$Q = 88.0C_vAU \tag{37}$$

where

- Q = airflow rate, cfm
- C_v = effectiveness of openings (C_v is assumed to be 0.5 to 0.6 for perpendicular winds and 0.25 to 0.35 for diagonal winds)
- A = free area of inlet openings, ft²
- U = wind speed, mph
- 88.0 = unit conversion factor

Inlets should face directly into the prevailing wind. If they are not advantageously placed, flow will be less than that predicted by Equation (37); if inlets are unusually well placed, flow will be slightly more. Desirable outlet locations are (1) on the leeward side of the building directly opposite the inlet; (2) on the roof, in the low-pressure area caused by a flow discontinuity of the wind; (3) on the side adjacent to the windward face where low-pressure areas occur; (4) in a dormer on the leeward side; (5) in roof ventilators; or

(6) by stacks. Chapter 24 gives a general description of the wind pressure distribution on a building. Inlets should be placed in exterior high-pressure regions; outlets should be placed in exterior low-pressure regions.

Flow Caused by Thermal Forces Only

If building internal resistance is not significant, flow caused by stack effect can be expressed by

$$Q = 60C_D A \sqrt{2g\Delta H_{NPL}(T_i - T_o)/T_i} \tag{38}$$

where

- Q = airflow rate, cfm
- C_D = discharge coefficient for opening
- ΔH_{NPL} = height from midpoint of lower opening to NPL, ft
- T_i = indoor temperature, °R
- T_o = outdoor temperature, °R

Equation (38) applies when $T_i > T_o$. If $T_i < T_o$, replace T_i in the denominator with T_o , and replace $(T_i - T_o)$ in the numerator with $(T_o - T_i)$. An average temperature should be used for T_i if there is thermal stratification. If the building has more than one opening, the outlet and inlet areas are considered equal. The discharge coefficient C_D accounts for all viscous effects such as surface drag and interfacial mixing.

Estimation of ΔH_{NPL} is difficult for naturally ventilated buildings. If one window or door represents a large fraction (approximately 90%) of the total opening area in the envelope, then the NPL is at the mid-height of that aperture, and ΔH_{NPL} equals one-half the height of the aperture. For this condition, flow through the opening is bidirectional (i.e., air from the warmer side flows through the top of the opening, and air from the colder side flows through the bottom). Interfacial mixing occurs across the counterflow interface, and the orifice coefficient can be calculated according to the following equation (Kiel and Wilson 1986):

$$C_D = 0.40 + 0.0025|T_i - T_o| \tag{39}$$

If enough other openings are available, airflow through the opening will be unidirectional, and mixing cannot occur. A discharge coefficient of $C_D = 0.65$ should then be used. Additional information on stack-driven airflows for natural ventilation can be found in Foster and Down (1987).

Greatest flow per unit area of openings is obtained when inlet and outlet areas are equal; Equations (38) and (39) are based on this equality. Increasing the outlet area over inlet area (or vice versa) increases airflow but not in proportion to the added area. When openings are unequal, use the smaller area in Equation (38) and add the increase as determined from Figure 8.

Fig. 8 Increase in Flow Caused by Excess Area of One Opening over the Other

Natural Ventilation Guidelines

Several general guidelines should be observed in designing for natural ventilation. Some of these may conflict with other climate-responsive strategies (such as using orientation and shading devices to minimize solar gain), with building codes that encourage compartmentalization to restrict fire and smoke movement, or with other design considerations.

System selection

- In hot, humid climates, use mechanical cooling. If mechanical cooling is not available, air velocities should be maximized in the occupied zones of rooms.
- In hot, arid climates, consider evaporative cooling. Airflow throughout the building should be maximized for structural cooling, particularly at night when the outside air temperature is low.

Building and surroundings characteristics

- Topography, landscaping, and surrounding buildings should be used to redirect airflow and give maximum exposure to breezes. Vegetation can funnel breezes and avoid wind dams, which reduce the driving pressure differential around the building. Site objects should not obstruct inlet openings.
- The building should be shaped to expose maximum shell openings to breezes.
- Architectural elements such as wing walls, parapets, and overhangs should be used to promote airflow into the building interior.
- The long façade of the building and the majority of door and window openings should be oriented with respect to prevailing summer breezes. If there is no prevailing direction, openings should be sufficient to provide ventilation regardless of wind direction.

Opening locations

- Windows should be located in opposing pressure zones. Two openings on opposite sides of a space increase ventilation flow. Openings on adjacent sides force air to change direction, providing ventilation to a greater area. The benefits of the window arrangement depend on the outlet location relative to the direction of the inlet airstream.
- If a room has only one external wall, better airflow is achieved with two widely spaced windows.
- If openings are at the same level and near the ceiling, much of the flow may bypass the occupied level and be ineffective in diluting contaminants there.
- Vertical distance between openings is required to take advantage of stack effect; the greater the vertical distance, the greater the ventilation rate.
- Openings in the vicinity of the NPL are least effective for thermally induced ventilation. If the building has only one large opening, the NPL tends to move to that level, which reduces pressure across the opening.

Opening characteristics

- Greatest flow per unit area of total opening is obtained by inlet and outlet openings of nearly equal areas. An inlet window smaller than the outlet creates higher inlet velocities. An outlet smaller than the inlet creates lower but more uniform airspeed through the room.
- Openings with areas much larger than calculated are sometimes desirable when anticipating increased occupancy or very hot weather.
- Horizontal windows are generally better than square or vertical windows. They produce more airflow over a wider range of wind directions and are most beneficial in locations where prevailing wind patterns shift.
- Window openings should be accessible to and operable by occupants, unless fully automated. For secondary fire egress, operable windows may be required.

- Inlet openings should not be obstructed by indoor partitions. Partitions can be placed to split and redirect airflow but should not restrict flow between the building's inlets and outlets. Vertical airshafts or open staircases can be used to increase and take advantage of stack effects. However, enclosed staircases intended for evacuation during a fire should not be used for ventilation.

Hybrid Ventilation

Application of purely natural ventilation systems may be limited in hot or humid climates, such as in much of the United States, by thermal comfort issues and the need for reliability. However, hybrid (or mixed-mode) ventilation systems or operational strategies offer the possibility of saving energy in a greater number of buildings and climates by combining natural ventilation systems with mechanical equipment (Emmerich 2006). The **air-side economizer** is one form of hybrid ventilation control scheme, and enjoys wide use in commercial, industrial, and institutional buildings in appropriate climates. The report of the International Energy Agency's (IEA) Annex 35 describes the principles of hybrid ventilation technologies, control strategies, design and analysis methods, and case studies (Heiselberg 2002). Integrated multizone airflow and thermal modeling is recommended when designing natural and hybrid ventilation systems (Axley 2001a; Li and Heiselberg 2003).

RESIDENTIAL AIR LEAKAGE

Most infiltration in U.S. residential buildings is dominated by envelope leakage. However, new construction tends toward tighter building envelopes.

Envelope Leakage Measurement

A building's envelope leakage can be measured with **pressurization testing**, commonly called a **blower-door test**. Fan pressurization is relatively quick and inexpensive, and it characterizes building envelope airtightness independent of weather conditions. In this procedure, a large fan or blower is mounted in a door or window and induces a large and roughly uniform pressure difference across the building shell [ASTM Standards E779 and E1827; Canadian General Standards Board (CGSB) Standard 149.10; ISO Standard 9972]. The airflow required to maintain this pressure difference is then measured. The leakier the building is, the more airflow is necessary to induce a specific indoor/outdoor pressure difference. The airflow rate is generally measured at a series of pressure differences ranging from about 0.04 to 0.30 in. of water.

The results of a pressurization test, therefore, consist of several combinations of pressure difference and airflow rate data. An example of typical data is shown in Figure 9. These data points characterize the air leakage of a building and are generally converted to a single value that serves as a measure of the building's airtightness. There are several different measures of airtightness, most of which involve fitting the data to a curve describing the relationship between the airflow Q through an opening in the building envelope and the pressure difference Δp across it. This relationship is called the **leakage function** of the opening. The form of the leakage function depends on the geometry of the opening. Background theoretical material relevant to leakage functions may be found in Chastain et al. (1987), Etheridge (1977), Hopkins and Hansford (1974), Kronvall (1980), and Walker et al. (1997).

Openings in a building envelope are not uniform in geometry and, generally, the flow never becomes fully developed. Each opening in the building envelope can be described by Equation (40), commonly called the **power law equation**:

$$Q = c(\Delta p)^n \quad (40)$$

where

- Q = airflow through opening, cfm
- c = flow coefficient, cfm/(in. of water) ^{n}
- n = pressure exponent, dimensionless

Sherman (1992a) showed how the power law can be developed analytically by looking at developing laminar flow in short pipes. Equation (40) only approximates the relationship between Q and Δp . Measurements of single cracks (Honma 1975; Kreith and Eisenstadt 1957) show that n can vary if Δp changes over a wide range. Additional investigation of pressure/flow data for simple cracks by Chastain et al. (1987) indicated the importance of adequately characterizing the three-dimensional geometry of openings and the entrance and exit effects. Walker et al. (1997) showed that, for the arrays of cracks in a building envelope over the range of pressures acting during infiltration, n is constant. A typical value for n is about 0.65. Values for c and n can be determined for a building by using fan pressurization testing.

Airtightness Ratings

In some cases, the predicted airflow rate is converted to an **equivalent or effective air leakage area** as follows:

$$A_L = 0.186 Q_r \frac{\sqrt{\rho/2\Delta p_r}}{C_D} \tag{41}$$

where

- A_L = equivalent or effective air leakage area, in²
- Q_r = predicted airflow rate at Δp_r (from curve fit to pressurization test data), cfm
- ρ = air density, lb_m/ft³
- Δp_r = reference pressure difference, in. of water
- C_D = discharge coefficient
- 0.186 = unit conversion factor

All openings in the building shell are combined into an overall opening area and discharge coefficient for the building when the equivalent or effective air leakage area is calculated. Some users of the leakage area approach set $C_D = 1$. Others set $C_D \approx 0.6$ (i.e., the discharge coefficient for a sharp-edged orifice). The air leakage area of a building is, therefore, the area of an orifice (with an assumed value of C_D) that would produce the same amount of leakage as the building envelope at the reference pressure.

An airtightness rating, whether based on an air leakage area or a predicted airflow rate, is generally normalized by some factor to account for building size. Normalization factors include floor area, exterior envelope area, and building volume.

With the wide variety of possible approaches to normalization and reference pressure difference, and the use of the air leakage area concept, many different airtightness ratings are used. Reference pressure differences include 0.016, 0.04, 0.10, 0.20, and 0.30 in. of

water. Reference pressure differences of 0.016 and 0.04 in. of water are advocated because they are closer to the pressure differences that actually induce air exchange and, therefore, better model the opening's flow characteristics. Although this may be true, they are outside the range of measured values in the test; therefore, predicted airflow rates at 0.016 and 0.04 in. of water are subject to significant uncertainty. This uncertainty and its implications for quantifying airtightness are discussed in Chastain (1987), Modera and Wilson (1990), and Persily and Grot (1985b). Round-robin tests by Murphy et al. (1991) to determine the repeatability and reproducibility of fan pressurization devices found that subtle errors in fan calibration or operator technique are greatly exaggerated when extrapolating the pressure versus flow curve out to 0.016 in. of water, with errors as great as $\pm 40\%$, mainly because of fan calibration errors at low flow.

Some common airtightness ratings include the effective air leakage area at 0.016 in. of water assuming $C_D = 1.0$ (Sherman and Grimsrud 1980); the equivalent air leakage area at 0.04 in. of water assuming $C_D = 0.611$ (CGSB *Standard* 149.10); and the airflow rate at 0.20 in. of water, divided by the building volume to give units of air changes per hour (Blomsterberg and Harrije 1979).

Conversion Between Ratings

Air leakage areas at one reference pressure difference can be converted to air leakage areas at another reference pressure difference according to

$$A_{r,2} = A_{r,1} \left(\frac{C_{D,1}}{C_{D,2}} \right) \left(\frac{\Delta p_{r,2}}{\Delta p_{r,1}} \right)^{n-0.5} \tag{42}$$

where

- $A_{r,1}$ = air leakage area at reference pressure difference $\Delta p_{r,1}$, in²
- $A_{r,2}$ = air leakage area at reference pressure difference $\Delta p_{r,2}$, in²
- $C_{D,1}$ = discharge coefficient used to calculate $A_{r,1}$
- $C_{D,2}$ = discharge coefficient used to calculate $A_{r,2}$
- n = pressure exponent from Equation (40)

Air leakage area at one reference pressure difference can be converted to airflow rate at some other reference pressure difference according to

$$Q_{r,2} = 5.39 C_{D,1} A_{r,1} \sqrt{\frac{\rho}{2}} (\Delta p_{r,1})^{0.5-n} (\Delta p_{r,2})^n \tag{43}$$

where

- $Q_{r,2}$ = airflow rate at reference pressure difference $\Delta p_{r,2}$, cfm
- 5.39 = unit conversion factor

Flow coefficient c in Equation (40) may be converted to air leakage area according to

$$A_L = \frac{c}{5.39 C_D} \sqrt{\frac{\rho}{2}} \Delta p_r^{(n-0.5)} \tag{44}$$

Finally, air leakage area may be converted to flow coefficient c in Equation (40) according to

$$c = 5.39 C_D A_L \sqrt{\frac{\rho}{2}} (\Delta p_r)^{0.5-n} \tag{45}$$

Equations (42) to (45) require assumption of a value of n , unless it is reported with the measurement results. When whole-building pressurization test data are fitted to Equation (40), the value of n generally lies between 0.6 and 0.7. Therefore, using a value of n in this range is reasonable.

Building Air Leakage Data

Fan pressurization measures a building property that ideally varies little with time and weather conditions. In reality, unless wind

Fig. 9 Airflow Rate Versus Pressure Difference Data from Whole-House Pressurization Test

Fig. 10 Envelope Leakage Measurements

and temperature differences during the measurement period are sufficiently mild, pressure differences they induce during the test interfere with test pressures and cause measurement errors. Modera and Wilson (1990) and Persily (1982) studied the effects of wind speed on pressurization test results. Several experimental studies also showed variations on the order of 20 to 40% over a year in the measured airtightness in homes (Kim and Shaw 1986; Persily 1982; Warren and Webb 1986).

Figure 10 summarizes envelope leakage measured North American housing (Sherman and Dickerhoff 1998) and from several European and Canadian sources (AIVC 1994). This figure shows

the large range of measured envelope tightness, but can still be used to illustrate typical and extreme values in the housing stock.

ASHRAE *Standard* 119 establishes air leakage performance levels for residential buildings. These levels are in terms of the normalized leakage area A_n :

$$A_n = 6.944(A_L/A_f)(H/H_o)^{0.3} \quad (46)$$

where

A_n = normalized leakage area, dimensionless

A_L = effective leakage area at 0.016 in. of water ($C_D = 1.0$), in²

A_f = gross floor area (within exterior walls), ft²

H = building height, ft

H_o = reference height of one-story building = 8 ft

Air Leakage of Building Components

The fan pressurization procedure discussed in the section on Envelope Leakage Measurement allows whole-building air leakage to be measured. The location and size of individual openings in building envelopes are extremely important because they influence the air infiltration rate of a building as well as the envelope's heat and moisture transfer characteristics. Additional test procedures for pressure-testing individual building components such as windows, walls, and doors are discussed in ASTM *Standards* E283 and E783 for laboratory and field tests, respectively.

Leakage Distribution

Dickerhoff et al. (1982) and Harje and Born (1982) studied air leakage of individual building components and systems. The following points summarize the percentages of whole-building air leakage area associated with various components and systems. Values in parentheses include the range determined for each component and the mean of the range.

Walls (18 to 50%; 35%). Both interior and exterior walls contribute to the leakage of the structure. Leakage can occur between the sill plate and foundation; through cracks below the bottom of the gypsum wallboard, electrical outlets, and plumbing penetrations; and into the attic at the top plates of walls.

Ceiling details (3 to 30%; 18%). Leakage across the top ceiling of the heated space is particularly insidious because it reduces the effectiveness of insulation on the attic floor and contributes to infiltration heat loss. Ceiling leakage also reduces the effectiveness of ceiling insulation in buildings without attics. Recessed lighting, plumbing, and electrical penetrations leading to the attic are some particular areas of concern.

Forced-air heating and/or cooling systems (3 to 28%; 18%). The location of the heating or cooling equipment, air handler, or ductwork in conditioned or unconditioned spaces; the venting arrangement of a fuel-burning device; and the existence and location of a combustion air supply all affect air leakage. Modera et al. (1991) and Robison and Lambert (1989), among others, found that the variability of leakage in ducts passing through unconditioned spaces is high, the coefficient of variation being on the order of 50%. Field studies have also shown that in-situ repairs can eliminate one-quarter to two-thirds of the observed leakage (Cummings and Tooley 1989; Cummings et al. 1990; Jump et al. 1996; Robison and Lambert 1989). The 18% contribution of ducts to total leakage significantly underestimates their effect because, during system operation, pressure differentials across duct leaks are approximately ten times higher than typical pressure differences across envelope leaks (Modera 1989; Modera et al. 1991) and result in large (factors of two to three) changes in ventilation rate (Cummings et al. 1990; Walker 1999; Walker et al. 1999).

Windows and doors (6 to 22%; 15%). More variation in window leakage is seen among window types (e.g., casement versus double-hung) than among new windows of the same type from different manufacturers (Weidt et al. 1979). Windows that seal by

compressing the weather strip (casements, awnings) show significantly lower leakage than windows with sliding seals.

Fireplaces (0 to 30%; 12%). When a fireplace is not in use, poorly fitting dampers allow air to escape. Glass doors reduce excess air while a fire is burning, but rarely seal the fireplace structure more tightly than a closed damper does. Chimney caps or fireplace plugs (with signs that warn they are in place) effectively reduce leakage through a cold fireplace.

Vents in conditioned spaces (2 to 12%; 5%). Exhaust vents in conditioned spaces frequently have either no dampers or dampers that do not close properly.

Diffusion through walls (<1%). Compared to infiltration through holes and other openings in the structure, diffusion is not an important flow mechanism. At 0.02 in. of water, the permeability of building materials produces an air exchange rate of less than 0.01 ach by wall diffusion in a typical house.

Component leakage areas. Individual building component leakage areas vary widely from house to house. Typical variability for an individual component is about a factor of 10, depending on the component's construction and installation. Testing should be used to establish the installed leakage of a component in applications where leakage is critical to building performance.

Multifamily Building Leakage

Leakage distribution is particularly important in multifamily apartment buildings. These buildings often cannot be treated as single zones because of the internal resistance between apartments. Moreover, leakage between apartments varies widely, from very small for well-constructed buildings with air/moisture retarders between units, to as high as 60% of the total apartment leakage in turn-of-the-century brick walk-up apartment buildings (Diamond et al. 1986; Modera et al. 1991).

Controlling Air Leakage

New Buildings. It is much easier to build a tight building than to tighten an existing building. Elmroth and Levin (1983), Eyre and Jennings (1983), Marbek Resource Consultants (1984), and Nelson et al. (1985) provide information and construction details on airtight building design for houses.

A continuous air infiltration retarder is one of the most effective means of reducing air leakage through walls, around window and door frames, and at joints between major building elements. Particular care must be taken to ensure its continuity at all wall, floor, and ceiling joints; at window and door frames; and at all penetrations of the retarder, such as electrical outlets and switches, plumbing connections, and utility service penetrations. Joints in the **air/vapor retarder** must be lapped and sealed. Plastic vapor retarders installed in the ceiling should be tightly sealed with the vapor retarder in the outside walls and should be continuous over the partition walls. A seal at the top of the partition walls prevents leakage into the attic; a plate on top of the studs generally gives a poor seal. The air infiltration retarder can be installed either on the inside of the wall framing, in which case it usually functions as a vapor retarder as well, or on the outside of the wall framing, in which case it should have a permeance rating high enough to allow diffusion of water vapor from the wall. For a discussion of moisture transfer in building envelopes, see Chapters 25 and 26.

Interior air/vapor retarders must be lapped and sealed at electrical outlets and switches, at joints between walls and floors and between walls and ceilings, and at plumbing connections penetrating the wall's interior finish. A continuous exterior air infiltration retarder installed on the outside of wall framing can cover these problem areas. Joints in the air infiltration retarder should be lapped and sealed or taped. Exterior air infiltration retarders are generally made of a material stronger than plastic film and are more likely to withstand damage during construction. Sealing the wall against air leakage at the exterior of the insulation also reduces convection

currents within the wall cavity, allowing insulation to retain more of its effectiveness.

Existing Buildings. Air leakage sites must first be located to tighten the envelope of an existing building. As discussed earlier, air leakage in buildings is caused by not only windows and doors, but also a wide range of unexpected and unobvious construction defects. Many important leakage sites can be very difficult to find. A variety of techniques developed to locate leakage sites are described in *ASTM Standard E1186* and Charlesworth (1988).

Once leakage sites are located, they can be repaired with materials and techniques appropriate to the size and location of the leak. Diamond et al. (1982), Energy Resource Center (1982), and Harrije et al. (1979) include information on airtightening or "weatherization" in existing residential buildings with caulking, sealing, weatherstripping, and use of door sweeps, for example. With these procedures, air leakage of residential buildings can be reduced dramatically: anywhere from 5% to more than 50%, depending on the extent of the tightening effort and the experience of those doing the work (Blomsterberg and Harrije 1979; Giesbrecht and Proskiw 1986; Harrije and Mills 1980; Jacobson et al. 1986; Verschoor and Collins 1986). Much less information is available for airtightening large, commercial buildings, but the same general principles apply (Parekh et al. 1991; Persily 1991).

RESIDENTIAL VENTILATION

Typical infiltration values in housing in North America vary by a factor of about ten, from tightly constructed housing with seasonal average air exchange rates as low as 0.1 air changes per hour (ach) to loosely constructed housing with air exchange rates as great as 2.0 ach. Figures 11 and 12 show histograms of infiltration rates measured in two different samples of North American housing (Grimsrud et al. 1982; Grot and Clark 1979). Figure 11 shows the average seasonal infiltration of 312 houses located in different areas in North America. The median infiltration value of this sample is 0.5 ach. Figure 12 represents measurements in 266 houses located in 16 U.S. cities. The median value of this sample is 0.9 ach. The group of houses in the Figure 11 sample is biased toward then-new, energy-efficient houses, whereas the group in Figure 12 represents older, low-income housing.

Additional studies have found average values for houses in regional areas. Palmiter and Brown (1989) and Parker et al. (1990) found a heating season average of 0.40 ach (range: 0.13 to 1.11 ach) for 134 houses in Pacific Northwest climates. In a comparison of 292 houses incorporating energy-efficient features (including measures to reduce air infiltration and provide ventilation heat recovery) with

Fig. 11 Histogram of Infiltration Values for Then-New Construction

331 control houses, Parker et al. (1990) found an average of about 0.25 ach (range: 0.02 to 1.63 ach) for the energy-efficient houses versus 0.49 (range: 0.05 to 1.63 ach) for the control. Ek et al. (1990) found an average of 0.5 ach (range: 0.26 to 1.09) for 93 double-wide manufactured homes in the Pacific Northwest. Canadian housing stock has been characterized by Riley (1990) and Yuill and Comeau (1989). Although these studies do not represent random samples of North American housing, they indicate the distribution of infiltration rates expected in a group of buildings.

Occupancy influences have not been measured directly and vary widely. Desrochers and Scott (1985) estimated that they add an average of 0.10 to 0.15 ach to unoccupied values. Kvisgaard and Collet (1990) found that, in 16 Danish dwellings, occupants on average provided 63% of the total air exchange rate.

Ventilation air requirements for houses in the United States have traditionally been met on the assumption that the building envelope is leaky enough that infiltration will suffice. Possible difficulties with this approach include low infiltration when natural forces (temperature difference and wind) are weak; unnecessary energy consumption when these forces are strong; drafts in cold climates; lack of control of ventilation rates to meet changing needs; poor humidity control; potential for interstitial condensation from exfiltration in cold climates or infiltration in hot humid climates; and lack of opportunity to recover energy used to condition ventilation air. The solution to these concerns is to have a tight building envelope and a properly designed and operated mechanical ventilation system.

ASHRAE *Standard 119* and the National Building Code of Canada (NRCC 1995) encourage the transition to tighter envelope construction. Hamlin (1991) found a 30% increase in airtightness of tract-built Canadian houses between 1982 and 1989. Also, 82% of newer houses had natural air exchange rates below 0.3 ach in March. Yuill (1991) derived a procedure to show the extent to which infiltration contributes toward meeting ventilation air requirements. As a result, the National Building Code of Canada has requirements for mechanical ventilation capability in all new dwelling units.

Canadian Standards Association (CSA) *Standard F326* expands the requirements for residential mechanical ventilation systems to cover air distribution within the house, thermal comfort, minimum temperatures for equipment and ductwork, system controls, pressurization and depressurization of the dwelling, installation requirements, and verification of compliance. Verification can be by design or by test, but the total rate of outside air delivery must be measured.

Mechanical ventilation is required by ASHRAE *Standard 62.2* and by code in some U.S. states; some details of these requirement are described in this chapter. The net benefit of using mechanical ventilation has been demonstrated and studied in various energy-efficient

and advanced housing programs (Barley 2001; Palmiter et al. 1991; Riley 1990). Systems can be characterized as local or central; exhaust, supply, or balanced; with forced-air or radiant/ hydronic heating/cooling systems; with or without heat recovery; and with continuous operation or controlled by occupants, demand (i.e., by pollutant sensing), timers, or humidity. Note that not all combinations are viable. Various options are described by Fisk et al. (1984), Hekmat et al. (1986), Holton et al. (1997), Lubliner et al. (1997), Palmiter et al. (1991), Reardon and Shaw (1997), Sherman and Matson (1997), Sibbitt and Hamlin (1991), and Yuill et al. (1991).

The simplest systems use bathroom and kitchen fans to exhaust moisture and pollutants and to augment infiltration. Noise, installed capacity, durability under continuous operation, distribution to all rooms (especially bedrooms), envelope moisture, combustion safety, and energy efficiency issues need to be addressed. Many present bath and kitchen fans are ineffective ventilators because of poor installation and design, and many fail to exhaust outdoors. However, properly specified and installed exhaust fans can form part of good whole-house ventilation systems and are so specified in some Canadian building codes.

Some central supply systems use a central air-handling unit blower to induce air from the outdoors and distribute it. However, the blower operates intermittently if thermostatically controlled and provides little ventilation in mild weather. Continuous blower operation increases energy consumption. If the blower operates continuously when the heat source is off, the combination of lower mixed air temperature and high air speed can cause cold air drafts. To offset these problems, some systems use electronically commutated blower motors, which allow efficient continuous operation at lower speeds. Some others use a timer to cycle the blower when thermostatic demands are inadequate to cause the blower to operate when needed for ventilation (Rudd 1998).

Central exhaust systems use leakage sites and, in some cases, intentional and controllable openings in the building envelope as the supply. Such systems are suitable for retrofit in existing houses. Energy can be recovered from the exhaust airstream with a heat pump to supplement domestic hot-water and/or space heating.

For new houses with tightly constructed envelopes, balanced ventilation with passive heat recovery (air-to-air heat exchangers or heat recovery ventilators) can be appropriate in some climates. Fan-induced supply and exhaust air flows at nearly equal rates over a heat exchanger, where heat and sometimes moisture is transferred between the airstreams. This typically reduces the energy required to condition ventilation air by 60 to 80% (Cutter 1987). It also reduces the thermal discomfort that occurs when untempered air is introduced directly into the house. Airflow balance, leakage between streams, biological contamination of wet surfaces, frosting, and first cost are concerns associated with these systems.

Air-side economizers, which allow outside air to be up to 100% of the supply air at appropriate times, are not typically used in small buildings with low internal heat gains relative to the building envelope. Because of heat transfer through building envelopes, these small buildings quickly require heating or cooling as the outside air temperature falls or rises. Consequently, from an energy conservation point of view, small envelope-load-dominated buildings do not benefit as much as internal-load-dominated buildings from daytime use of air-side economizers; night ventilation during the cooling season may be very attractive. Also, ventilation rates increase dramatically when air-side economizers are in operation, so the extra moisture introduced or removed must be considered.

The type of ventilation system can be selected based on house leakage class as defined in ASHRAE *Standard 119*. Balanced air-to-air systems with heat recovery are optimal for tight houses (leakage classes A–C). The leakier the house is, the larger is the contribution from infiltration and the less effective is heat recovery ventilation. Tightening the envelope beyond the level of ASHRAE *Standard 119* may be warranted in extreme climates to better use the

Fig. 12 Histogram of Infiltration Values for Low-Income Housing

heat recovery effect (Sherman and Matson 1997). In mild climates, these systems can also effectively be used in leakage classes D–F. Central exhaust systems should not be used for leakage classes A–C unless special provisions are made for air inlets; otherwise their operation may depressurize the house enough to cause backdrafting through fossil-fueled appliances. Unbalanced systems (either supply or exhaust) are optimal for leakage classes D–F. Ventilation systems are normally not needed for leakage classes G–J, but when they are needed, an unbalanced system is usually the best choice. More discussion of mechanical systems for residences is available in Russell et al. (2005); some information on practices outside North America can be found in McWilliams and Sherman (2005).

Residential Ventilation Zones

For guidance in the selection of residential ventilation systems, Sherman (1995) developed four climatic zones for the United States. These zones are shown in Figure 13 for the continental United States. Alaska is in zone 1, and Hawaii is in zone 4.

Zone 1 includes the severe climates of the northern tier of states. A zone 1 residence that meets airtightness and energy conservation standards probably cannot meet its ventilation needs through infiltration, and will require mechanical ventilation. Zone 2 includes moderate climates where careful design and construction may allow buildings to simultaneously meet energy standards and ventilation needs through infiltration and mechanical exhaust. The mild climates in zone 3 allow residences to meet both ASHRAE *Standards* 119 and 62.2 over a substantial range of airtightness. Zone 4 residences have relatively small energy penalties associated with infiltration or ventilation. In this zone, natural ventilation is usually preferred to mechanical ventilation as a technique to supplement infiltration.

Shelter in Place

The most fundamental function of a house is to provide shelter from outdoor conditions. The building is intended to be the first line of defense at separating the relatively uncontrolled outdoor environment from the desired indoor environment.

A first response to poor outdoor air quality is to go inside, close the windows, and turn off central heating, air-conditioning, and ventilating systems, as well as any other fans. Closing windows and other air intakes reduces air exchange with the outdoors, decreasing the immediate intrusion of outdoor air into the home. However, because no home is perfectly airtight, closing doors and windows does not eliminate intrusion. Because all indoor air ultimately comes from outdoors, all else being equal, indoor conditions eventually come to dynamic equilibrium with outdoor conditions. The tighter the building, the longer the time needed to come to equilibrium.

The delay time (the time it takes to completely change the air in a building) is determined by the ventilation rate. The effectiveness

of sheltering within the home thus depends on envelope tightness. For a home with 0.35 air changes per hour, the delay time is roughly 3 h. For a tight house without mechanical ventilation, the delay time can easily be twice as long. Most houses in the United States are leaky (i.e., typically one air change per hour) and thus could have a delay time on the order of one hour (Sherman and Matson 1997).

Reactive gases in outdoor air, such as ozone, can be decreased to some degree by the building envelope. For other outdoor contaminants, the building envelope serves to delay, not reduce, their introduction into the indoor environment. Such a delay is not very helpful at reducing exposures to outdoor contaminants that persist over days, but can be an effective strategy for short-duration (less than a few hours) sources. In houses without indoor ozone sources, ozone levels tend to be higher in houses that do not have air conditioners than in those with air conditioners; ozone levels also are higher when windows are open than when they are closed (Weschler 2000). For outdoor exposure times shorter than the delay time, the house serves as a reservoir of cleaner air. After the outdoor contaminant is gone, windows can be opened to flush out pollutants that entered during the exposure period.

Safe Havens

Simply going inside may not be sufficient for highly unusual but potentially lethal events. Chemical spills or fires, explosions, bioterrorism, or similar toxic air pollutant releases can temporarily create dangerous outdoor conditions that render other air quality issues insignificant. With sufficient warning, occupants should leave the vicinity, but the unexpected nature of these events means that the only viable alternative may be to shelter in place.

This strategy may work for short-term releases. Homes are often too leaky to provide the protection needed for longer-duration events, but individual rooms can be temporarily sealed to become safe havens. A safe haven should be chosen to have as little contact as possible with outside walls, and preferably be on the side of the house furthest downwind from the source. Duct tape can be used to seal leaks, cracks, seams, register grilles, and doors, with thick plastic sheeting used to span larger gaps (Sorensen and Vogt 2001). If such a shelter has an air change rate of 0.15 ach with the house, it will take 4 to 6 h for contaminated outdoor air to reach the safe haven.

There may, however, be a very small population of at-risk individuals or locations for which emergencies are somewhat more likely. In such cases, a safe haven can be designed in advance with a highly efficient particle/gas-phase filtration system capable of providing several hours, days, or weeks of protection (Ormerod 1983). A short-term safe haven might be effectively combined with other emergency shelters (e.g., tornado, hurricane, civil defense) to reduce cost.

RESIDENTIAL VENTILATION AND IAQ CONTROL REQUIREMENTS

ASHRAE *Standard* 62.2 presents minimum requirements for residential ventilation air and acceptable indoor air quality, and its user's manual (ASHRAE 2006) has detailed information for designing and constructing residential buildings in compliance with the standard. Best or good practice may require going beyond the standard's minima. This section describes good practice; however, this presumes that the minimum requirements of 62.2 are met as well.

Traditionally, ventilation air for residences has been provided by natural ventilation and infiltration. Sherman and Matson (1997) showed that most of the older building stock is sufficiently leaky that infiltration alone can meet the minimum requirements of ASHRAE *Standard* 62.2. Houses built or retrofitted to new standards have substantially tighter envelopes and insufficient infiltration to meet ventilation standards. Studies have shown that concerns over safety, noise, comfort, air quality, and energy minimize occupant use of

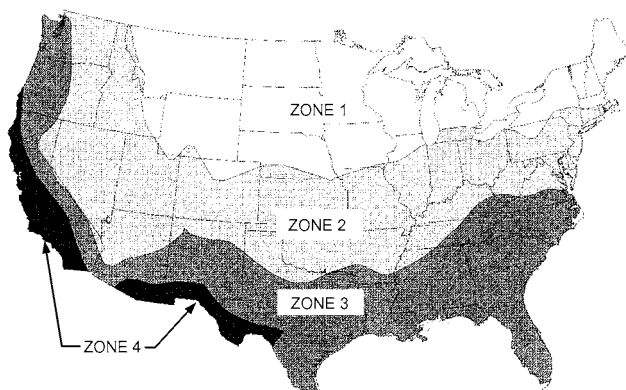

Fig. 13 Airtightness Zones for Residences in the United States (Sherman 1995)

operable windows (Johnson and Long 2005; Price and Sherman 2006). As a result, these houses require supplemental mechanical ventilation to satisfy current standards.

Simply meeting minimum residential ventilation rates is not always sufficient to adequately dilute all contaminants. For some buildings, such ventilation may not meet the requirements of individuals with allergies or chemical sensitivities or when there are unusual sources such as radon or mold. In these cases, source control or extra ventilation is required to manage the contaminant levels. Therefore, especially in single-family dwellings, occupants must be responsible for introducing, monitoring, and controlling the sources in the indoor environment, as well as for operating the dwelling unit to meet their individual needs. Increasingly, residences are also used for business or hobby purposes, which may introduce air contaminants not addressed in *Standard 62.2*; portions of these residences may require ventilation air as required by *Standard 62.1* or industrial guidelines.

Source Control

When considering how much whole-house ventilation should be supplied, typical and unusual significant sources of indoor pollution need to be controlled. This can be done either by mitigating the source itself or by using local exhaust to extract contaminants before they can mix into the indoor environment. Typical sources that should be considered include the following:

Clothes Dryers and Central Vacuum Systems. Clothes dryer exhaust is heavily laden with moisture and laundry by-products such as flammable lint and various gaseous contaminants. Many moisture problems have been traced to clothes dryers vented indoors. Exhaust from clothes dryers, which is typically about 150 cfm, should be vented directly to the outdoors. Similarly, central vacuum systems should be vented directly outdoors to exhaust the finer particles that pass through their filters.

Combustion. Water and carbon dioxide are always emitted during combustion of hydrocarbons in air. Other dangerous compounds are created, as well. All these by-products should be vented directly outdoors, preferably using sealed combustion or direct-vent equipment. Venting should meet all applicable codes. For buildings with naturally aspirated combustion appliances, excessive depressurization by exhaust systems must be avoided, which can be done by keeping combustion equipment outside the pressure boundary. In addition, a depressurization safety test should be considered, such as described in *ASTM Standard E1998* or *CGSB Standard 51.71*. Fireplace combustion products should be isolated from the occupied space using tight-fitting doors and outdoor air intakes, when necessary. Flues and chimneys must be designed and installed to disperse combustion products well away from air intakes and operable windows, for example. Chapter 34 of the 2008 *ASHRAE Handbook—HVAC Systems and Equipment* has more information on venting systems.

Carbon monoxide is one of the most pervasive indoor contaminants. It can come from virtually any source of combustion, including automobiles. Because even combustion appliances that meet manufacturers' specifications can interact with the building and emit carbon monoxide, at least one carbon monoxide alarm meeting safety standards such as *CSA Standard 6.19* should be installed near sleeping areas in each dwelling, including each unit of multifamily residential buildings, that has combustion appliances (e.g., fireplaces, stoves, furnaces, water heaters) within the pressure boundary, or has attached garages or storage sheds. Carbon monoxide alarms also should be considered for nonresidential buildings: poisonings have occurred in many building types, including hotels, motels, stores, restaurants, nursing homes, dormitories, laundromats, and schools.

Garages. Garages and storage spaces contain many sources of contaminants. Doors between them and occupied space should be well sealed with gaskets or weatherstripping and possibly be self-closing. Depressurized sections of HVAC systems, such as air

handlers or return or intake ducts, should not be located in garages. If such sections must pass through garages, they must be well sealed. Care should be taken to ensure that there is a good pressure barrier between the garage and the occupied space, typically using an air/moisture retarder such as heavy polyethylene, and other measures. Carbon monoxide sources may be present in garages, so pressure barriers, fire-rated compartmentation, and ventilation of attached residences are life-safety measures. Separate ventilation systems that slightly depressurize attached garages and storage spaces and exhaust directly outdoors should be considered, especially when these support spaces are tightly constructed or are in cold climates. Several studies (Batterman et al. 2006; Emmerich et al. 2003; Fugler 2004) of contaminant sources and transport in garages found that, in some cases, significant fractions of infiltration air enter houses from attached garages, and that modern residential garages are tighter than older garages, which were commonly assumed to be leaky enough to avoid many IAQ problems.

Particulates. The ventilation system should be designed such that return and outdoor air is filtered before passing through the thermal-conditioning components. Pressure drops associated with this filtration should be considered in the design of the air-handling system. Particulate filters or air cleaners should have a minimum efficiency of 60% for 0.125 in. particles, which is equivalent to a MERV 6 designated filter according to *ASHRAE Standard 52.2*.

Microbiologicals. Because ventilation can increase the source as well as removal rates of various air pollutants, it is, at best, moderately effective at reducing exposures to many airborne microbiologicals. Ventilation can, however, be part of the moisture balance that is critical to retarding fungal growth on surfaces and spores released into the air, depending on indoor/outdoor conditions.

Radon and Soil Gas. Buildings are exposed to gases that migrate from the soil through cracks or leaks. Soil gases vary with time and conditions, and can contain toxins from pesticides, landfill, fuel, or sewer gas, but the highest-profile pollutant in this category is radon and its radioactive-decay-produced "daughters." Source control measures, such as differential pressure control and airtightening, are far more effective than ventilation mechanisms at controlling exposure to soil gas. See Chapter 11 for more information.

Volatile Organic Compounds (VOCs). VOCs are ubiquitous in modern life. Products that emit VOCs include manufactured wood products, paints, stains, varnishes, solvents, pesticides, adhesives, wood preservatives, waxes, polishes, cleansers, lubricants, sealants, dyes, air fresheners, fuels, plastics, copy machines, printers, tobacco products, perfumes, cooking by-products, and dry-cleaned clothes. Whenever possible, VOCs and other toxic compounds should be stored outside the occupied space in loosely constructed or ventilated enclosures such as garden sheds, and away from occupied buildings' ventilation intakes. When unusual amounts of such compounds are present, additional ventilation should be considered.

Outdoor Air. Outdoor air may at times contain unacceptably high levels of pollutants, including ozone, pollen, carbon monoxide, particulate matter, odors, toxic agents, etc. At such times, it may be impossible to provide acceptable indoor air quality using solely outdoor air, and increased ventilation rates can actually decrease indoor air quality. In areas in which this problem may be anticipated, automatic or manual controls should be provided to allow reducing the ventilation rate. Cleaning recirculated air or using effective portable air cleaners should be considered for sensitive individuals.

Local Exhaust

After source elimination, the single most important source control mechanism in dwellings is local exhaust. All wet rooms and other spaces (e.g., kitchens, utility rooms, bathrooms, lavatories, toilets) designed to allow specific contaminant release should be provided with local exhaust. Workshops, recreation rooms, smoking

areas, art studios, greenhouses, and hobby rooms may also require local ventilation and/or air cleaning to remove contaminants generated by the activities involved. Contaminants of concern should be evaluated to determine how much additional ventilation is required. Many of these rooms can be adequately ventilated by following the requirements for kitchens or bathrooms. If unvented combustion appliances must be used, rooms with these appliances should also meet general ventilation requirements for kitchens, because such appliances generate significant amounts of moisture and, often, ultrafine particles, even when burning properly.

Mechanical exhaust is the preferred method of providing local ventilation. Normally, it is designed to operate intermittently under manual control to exhaust contaminated air outside when the contaminant is being produced and occupants recognize the need for ventilation. However, in many circumstances, a continuous, lower-flow-rate exhaust can work as well.

Continuous Local Mechanical Exhaust. A continuously operating mechanical exhaust is intended to operate without occupant intervention. This exhaust may be part of a balanced mechanical ventilation system. The system should be designed to operate during all hours in which the dwelling is occupied. Override control should be provided if needed. The minimum delivered ventilation should be at least that given in Table 1.

Intermittent Local Mechanical Exhaust. An intermittently operating local mechanical exhaust is intended to be operated as needed by the occupant and should be designed with this intent. Shutoff timers, occupancy controls, multiple-speed fans, and switching integral with room lighting are helpful, provided they do not impede occupant control. The minimum airflow rate should be at least that given in Table 2.

Alternatives. Cleaning recirculated air can sometimes be substituted for local exhaust, if it can be shown to be effective in removing contaminants of concern. Natural ventilation is not generally a suitable method for local exhaust and ventilation air needs in most climates and spaces. Using natural ventilation can cause reentrainment problems when air flows into rather than out of the space, and contaminated exhaust or exfiltrating air reenters the building. In milder climates, natural ventilation may be acceptable when the contaminant of concern is related to odor rather than health or safety. Purpose-designed passive exhaust systems have shown acceptable ventilation in some European settings, and may be considered in lieu of mechanical systems. Axley (2001b) discusses evaluation and design of passive residential ventilation systems further.

Table 1 Continuous Exhaust Airflow Rates

Application	Airflow Rate	Notes
Kitchen	5 ach	Based on kitchen volume
Utility room, bathroom, toilet, lavatory	20 cfm	Not less than 2 ach

Table 2 Intermittent Exhaust Airflow Rates

Application	Airflow Rate	Notes
Kitchen	100 cfm	Vented range hood required if less than 5 ach
Utility room, bathroom, toilet, lavatory	50 cfm	Not less than 2 ach

Table 3 Total Ventilation Air Requirements

Area Based	Occupancy Based
1 cfm/100 ft ² of floor space	7.5 cfm per person, based on normal occupancy

Whole-House Ventilation

Although control of significant sources of pollution in a dwelling is important, whole-house ventilation through centrally introduced, conditioned, and distributed outside air may still be needed. Each dwelling should be provided with outdoor air according to Table 3. The rate is the sum of the Area-Based and Occupancy-Based columns. Design occupancy can be based on the number of bedrooms as follows: first bedroom, two persons; each additional bedroom, one person. Additional ventilation should be considered when occupant densities exceed 1/250 ft².

Natural whole-house ventilation that relies on occupant operation should not be used to make up any part of the minimum total whole-house ventilation air requirement. However, because occupancy and sources vary significantly, the capacity to ventilate above minimum rates can be provided by operable exterior openings such as doors and windows.

Air Distribution

Ventilation air should be provided to each habitable room through mechanical and natural air distribution. If a room does not have a balance between air supply and return or exhaust, pathways for transfer air should be provided. These pathways may be door undercuts, transfer ducts with grilles, or simply grilles where ducts are not necessary or required by code.

In houses without central air handlers, special provisions to distribute outdoor air may be required. Rooms in which occupants spend many continuous hours, such as bedrooms, may require special consideration. Local and whole-house ventilation equipment should be chosen to be energy efficient, easy to maintain, reliable, durable, and quiet. Heat recovery should be considered, especially in cold climates.

Selection Principles for Residential Ventilation Systems

Occupant comfort, energy efficiency, ease of use, service life, first and life-cycle cost, value-added features, and indoor environmental quality should be considered when selecting a strategy and system. HVAC and related systems can be a potential cause of poor indoor air quality. For example, occupants may not use the ventilation systems as intended if operation results in discomfort (e.g., drafts) or excessive energy use. The resulting lack of ventilation might produce poor indoor air quality. Therefore, careful design, construction, commissioning, operation, and maintenance is necessary to provide optimum effectiveness.

All exhaust, supply, or air-handler fans have the potential to change the pressure of the living space relative to the outside. High-volume fans, such as the air handler and some cooking exhaust fans, can cause high levels of depressurization, particularly in tightly constructed homes. Considering these effects is essential in design. Excessive depressurization of the living space relative to outside may cause backdrafting of combustion appliances and the migration of contaminants such as radon or other soil gases, car exhaust, or insulation particles into the living space. Depressurization can also result in moisture intrusion into building cavities in warm, moist climates, which may cause structural damage and fungal growth. Pressurization of the living space can cause condensation in building cavities in cold climates, also resulting in structural damage. Excess pressure can best be prevented by balanced ventilation systems and tightly sealed duct systems. In addition, adequate pathways must be available for all return air to the air-handling devices.

Occupant activities, operation of fans that exhaust air from the home, and leaky ducts on air conditioners, furnaces, or heat pumps may depressurize the structure. Options to address backdrafting concerns include

- Using combustion appliances with isolated (or sealed) combustion systems

- Locating combustion appliances in a ventilated room isolated from depressurized zones by well-sealed partitions
- Installing supply fans to balance or partially balance exhaust from the zone
- Testing to ensure that depressurization is not excessive

The system must be designed, built, operated, and maintained in a way that discourages growth of biological contaminants. Typical precautions include sloping condensate drain pans toward the drain, keeping condensate drains free of obstructions, keeping cooling coils free of dirt and other obstructions, maintaining humidifiers, and checking and eliminating any cause of moisture inside ducts.

Outside and exhaust airstreams of ventilation systems can be coupled using a heat pump or other device to recover thermal energy, when appropriate. Such heat pump or other equipment may reverse mode with the seasons or sensed temperature differences, for example. Heat can also be recovered from air to preheat potable water, for example.

SIMPLIFIED MODELS OF RESIDENTIAL VENTILATION AND INFILTRATION

This section describes several calculation procedures, ranging from simple estimation techniques to more physical models. Orme (1999) provides a more thorough review of simplified models. A building's air exchange rate cannot be reliably deduced from the building's construction or age, or from a simple visual inspection. Some measurement is necessary, such as a pressurization test of envelope airtightness or a detailed quantification of the leakage sites and their magnitude. The air exchange rate of a building may be calculated given (1) the location and leakage function for every opening in the building envelope and between major building zones, (2) the wind pressure coefficients over the building envelope, and (3) any mechanical ventilation airflow rates. These inputs are generally unavailable for all except very simple structures or extremely well studied buildings. Therefore, their values must be assumed. The appropriateness of these assumptions influences the accuracy of predictions of air exchange rates.

Empirical Models

These models of residential infiltration are based on statistical fits of infiltration rate data for specific houses. They use pressurization test results to account for house airtightness and take the form of simple relations between infiltration rate, an airtightness rating, and, in most cases, weather conditions. Empirical models account for envelope infiltration only and do not deal with intentional ventilation. In one approach, the calculated air exchange rate at 0.20 in. of water based on a pressurization test is simply divided by a constant approximately equal to 20 (Sherman 1987). This technique does not account for the effect of infiltration-driving mechanisms on air exchange. Empirical models that do account for weather effects have been developed by Kronvall (1980), Reeves et al. (1979), and Shaw (1981).

The latter two models account for building air leakage using the values of c and n from Equation (40). The only other inputs required are wind speed and temperature difference. These empirical models predict long-term (one-week) infiltration rates very well in the houses from which they were developed; they do not, however, work as well in other houses because of the building-specific nature of leakage distribution, wind pressure, and internal partitioning. Persily (1986) and Persily and Linteris (1983) compared measured and predicted house infiltration rates for these and other models. The average long-term differences between measurements and predictions are generally on the order of 40%, although individual predictions can be off by 100% or more (Persily 1986; Walker and Wilson 1998).

Multizone Models

Multicell models of air exchange treat buildings as a series of interconnected zones and assume that air within each zone is well mixed. Several such models have been developed by Allard and Herrlin (1989), Etheridge and Alexander (1980), Feustel and Raynor-Hoosen (1990), Herrlin (1985), Liddament and Allen (1983), Walton (1984, 1989), and Walton and Dols (2003). They are all based on a mass balance for each zone of the building. These mass balances are used to solve for interior static pressures in the building by requiring that inflows and outflows for each zone balance to zero. The user must input information describing building envelope leakage, values to account for wind pressure on the building envelope, temperatures for each zone, and any mechanical ventilation airflow rates. Wind pressure coefficient data in the literature, air leakage measurement results from the building or its components, and air leakage data from the literature can be used as estimates. These models not only solve for whole-building and individual zone air exchange rates, but also determine airflow rates and pressure differences between zones. These interzone airflow rates are useful for predicting pollutant transport within buildings with well mixed zones. Chapter 13 has more details on multizone airflow and IAQ modeling.

Single-Zone Models

Several procedures have been developed to calculate building air exchange rates that are based on physical models of the building interior as a single zone. These single-zone models are only appropriate for buildings with no internal resistance to airflow, and are therefore inappropriate for large, multizone buildings. Some models of this type have been developed by Cole et al. (1980), Sherman and Grimsrud (1980), Walker and Wilson (1998), and Warren and Webb (1980). The section on Residential Calculation Examples uses both basic and enhanced models (Bradley 1993; CHBA 1994; Hamlin and Pushka 1994; Palmiter and Bond 1994; Walker and Wilson 1998).

The **basic model** uses effective air leakage area A_L at 0.016 in. of water, which can be obtained from a whole-building pressurization test. The **enhanced model** uses pressurization test results to characterize house air leakage through leakage coefficient c and pressure exponent n . The enhanced model improves on the basic model by using a power law to represent envelope leakage, including a flue as a separate leakage site, and having separate wind effects for houses with crawlspaces or slab/basement foundations.

For both models, the user must input wind speed, temperature difference, information on distribution of leakage over the building envelope, a wind shelter (or local shielding for the basic model) parameter, and a terrain coefficient. The predictive accuracy of the enhanced model can be very good, typically $\pm 10\%$ when parameters are well known for the building in question (Palmiter and Bond 1994; Sherman and Modera 1986; Walker and Wilson 1998). All these single-zone models are sensitive to values of inputs, which are quite difficult to determine.

Superposition of Wind and Stack Effects

Simplified physical models of infiltration solve the problem of two natural driving forces, wind and stack, separately and then combine them in a process called **superposition**. Superposition is necessary because each physical process can affect internal and external pressures on the structure, which can cause interactions between physical processes that are otherwise independent. An exact solution is impossible because detailed properties of all the building leaks are unknown and because leakage is a nonlinear process. For this reason, most modelers have developed a simplified superposition process to combine stack and wind effects. Sherman (1992b) compared various superposition procedures and derived a generalized superposition equation involving simple leakage distribution parameters, and showed that the result is always subadditive.

Typically, only 35% of infiltration from the smaller effect can be added to the larger effect. Depending on details, that percentage could go as high as 85% or as low as zero. Walker and Wilson (1993) compared several superposition techniques to measured data. Sherman, as well as Walker and Wilson, found quadrature, shown in Equation (47), to be a robust superposition technique:

$$Q = \sqrt{Q_s^2 + Q_w^2} \quad (47)$$

The following sections discuss how superposition is combined with calculation of wind and stack flows to determine total flow.

Residential Calculation Examples

Basic Model. The following calculations are based on the Sherman and Grimsrud (1980) model, which uses the effective air leakage area at 0.016 in. of water. This leakage area can be obtained from a whole-building pressurization test. Using effective air leakage area, the airflow rate from infiltration is calculated according to

$$Q = A_L \sqrt{C_s \Delta t + C_w U^2} \quad (48)$$

where

- Q = airflow rate, cfm
- A_L = effective air leakage area, in²
- C_s = stack coefficient, cfm²/(in⁴·°F)
- Δt = average indoor-outdoor temperature difference for time interval of calculation, °F
- C_w = wind coefficient, cfm²/(in⁴·mph²)
- U = average wind speed measured at local weather station for time interval of calculation, mph

Table 4 presents values of C_s for one-, two-, and three-story houses. The value of wind coefficient C_w depends on the local shelter class of the building (described in Table 5) and the building height. Table 6 presents values of C_w for one-, two-, and three-story houses in shelter classes 1 through 5. In calculating values in Tables 4 and 6, the following assumptions were made regarding input to the basic model:

Table 4 Basic Model Stack Coefficient C_s

	House Height (Stories)		
	One	Two	Three
Stack coefficient	0.0150	0.0299	0.0449

Table 5 Local Shelter Classes

Shelter Class	Description
1	No obstructions or local shielding
2	Typical shelter for an isolated rural house
3	Typical shelter caused by other buildings across street from building under study
4	Typical shelter for urban buildings on larger lots where sheltering obstacles are more than one building height away
5	Typical shelter produced by buildings or other structures immediately adjacent (closer than one house height): e.g., neighboring houses on same side of street, trees, bushes, etc.

Table 6 Basic Model Wind Coefficient C_w

Shelter Class	House Height (Stories)		
	One	Two	Three
1	0.0119	0.0157	0.0184
2	0.0092	0.0121	0.0143
3	0.0065	0.0086	0.0101
4	0.0039	0.0051	0.0060
5	0.0012	0.0016	0.0018

- Terrain used for converting meteorological to local wind speeds is that of a rural area with scattered obstacles
- $R = 0.5$ (half the building leakage in the walls)
- $X = 0$ (equal amounts of leakage in the floor and ceiling)
- Heights of one-, two-, and three-story buildings = 8, 16, and 24 ft, respectively

Example 2. Estimate the infiltration at design conditions for a two-story house in Lincoln, Nebraska. The house has effective air leakage area of 77 in² and volume of 12,000 ft³, and the predominant wind is perpendicular to the street (shelter class 3). The indoor air temperature is 68°F.

Solution: The 99% design temperature for Lincoln is -2°F. Assume a design wind speed of 15 mph. From Equation (48), with $C_s = 0.0299$ from Table 4 and $C_w = 0.0086$ from Table 6, the airflow rate caused by infiltration is

$$Q = 77 \sqrt{(0.0299)(70) + (0.0086)(15^2)} = 155 \text{ cfm} = 9300 \text{ ft}^3/\text{h}$$

From Equation (2), air exchange rate I is equal to Q divided by the building volume:

$$I = (9300 \text{ ft}^3/\text{h})/12,000 \text{ ft}^3 = 0.78 \text{ h}^{-1} = 0.78 \text{ ach}$$

Example 3. Predict the average infiltration during a one-week period in January for a one-story house in Portland, Oregon. During this period, the average indoor/outdoor temperature difference is 30°F, and average wind speed is 6 mph. The house has volume of 9000 ft³ and effective air leakage area of 107 in², and it is located in an area with buildings and trees within 30 ft in most directions (shelter class 4).

Solution: From Equation (48), the airflow rate caused by infiltration is

$$Q = 107 \sqrt{(0.0150)(30) + (0.0039)(6^2)} = 82.2 \text{ cfm} = 4930 \text{ ft}^3/\text{h}$$

The air exchange rate is therefore

$$I = 4930/9000 = 0.55 \text{ h}^{-1} = 0.55 \text{ ach}$$

Example 4. Estimate the average infiltration over the heating season in a two-story house with volume of 11,000 ft³ and leakage area of 131 in². The house is located on a lot with several large trees but no other close buildings (shelter class 3). Average wind speed during the heating season is 7 mph, and the average indoor/outdoor temperature difference is 36°F.

Solution: From Equation (48), the airflow rate from infiltration is

$$Q = 131 \sqrt{(0.0299)(36) + (0.0086)(7^2)} = 160 \text{ cfm} = 9620 \text{ ft}^3/\text{h}$$

The average air exchange rate is therefore

$$I = 9620/11,000 = 0.87 \text{ h}^{-1} = 0.87 \text{ ach}$$

Enhanced Model. This section presents a simple, single-zone approach to calculating air infiltration rates in houses based on the Walker and Wilson (1998) model. The airflow rate from infiltration is calculated using

$$Q_s = c C_s \Delta t^n \quad (49)$$

$$Q_w = c C_w (sU)^{2n} \quad (50)$$

where

- Q_s = stack airflow rate, cfm
- Q_w = wind airflow rate, cfm
- c = flow coefficient, cfm/(in. of water) ^{n}
- C_s = stack coefficient, (in. of water) ^{n} /°F ^{n}
- C_w = wind coefficient, (in. of water/mph²) ^{n}
- s = shelter factor

In calculating tabulated values of C_s , C_w , and s , the following assumptions were made:

- Each story is 8 ft high.
- The flue is 6 in. in diameter and reaches 6 ft above the upper ceiling.

- The flue is unsheltered.
- Half of envelope leakage (not including the flue) is in the walls and one-quarter each is at the floor and ceiling, respectively.
- $n = 0.67$

Using typical values for terrain factors, house height, and wind speed measurement height, wind speed multiplier G (given in Table 7) uses a relationship based on equations found in Chapter 24 and used in the following examples.

Example 5. Estimate the infiltration at design conditions for a two-story slab-on-grade house with a flue in Lincoln, Nebraska. The house has a flow coefficient of $c = 2.6$ cfm/(in. of water) ^{n} and a pressure exponent of $n = 0.67$ (this corresponds to effective leakage area of 77 in² at 0.016 in. of water). The building volume is 12,000 ft³. The 97.5% design temperature is -2°F, and design wind speed is 15 mph.

Solution: For a slab-on-grade two-story house with a flue, Table 8 gives $C_s = 2.41$ [(in. of water)^{°F}] ^{n} and $C_w = 2.14$ [(in. of water)/mph²] ^{n} . The house is maintained at 68°F indoors. The building wind speed is determined by taking design wind speed U_{met} and multiplying by the wind speed multiplier G from Table 7:

$$U = GU_{met} = 0.59(15) = 8.9 \text{ mph}$$

From Table 5, the shelter class for a typical urban house is 4. Table 9 gives the shelter factor for a two-story house with a flue and shelter class 4 as $s = 0.64$. The stack flow is calculated using Equation (49):

$$Q_s = (2.6)(2.41)[68 - (-2)]^{0.67} = 108 \text{ cfm}$$

The wind flow is calculated using Equation (50):

$$Q_w = (2.6)(2.14)[0.64 \times 8.9]^{1.34} = 57 \text{ cfm}$$

Substituting Q_s and Q_w into Equation (47) gives $Q = 122$ cfm = 7300 ft³/h. From Equation (2), air exchange rate I is equal to Q divided by building volume:

$$I = (7300 \text{ ft}^3/\text{h})/12,000 \text{ ft}^3 = 0.61 \text{ h}^{-1} = 0.61 \text{ ach}$$

Example 6. Estimate the average infiltration over a one-week period for a single-story crawlspace house in Redmond, Washington. The house has a flow coefficient of $c = 4.1$ cfm/(in. of water) ^{n} and a pressure exponent of $n = 0.6$ (this corresponds to effective leakage area of 107 in² at 0.016 in. of water). The building volume is 9000 ft³. During this period, the average indoor/outdoor temperature difference is 29°F, and wind speed is 6 mph. The house is electrically heated and has no flue.

Solution: For a single-story house with no flue, $C_s = 1.46$ [(in. of water)^{°F}] ^{n} . For a crawlspace, $C_w = 1.75$ [(in. of water)/mph²] ^{n} . From Table 7, for a one-story house, $G = 0.48$.

$$U = GU_{met} = 0.48(6) = 2.9 \text{ mph}$$

Table 9 gives shelter factor $s = 0.50$ for a house with no flue and shelter class 4. Stack flow is calculated using Equation (49):

Table 7 Enhanced Model Wind Speed Multiplier G

	House Height (Stories)		
	One	Two	Three
Wind speed multiplier G	0.48	0.59	0.67

Table 8 Enhanced Model Stack and Wind Coefficients

	One Story		Two Story		Three Story	
	No Flue	With Flue	No Flue	With Flue	No Flue	With Flue
C_s	1.46	1.87	2.13	2.41	2.68	2.92
C_w for base-ment slab	2.14	1.95	2.34	2.14	2.34	2.29
C_w for crawl-space	1.75	1.75	1.95	1.95	2.07	2.11

$$Q_s = (4.1)(1.46)(29)^{0.6} = 45 \text{ cfm}$$

Wind flow is calculated using Equation (50):

$$Q_w = (4.1)(1.75)[0.50 \times 8.9]^{1.2} = 11.2 \text{ cfm}$$

Substituting Q_s and Q_w into Equation (47) gives $Q = 46$ cfm = 2800 ft³/h. From Equation (2), air exchange rate I is equal to Q divided by building volume:

$$I = (2800 \text{ ft}^3/\text{h})/9000 \text{ ft}^3 = 0.31 \text{ h}^{-1} = 0.31 \text{ ach}$$

Example 7. Estimate the infiltration for a three-story house in San Francisco, California. The house has a flow coefficient of $c = 5.2$ cfm/(in. of water) ^{n} and a pressure exponent of $n = 0.67$ (this corresponds to effective leakage area of 155 in² at 0.016 in. of water). The building volume is 14,200 ft³. The indoor/outdoor temperature difference is 9°F and wind speed is 10 mph. The house has a flue and a crawlspace.

Solution: For a three-story house with a flue, $C_s = 2.92$ [(in. of water)^{°F}] ^{n} . For a crawlspace, $C_w = 2.11$ [(in. of water)/mph²] ^{n} . From Table 7, for a three-story house, $G = 0.67$.

$$U = GU_{met} = 0.67(10) = 6.7 \text{ mph}$$

The prevailing wind blows along the row of houses parallel to the street, so the house has a shelter class of 5. Table 9 gives the shelter factor for a three-story house with a flue and shelter class 5 as $s = 0.43$.

$$Q_s = (5.2)(2.92)(9)^{0.67} = 66 \text{ cfm}$$

$$Q_w = (5.2)(2.11)[0.43 \times 6.7]^{1.34} = 45 \text{ cfm}$$

Substituting Q_s and Q_w in Equation (47) gives $Q = 80$ cfm = 4800 ft³/h.

$$I = (4800 \text{ ft}^3/\text{h})/(14,200) \text{ ft}^3 = 0.34 \text{ h}^{-1} = 0.34 \text{ ach}$$

Combining Residential Infiltration and Mechanical Ventilation

Significant infiltration and mechanical ventilation often occur simultaneously in residences. The pressure difference from Equation (31) can be used for each building leak, and the flow network (including mechanical ventilation) for the building can be solved to find the flow through all the leaks while accounting for the effect of the mechanical ventilation. However, for simplified models, natural infiltration and mechanical ventilation are usually determined separately and require a superposition method to combine the flow rates.

Sherman (1992b) compared various superposition procedures and derived a generalized superposition equation that involves simple leakage distribution parameters. The result is always subadditive. For small unbalanced fans, typically only half the flow contributes to the total, but this fraction can be anywhere between 0 and 100%, depending on leakage distribution. When fan flow is large, infiltration may be ignored.

In special cases when the leakage distribution is known and highly skewed, it may be necessary to work through the superposition method in more detail. For example, in a wind-dominated situation, a supply fan has a much bigger effect than an exhaust fan on changing the total ventilation rate; the same is true for houses with high neutral levels in cold climates. For the general case, when

Table 9 Enhanced Model Shelter Factor s

Shelter Class	One Story		Two Story		Three Story	
	No Flue	with Flue	No Flue	with Flue	No Flue	with Flue
1	1.00	1.10	1.07	1.07	1.06	1.06
2	0.90	1.02	0.98	0.98	0.97	0.97
3	0.70	0.86	0.81	0.81	0.79	0.79
4	0.50	0.70	0.64	0.64	0.61	0.61
5	0.30	0.54	0.47	0.47	0.43	0.43

details are not known or can be assumed to be broad and typical, the following superposition gives good results:

$$Q_{comb} = Q_{bal} + \sqrt{Q_{unbal}^2 + Q_{infiltration}^2} \quad (51)$$

Typical Practice

The preceding sections on estimating infiltration in low-rise residences represent current analytical techniques typically used for research and remediation purposes, but most small residential buildings are designed and constructed without direct involvement of ventilation engineers. Contractors, who typically prepare these buildings’ designs, are required to follow mandates in various codes and standards, and they apply experience-based rules of thumb when determining, for example, exhaust needs. Often, leaky buildings or air quality problems result. Research and experience has shown that tightening building envelopes, and potentially using mechanical ventilation with heat recovery, can yield improved indoor air quality and reduced energy consumption. Retaining the services of a ventilation engineer before construction begins is advisable in some situations.

COMMERCIAL AND INSTITUTIONAL AIR LEAKAGE

Commercial Building Envelope Leakage

ASTM *Standard E779* and CGSB *Standard 149.10* include methods to measure the airtightness of building envelopes of single-zone buildings. Although many multizone buildings can be treated as single-zone buildings by opening interior doors or by inducing equal pressures in adjacent zones, these standards provide no guidelines for dealing with problems arising in tall buildings, such as stack and wind effects. Tall buildings require refinement and extensions of established procedures because they have obstacles to accurate measurement not present in small buildings, including large envelope leakage area, interfloor leakage, vertical shafts, and large wind and stack pressures. In conducting a fan pressurization test in a large building, the building’s own air-handling equipment sometimes can be used to induce test pressures, as described in CGSB *Standard 149.15*. In other cases, a large fan is brought to the building to perform the test, as described by CIBSE *Standard TM-23*. Bahnfleth et al. (1999) also discuss how to address some of these issues.

Building envelopes of large commercial buildings are often assumed to be quite airtight. Tamura and Shaw (1976a) found that, assuming a flow exponent *n* of 0.65 in Equation (40), air leakage measurements in eight Canadian office buildings with sealed windows ranged from 0.120 to 0.480 cfm/ft². Persily and Grot (1986) ran whole-building pressurization tests in large office buildings that showed that pressurization airflow rate divided by building volume is relatively low compared to that of houses. However, if these airflow rates are normalized by building envelope area instead of by volume, the results indicate envelope airtightness levels similar to those in typical American houses. The same study also looked at eight U.S. office buildings and found air leakage ranging from 0.213 to 1.028 cfm/ft² at 0.30 in. of water. This means that office building envelopes are leakier than expected. Typical air leakage values per unit wall area at 0.30 in. of water are 0.10, 0.30, and 0.60 cfm/ft² for tight, average, and leaky walls, respectively (Tamura and Shaw 1976a).

Emmerich and Persily (2005) summarize available measured airtightness data for 203 U.S. commercial and institutional buildings. Sources of data included 9 buildings tested by the National Institute of Standards and Technology (Musser and Persily 2002; Persily and Grot 1986; Persily et al. 1991), 90 tested by the Florida Solar Energy Center (Cummings et al. 1996, 2000), 2 tested by Pennsylvania State University (Bahnfleth et al. 1999), 23 tested by Camroden Associates

(Brennan et al. 1992 and previously unpublished data), and 79 buildings tested by the U.S. Army Corps of Engineers (previously unpublished data). Tested buildings were of a wide range of types and ages but were primarily low-rise buildings. The overall average airtightness of 1.55 cfm/ft² of above-grade envelope surface area at 0.0109 psi is in the same range as that reported for typical U.S. houses, and is similar to averages reported by Potter (2001) for U.K. commercial buildings built before recent airtightness regulations. The data show that taller buildings tend to be tighter, and a lack of correlation between year of construction and observed building air leakage. This study also found a trend, with considerable scatter, toward tighter buildings in colder climates. The authors caution that conclusions from this analysis are limited by the small sample size and a lack of random sampling. None of the buildings are known to have been constructed to meet a specified air leakage criterion, which has been identified as a key to achieving tight building envelopes in practice.

Grot and Persily (1986) also found that eight recently constructed office buildings had infiltration rates ranging from 0.1 to 0.6 ach with no outdoor air intake. The infiltration rates of these buildings exhibited varying degrees of weather dependence, generally much lower than that measured in houses. Infiltration in commercial buildings can have many negative consequences, including reduced thermal comfort, interference with proper operation of mechanical ventilation systems, degraded indoor air quality, moisture damage of building envelope components, and increased energy consumption. These results suggest strongly that commercial buildings’ envelopes require tighter construction, and that continuous air barrier systems should be used in all conditioned buildings. Since 1997, the Building Environment and Thermal Envelope Council of the National Institute of Building Sciences has sponsored several symposia on air barriers for buildings in North American climates. Others have also published articles on the importance of limiting air leakage in commercial buildings (Anis 2001; Ask 2003; Fennell and Haehnel 2005).

Envelope leakage in commercial buildings also depends on HVAC system operation. Often, commercial buildings, and their HVAC systems, are in operation during normal daytime business hours but switch into “unoccupied” operation at nights and on weekends. If pressurized while their HVAC systems operate, infiltration is often very low or even eliminated in buildings with tight envelopes. However, in unoccupied mode, this pressurization is often lost, so infiltration and potentially moisture intrusion may be significant at times.

Air Leakage Through Internal Partitions

In large buildings, air leakage associated with internal partitions becomes very important. Elevator, stair, and service shaft walls; floors; and other interior partitions are the major separations of concern in these buildings. Their leakage characteristics are needed to determine infiltration through exterior walls and airflow patterns in a building. These internal resistances are also important in the

Table 10 Air Leakage Areas for Internal Partitions in Commercial Buildings (at 0.30 in. of water and *C_D* = 0.65)

Construction Element	Wall Tightness	Area Ratio
		<i>A_L</i> / <i>A_w</i>
Stairwell walls	Tight	0.14 × 10 ⁻⁴
	Average	0.11 × 10 ⁻³
	Loose	0.35 × 10 ⁻³
Elevator shaft walls	Tight	0.18 × 10 ⁻³
	Average	0.84 × 10 ⁻³
	Loose	0.18 × 10 ⁻²
		<i>A_L</i> / <i>A_f</i>
Floors	Average	0.52 × 10 ⁻⁴

A_L = air leakage area *A_w* = wall area *A_f* = floor area

Fig. 14 Air Leakage Rates of Elevator Shaft Walls

event of a fire to predict smoke movement patterns and evaluate smoke management systems.

Table 10 gives air leakage areas calculated at 0.30 in. of water with $C_D = 0.65$ for different internal partitions of commercial buildings (Klote and Milke 2002). Figure 14 presents examples of measured air leakage rates of elevator shaft walls (Tamura and Shaw 1976b), the type of data used to derive the values in Table 10. Consult Chapter 52 of the 2007 *ASHRAE Handbook—HVAC Applications* for performance models and applications of smoke management systems.

Leakage openings at the top of elevator shafts are equivalent to orifice areas of 620 to 1550 in². Air leakage rates through stair shaft and elevator doors are shown in Figure 15 as a function of average crack width around the door. Air leakage areas associated with other openings in commercial buildings are also important for air movement calculations. These include interior doors and partitions, suspended ceilings in buildings where space above the ceiling is used in air distribution, and other components of the air distribution system.

Air Leakage Through Exterior Doors

Door infiltration depends on the type and use of door, room, and building, and on air speed and pressure differentials. In residences and small buildings where doors are used infrequently, air exchange associated with a door can be estimated based on air leakage through cracks between door and frame. Airflow increases significantly as door-opening frequency increases. Vestibules or revolving doors should be considered for high-frequency applications.

Air Leakage Through Automatic Doors

Automatic swinging, sliding, rotating, or overhead doors are a major source of air leakage in buildings. They are normally installed where large numbers of people use the doors or bulk goods are transported through the doorways. These doors stay open longer with each use than manual doors. Air leakage through automatic doors can be reduced by installing a vestibule. However, pairs of automatic doors on the inside and outside of a vestibule normally have overlapping open periods, even when used by only one person at a time. Therefore, it is important that designers take into account airflow through automatic doors when calculating heating and cooling loads in adjacent spaces.

Fig. 15 Air Leakage Rate of Door Versus Average Crack Width

Fig. 16 Airflow Coefficient for Automatic Doors

To calculate the average airflow rate through an automatic door, the designer must take into account the area of the door, the pressure difference across it, the discharge coefficient of the door when it is open, and the fraction of time that it is open. Obtaining the discharge coefficient is complicated by the fact that it changes as the door opens and closes.

To simplify this calculation, ASHRAE research project RP-763 (Yuill 1996) developed Figure 16 to combine the discharge coefficients of doors as they open and close with the fraction of time that doors are open at a particular level of use. This figure presents an overall airflow coefficient as a function of the number of people using a door per hour. To obtain the average infiltration rate through an automatic door, multiply this coefficient by the door’s opening area and by the square root of the pressure difference between the outdoor and indoor air at the door’s location. The pressure difference across a door in a building depends on wind pressure on the building, stack effect caused by the indoor/outdoor temperature difference, and effects of air-handling system operation. It also depends on leakage characteristics of the building’s exterior walls and of internal partitions.

Fig. 17 Pressure Factor for Automatic Doors

Two simple methods are presented here. The first method uses simplifying assumptions to determine design values for R_p , the square root of the pressure difference across the automatic door, given in Figure 17. The second method requires explicit calculation of envelope pressures.

In Figure 17, airflows shown for outside air temperatures of 80 and 100°F, represented by dotted lines, are outward flows. They intercept the vertical axis at a lower point than the other lines because wind pressure coefficients on the building's downwind face, where the greatest outward flows occur, are lower than on the upward face. In many buildings, air pressure in the building is controlled by varying the flow rate through return fan(s) or by controlling the relief air dampers. These systems are usually set to maintain a pressure slightly above ambient in the lobby, but in a large building, multiple sensors may be used to regulate air pressure on each floor, for example. Subtracting the interior pressure maintained from the wind pressure gives the net pressure for estimating airflow through an exterior door.

Method 1. For the first method, the infiltration rate through the automatic door is given by

$$Q = C_A A R_p \tag{52}$$

where

- Q = airflow rate, cfm
- C_A = airflow coefficient from Figure 16, cfm/[ft²·(in. of water)^{0.5}]
- A = area of the door opening, ft²
- R_p = pressure factor from Figure 17, in. of water^{0.5}

Method 2. Airflow Q is given by

$$Q = C_A A \sqrt{\Delta p} \tag{53}$$

where

- Q = airflow rate, cfm
- C_A = airflow coefficient from Figure 16, cfm/[ft²·(in. of water)^{0.5}]
- A = area of the door opening, ft²
- Δp = pressure difference across door, in. of water

To find Δp , it is necessary to find the pressure differential from wind and that from stack effect. To give the largest possible pressure difference across the door, there are no interactions between the two natural pressures:

$$\Delta p = p_w - \Delta p_s \tag{54}$$

where

- p_w = wind-induced surface pressure relative to static pressure, in. of water
- Δp_s = pressure difference due to stack effect, in. of water

Example Calculations

Find the maximum possible infiltration through an automatic door located on the ground floor of a 20-story building. The area of the door is 36 × 84 in. = 3024 in² = 21 ft². Each floor is 13 ft high. Approximately 300 people per hour pass through the door. The design wind conditions are 15 mph, indoor temperature is 70°F, and outdoor temperature is 20°F. The airflow coefficient from Figure 16, using the line for doors without vestibules, is approximately 920 cfm/[ft²·(in. of water)^{0.5}].

Method 1:

The pressure factor from Figure 17 is 0.5 (in. of water)^{0.5}. Equation (52) gives the door flow as

$$Q = 920(21)0.5 = 9660 \text{ cfm}$$

Method 2:

The worst possible case for wind surface pressure coefficient C_p at any point and in any position on the ground floor of the building is inferred from figures in Chapter 24 to be about 0.75. Using this in Equation (25), together with the specified wind speed, results in $p_w = 0.082$ in. of water. Assume that H is one-half the door height (42 in.). To have maximum pressure across the door, assume the neutral pressure plane is located halfway up the building such that

$$H_{NPL} = \frac{1}{2}(20 \text{ stories}) \frac{13 \text{ ft}}{\text{story}} = 130 \text{ ft}$$

Substituting these values into Equation (24) gives $\Delta p_s = -0.19$ in. of water. This is the maximum stack pressure difference given no internal resistance to airflow. To find the actual stack pressure difference, it is necessary to multiply this by a draft coefficient. For this example, the coefficient is assumed to be 0.9, which is the highest value that has been found for tall buildings. Therefore, $\Delta p_s = 0.9(-0.19 \text{ in. of water}) = -0.17$ in. of water. The total pressure is then $\Delta p = 0.082 - (-0.17) = 0.252$ in. of water. Substituting into Equation (53),

$$Q = 920(21)\sqrt{0.252} = 9700 \text{ cfm}$$

If the building has a vestibule, the airflow coefficient is read from Figure 16 using the line for doors with vestibules, and it is approximately 626 cfm/[ft²·(in. of water)^{0.5}], reducing airflow to 6600 cfm into the building.

Air Exchange Through Air Curtains

Air curtains are jets of air projected across envelope openings with the intention of reducing air exchange and the entrance of dust and insects, for example. They are commonly applied to loading dock doorways and high-use building entrances. Performance of air curtains is highly dependent on factors such as jet characteristics, wind, and building pressurization. More discussion on air curtain performance is available in Chapter 17 of the 2004 *ASHRAE Handbook—HVAC Systems and Equipment*.

COMMERCIAL AND INSTITUTIONAL VENTILATION

ASHRAE Standard 62.1 contains requirements on ventilation and indoor air quality for commercial, institutional, and high-rise residential buildings. These requirements address system and equipment issues, design ventilation rates, commissioning and systems start-up, and operation and maintenance. The user's manual for Standard 62.1-2007 (ASHRAE 2007) provides details to help the user design, install, and operate buildings to meet requirements. The design requirements include two alternative procedures:

- The prescriptive **ventilation rate procedure (VRP)** contains a table of outdoor air ventilation requirements for a variety of space types, with adjustments for air distribution in rooms and systems serving multiple spaces. These requirements consist of both a per-person rate and a per-floor-area rate. Minimum outside air ventilation rates are based, in part, on research by Berg-Munch et al. (1986), Cain et al. (1983), Iwashita et al. (1989), and Yaglou et al.

(1936), as well as years of experience of designers and building operators.

- The **indoor air quality procedure (IAQP)**, which achieves acceptable indoor air quality by controlling indoor contaminant concentrations through source control, air cleaning, and ventilation. It allows for either or both improved indoor air quality and reduced energy consumption. Chapter 28 of the 2008 *ASHRAE Handbook—HVAC Systems and Equipment* has information on air cleaning.

The ventilation rate procedure is by far the more commonly used.

Combining source control and local exhaust, as opposed to dilution with ventilation air, is the method of choice in many industrial environments. Industrial ventilation is discussed in Chapters 29 and 30 of the 2007 *ASHRAE Handbook—HVAC Applications* and in *Industrial Ventilation: A Manual of Recommended Practice* (ACGIH 2001). Ventilation of medical facilities, where high indoor air quality is expected, is discussed in *ASHRAE Standard 62.1*, Chapter 7 of the 2007 *ASHRAE Handbook—HVAC Applications*, and other publications [e.g., AIA et al. (2006)].

Commercial and institutional building ventilation systems are typically designed to provide slight pressurization to minimize infiltration. This pressurization is achieved by having the outside or makeup airflow rate higher than the exhaust or relief airflow rate. In these buildings, infiltration is usually neglected except in areas such as lobbies and loading docks, where infiltration can be important because of doors. However, as discussed previously, this may only be achieved in practice with tight envelope construction such as by including a continuous air barrier. As discussed in the section on Driving Mechanisms for Ventilation and Infiltration, wind and the stack effect can also cause significant infiltration and exfiltration. Ventilation airflow rates for commercial and institutional buildings are typically determined using procedures in *ASHRAE Standard 62.1*. In these procedures for designing mechanical ventilation systems, no credit is given for infiltration. However, weather-driven pressure differentials may be significant and need to be considered when designing the ventilation system.

Ventilation Rate Procedure

Per *ASHRAE Standard 62.1*, the design ventilation rate is determined based on a table of minimum ventilation requirements for different space types. These requirements are expressed as an outdoor airflow rate per occupant or per unit floor area, or often both, depending on space type. These ventilation rates are based on air pollutants generated by people, activities, and building materials and furnishings. The rates are then adjusted for various parameters (e.g., multiple zones, type of room air distribution).

The HVAC designer faces several challenges in designing an air distribution system to deliver outdoor air to building occupants. The first is to determine whether the outdoor air is acceptable for use, and to design a system for cleaning the air if it is not acceptable. A second is to design an air intake and distribution system that will *deliver* the required level of outdoor air to the occupied portions of the building, and not just *admit* it to an air handler. This outdoor air must be delivered not only at design conditions, but throughout the year. The task is complicated by weather-related variations in indoor/outdoor pressure difference. Other complications include pressure variations caused by building components such as exhaust fans or dirty filters, and probably most significantly by supply flow variations associated with variable-air-volume (VAV) systems (Janu et al. 1995; Mumma and Wong 1990). This delivery issue is related to the discussion in the section on Air Change Effectiveness.

Survey of Ventilation Rates in Office Buildings

Relatively few measurements of as-built office building ventilation performance have been conducted, and those data generally have not used consistent measurement methods or involved representative

collections of buildings. The U.S. Environmental Protection Agency (EPA) Building Assessment Survey and Evaluation (BASE) study involved indoor environmental measurements, including ventilation, in 100 randomly selected office buildings using a standardized protocol (EPA 2003). Persily et al. (2005) analyzed the BASE data and found that outdoor ventilation rates measured using duct traverses at air handler intakes were higher than might be expected, with a mean of about 117 cfm per person. However, these elevated values are partially explained by low occupant density (mean of about four persons per 1000 ft²) and high outdoor air fractions (mean of about 35%). Considering only values that correspond to minimum outdoor air intake, the mean ventilation rate was 23 cfm per workstation. About one-half the ventilation rates under minimum outdoor air intake were below 20 cfm per person. Another key outcome of this study is documentation of measured airflow rates that are quite different from their design values. This finding highlights the need for good system commissioning and maintenance to achieve design intent. Designing and configuring systems to encourage regular maintenance by providing easy access to key system components is also important.

OFFICE BUILDING EXAMPLE

Ventilation and infiltration principles from this chapter, *Standard 62.1-2007*, and elsewhere are applied to a conventional office building in Atlanta, Georgia. The building's floor plans, elevations, and wall sections are available in Chapter 18. The infiltration, local exhaust, or ventilation airflow rates in this example can be used later in the design process (1) as input for the heating and cooling load calculations; (2) for sizing fans, ducts, and dampers; and (3) for inclusion in the construction documents' air-handling units (AHUs) schedules and specifications.

This example relies on the 2007 edition of *ASHRAE Standard 62.1*; because this and other standards are updated frequently, users should check for the latest edition.

Location

The example building is about 8 mi northeast of downtown Atlanta, and is close to a major highway and its access roads. Atlanta's climate is hot and humid in the summer, and has relatively mild winters. The average annual outdoor air temperature is about 60.6°F and the heating degree-days per year, base 65°F (HDD₆₅), are about 3265 (Rock 2005). From Chapter 14, the winter 99% design outdoor air (OA) temperature is 23°F, whereas the 1% cooling dry-bulb temperature is 91°F, with a mean coincident wet-bulb temperature of 74°F. The 99.6 and 0.4% design wind speeds are 12 mph in the winter and 9 mph in the summer, both out of the northwest. Warm and humid winds also travel north from the Gulf of Mexico, and occasionally the wind is from the Atlantic Ocean from the southeast.

Building

The approximately 30,500 ft² building is a two-story, flat-roofed, slab-on-grade commercial office building with a substantial roof overhang in each direction. Materials and construction quality are average commercial grade. The double-paned windows, and similar spandrel glass, are fixed in their metal curtain wall frames; all windows are nonoperable. The remaining portions of the exterior walls are brick. There are relatively few doors to the outside, as described later in this example. The building is surrounded by black asphalt driveways, a parking lot, and some vegetation. The nearby highway is across a parallel two-lane access road, to the northwest.

Occupancy

The building is occupied during normal weekday business hours, and occasionally for special weekend events. Night and weekend thermostat setbacks are used. On the perimeter of the building are mostly single-person offices and conference rooms. The core of the building is mainly open-plan with cubicle workspaces, as well as

various support rooms, restrooms, two stair towers, and an elevator. There is a large mailroom on the first floor and a lunchroom on the second. Occupant density is high during workdays. The overhead fluorescent lighting is typical of such office buildings, and there are significant computing, printing, and copying equipment loads. Smoking is not allowed in the building.

The building is owner-occupied. Owners generally have long-term interests in minimizing costs, and in maximizing indoor air quality and thermal comfort so that productivity is high.

Infiltration

For this example, assume a conventional all-air overhead HVAC system, and that the building is well sealed. Consequently, a slightly positive overall building pressurization is assumed during occupied hours, because many existing commercial buildings are too leaky to be pressurized effectively. Because water condensation in the exterior envelope of the building is possible, air pressurization should be as low as is practical, and continuous vapor retarders should be installed. As a more expensive alternative to slight pressurization, the automatic control system could actively manage the dampers' positions and fans' operation to maintain an average neutral pressurization, relative to the outdoors. In either case, a good assumption is that infiltration is minimized, the windows and spandrel glass are fixed and well sealed, and the exterior doors are normally kept closed. During high-wind conditions beyond design, windward perimeter spaces may have some infiltration loads, but under non-peak outdoor temperatures, a well-zoned HVAC system should have enough capacity to handle these extra loads. If both the OA temperature and wind are extreme, then these upwind perimeter spaces may become slightly uncomfortable. These extreme conditions are expected to occur only a few hours in a typical year.

Spaces with exterior doors can experience significant infiltration loads when people enter and leave. The first-floor vestibules on the north and south sides of the building help limit this infiltration through the two main entrances. The double doors from stair tower #2 have infrequent use, and a high level of thermal comfort in stair towers is not typically expected. Thus, brief infiltration surges in stair tower #2 are deemed acceptable. However, the doors from the parking lot to the mailroom are frequently used by staff for shipping, receiving, entrance, and egress, and infiltration loads on the vestibules and mailroom are of concern. Many designers choose to ignore these extra loads in pressurized buildings, because they are transient and not easily characterized; the systems' capacities are likely sufficient to minimize uncomfortable conditions in these spaces. In this example, however, the HVAC designer is concerned about summertime airborne moisture, especially in the mailroom where books and other publications are stored, because strong, humid, southerly winds easily overcome a slight indoor pressurization when the large doors to the parking lot are open.

This chapter and many of its supporting references describe detailed methods for estimating infiltration or air leakage. Typically, pressure differences, openings' coefficients, and hour-by-hour weather data are required to perform these transient calculations, usually using a computer program separate from that used for thermal load calculations. For HVAC design purposes for a building similar to the example, an air exchange rate of unconditioned outside air through infiltration, per space, expressed in air changes per hour (ach) or airflow rate (cfm) is of more immediate use. Either value is then entered into the load calculation program. Unfortunately, accurate air changes per hour are difficult, if not impossible, to predict, so design estimates must be made. For example,

North Vestibule, Room 101

- Gross floor area $\approx 11 \text{ ft} \times 13 \text{ ft} = 143 \text{ ft}^2$
- Room volume $\approx 143 \text{ ft}^2 \times 9 \text{ ft} = 1287 \text{ ft}^3$
- $\text{ach}_{inf} \approx 1.0$, so
- $Q_{inf} \approx (1287 \text{ ft}^3 \times 1.0)/60 \text{ min/h} \approx 22 \text{ cfm}_{oa}$

Either 1.0 ach or 22 cfm of infiltration is then used as input for the load calculation program for this space. The 1.0 ach assumption was made by the designer during on-site observation that these particular manually operated exterior doors have low usage. If passage rates were known, Yuill's (1996) flow rate estimation method would have been used instead.

South Vestibule, Room 115

- Gross floor area $\approx 8 \text{ ft} \times 10 \text{ ft} = 80 \text{ ft}^2$
- Room volume $\approx 80 \text{ ft}^2 \times 9 \text{ ft} = 720 \text{ ft}^3$
- $\text{ach}_{inf} \approx 2.0$, so
- $Q_{inf} \approx (720 \text{ ft}^3 \times 2.0)/60 \text{ min/h} \approx 24 \text{ cfm}_{oa}$

In practice, this back entrance from the parking lot on the south-east side of the building is the primary means of entrance and egress, and as such, the estimated infiltration for it is increased to 2.0 ach, compared to the north vestibule's 1.0 ach.

In colder U.S. climates, it is common practice for low-cost commercial buildings to have only space heating, and not cooling, in stair towers and vestibules. However, for this building in the Southeast, the designer decided to provide cooling for these vestibules. Thus, the estimated infiltration rates are applied to both the heating and cooling load calculations for these spaces. The building's mailroom, which also has exterior doors, is to be heated and cooled, too.

Mailroom, Room 114

- Gross floor area $\approx (51 \text{ ft} \times 22 \text{ ft}) + (33 \text{ ft} \times 10 \text{ ft}) = 1452 \text{ ft}^2$
- Room volume $\approx 1452 \text{ ft}^2 \times 9 \text{ ft} = 13,068 \text{ ft}^3$
- $\text{ach}_{inf} \approx 0.5$, so
- $Q_{inf} \approx (13,068 \text{ ft}^3 \times 0.5)/60 \text{ min/h} \approx 109 \text{ cfm}_{oa}$

Even though the mailroom has only a single layer of doors to the outside, and not a vestibule, the designer estimated the infiltration at a lower rate (0.5 ach) than those for the vestibules. This is because of the mailroom's large interior volume relative to its exterior doorway's area.

Note that *no* estimate of air changes will be accurate at all times; this portion of HVAC design is still largely an art because of the many unknowns and variability of weather and building use. For improved energy conservation, all exterior doors must be extremely well weatherstripped and have automatic closers, and a sign indicating doors should be kept closed when not in use should be placed on the mailroom's doors. High-quality gaskets and sealants for the windows and spandrel glass are also required.

Local Exhausts

(This section assumes that ANSI/ASHRAE *Standard* 62.1-2007 has been adopted into the local building code without modification.) At least 10 rooms require direct, powered air exhaust: the two restrooms per floor, the darkroom, three designated photocopy spaces, and the two janitors' closets. The restrooms have three flushable fixtures each, so from Table 6.4 of *Standard* 62.1, with intermittent use, each restroom requires

$$Q_{ea} = 3 \text{ units} \times 50 \text{ cfm/unit} = 150 \text{ cfm}$$

Also from Table 6.4, the darkroom (room 222) of the second floor needs

$$\text{Gross floor area} \approx 10 \text{ ft} \times 15 \text{ ft} = 150 \text{ ft}^2$$

$$Q_{ea} = 150 \text{ ft}^2 \times 1.00 \text{ cfm/ft}^2 = 150 \text{ cfm}$$

Similarly, the designated photocopy areas need $0.50 \text{ cfm}_{ea}/\text{ft}^2$, so

$$\text{First floor, plan east: } \approx 80 \text{ ft}^2 \times 0.50 \text{ cfm/ft}^2 = 40 \text{ cfm}_{ea}$$

$$\text{First floor, plan southwest: } \approx 160 \text{ ft}^2 \times 0.50 \text{ cfm/ft}^2 = 80 \text{ cfm}_{ea}$$

Second floor, plan east: $\approx 112 \text{ ft}^2 \times 0.50 \text{ cfm/ft}^2 = 56 \text{ cfm}_{ea}$

The two small janitors' closets, one on each floor, also require exhaust:

$$60 \text{ ft}^2 \times 1.00 \text{ cfm/ft}^2 = 60 \text{ cfm}_{ea}$$

These local exhaust airflow rates are then entered into the load calculation program. They are room loads, attached to each particular space, and are *not* combined and entered as systems-level loads. The load calculation program evaluates the room loads, appropriately combines them, and then finds the systems-level loads for various peak hours.

Some local code authorities amend the requirements of *Standard* 62.1, or have not yet adopted the most current version, so significant deviations from these examples are possible. For example, in much of the United States, janitorial closets and photocopy rooms have not been required to have local exhausts. *Standard* 62.1-2007 recognized that these spaces can be significant sources of airborne pollutants, and some direct exhaust from them can be very beneficial for improving indoor air quality.

Ventilation

(This section assumes that ANSI/ASHRAE *Standard* 62.1-2007 has been adopted into local code without changes.) Ventilation air is needed to maintain acceptable indoor air quality. The example building is well sealed, natural ventilation is not used, and no credit for any infiltration is taken toward ventilation air requirements, as is typical for conventional commercial buildings. Thus, minimum ventilation air required by *Standard* 62.1 is provided mechanically through the AHUs. Because smoking is not allowed in the building, no extra ventilation for environmental tobacco smoke (ETS) is needed. However, considering outdoor air pollution from the major highway nearby as well as metropolitan Atlanta's smog, some outdoor air pre-treatment may be considered later in the design process.

Standard 62.1 has two methods for determining needed ventilation airflow rates: the performance IAQ procedure (IAQP), and the prescriptive ventilation rate procedure (VRP). Most HVAC designers of conventional buildings with normal occupancies and outdoor air conditions use the VRP, which is appropriate for this example building.

Required ventilation air (conditioned outside air) is admitted to this building through two air-handling units; each AHU serves one floor. Flow rates of outside air are input values for, and carried through to the results of, the load calculation simulation. Energy needed to condition the outside air ultimately is a systems-level load, because all of this ventilation air is conditioned by the AHUs before its introduction to the building.

Commercial load calculation programs often provide suggested values of ventilation airflow rates and occupancy schedules, but may not have been updated to reflect the latest VRP requirements and procedures of *Standard* 62.1. As such, it is difficult to present an example here; instead, a sample check using some assumed values for the first-floor executive director's office (room 132) is given. It is assumed that this room is a separate thermal zone because of its use and its location on the southwest corner of the building and its two solar exposures.

Executive Director's Office, Room 132

- Gross floor area $\approx 12 \text{ ft} \times 21 \text{ ft} = 252 \text{ ft}^2$
- Room volume $\approx 252 \text{ ft}^2 \times 9 \text{ ft} = 2268 \text{ ft}^3$
- Assumed supply air $Q_{sa} = 412 \text{ cfm}$

The supply airflow rate was estimated at 300 ft³/ton, a sensible heat factor of 0.9, a cooling supply (55°F) to room (75°F) air temperature difference of 20°F, 12,000 Btu/h per ton of cooling, and the sensible heat equation $1.1 \times \text{cfm}_{sa} \times \Delta T$. From Table 6.1 of *Standard* 62.1, the office's population P can be estimated as

$$P = 252 \text{ ft}^2 \times 5 \text{ occupants/1000 ft}^2 = 1.26$$

In this case, however, there is only one regular occupant of the space. The needed ventilation airflow rate to the breathing zone V_{bz} is then found from the table as follows:

$$V_{bz} = R_p P_z + R_a A_z$$

$$V_{bz} = (5 \text{ cfm/person} \times 1 \text{ person}) + (0.06 \text{ cfm/ft}^2 \times 252 \text{ ft}^2) \\ = 20.12 \text{ cfm}$$

where

- R_p = outdoor airflow rate required per person, from *Standard* 62.1's Table 6-1, cfm
- P_z = zone population (largest number of people expected to occupy the zone during typical use)
- R_a = outdoor airflow rate required per unit area, from *Standard* 62.1's Table 6-1, cfm
- A_z = occupiable floor area of zone, ft²

Note that *Standard* 62.1's VRP includes a building component $R_a A_z$, as well as the traditional per-person people component.

Because this is a conventional office building, with ceiling plenums and no raised floors, overhead air supply and return is assumed. The cooling mode, not heating, is dominant in this and most other U.S. office buildings that have high internal heat gains as well as well-sealed envelopes. From the standard's Table 6.2, with ceiling supply of cool air, the zone air distribution effectiveness E_z is estimated as 1.0. From Equation (6-2) of the standard, the design zone outdoor airflow rate V_{oz} is then

$$V_{oz} = V_{bz}/E_z = 20.12 \text{ cfm}/1.0 = 20.12 \text{ cfm}$$

But this is still not the amount of outside air that must be conditioned by the air handler: the rate must be adjusted for inefficiencies and recirculation in the air distribution system.

Because single-duct VAV with terminal reheat air distribution systems were initially planned by the designer, *Standard* 62.1's multiple-zone recirculating systems adjustment is needed. For this thermal zone, the primary outdoor air fraction Z_p for its VAV terminal unit and downstream is

$$Z_p = V_{oz}/V_{pz} = 20.12 \text{ cfm}/412 \text{ cfm} = 0.05, \text{ or } 5\%$$

However, for VAV systems, the minimum expected primary airflow rate should be used. In this case, 412 cfm is the peak design airflow rate. Designers often assume about 30% of this peak flow as the minimum in VAV systems, so for this space, $412 \times 0.3 = 124 \text{ cfm}$. The adjusted primary outdoor air fraction is then

$$Z_p = V_{oz}/V_{pz} = 20.12 \text{ cfm}/124 \text{ cfm} = 0.16, \text{ or } 16\%$$

The preceding calculations need to be performed for every thermal zone on each air handler. Then, for each system, the highest primary outside air fraction is used to estimate the air distribution systems' ventilation effectiveness; ASHRAE (2007) includes a spreadsheet for doing these calculations.

For the purposes of this example, 0.16 is assumed to be the maximum Z_p , so, from Table 6.3 of *Standard* 62.1, the system ventilation efficiency E_v is 0.9. If, instead, the standard's Appendix A method for determining E_v were used, a value closer to 1.0 (perfect mixing) would likely result for this example's conventional overhead all-air cooling system. Table 6.3's value of 0.9 is likely somewhat conservative, but is obtained quickly for design purposes.

Next, the uncorrected outdoor air intake flow rate V_{ou} is needed; *Standard* 62.1's Equation (6-6) includes diversity factor D to adjust the people component of the flow rate. All zones' flow rates are needed to perform this calculation. For this example, the uncorrected outdoor air intake flow rate for the first floor's AHU was estimated from floor area, an occupancy of 5 people per 1000 ft², and

20 cfm per person, and is assumed to be 1525 cfm. The adjusted outdoor air intake flow rate V_{ot} for this AHU is then

$$V_{ot} = V_{ou}/E_v = 1525 \text{ cfm}/0.9 = 1700 \text{ cfm}_{oa}$$

After load calculations are complete, these assumed airflow rates can be replaced with actual values for each zone, and the outside airflow rate can be updated. Repeating the load calculations may be necessary. The final value of the adjusted outdoor air intake flow rate is then reported on the AHU's schedule so that testing, adjusting, and balancing (TAB) personnel and others can use this information to ensure that the system admits the desired flow rate of ventilation air. The information is also used to select air cleaners, dampers, coils, ducts, and fans.

For more examples on determining ventilation air rates for commercial buildings, see the user's manual for *Standard 62.1* (ASHRAE 2007). For low-rise residential buildings, consult ASHRAE *Standard 62.2* and its user's manual (ASHRAE 2006).

SYMBOLS

- A = area, ft² or in²
- c = flow coefficient, cfm/(in. of water) ^{n}
- c_p = specific heat, Btu/lb·°F
- C = concentration, ppm
- \bar{C} = time averaged concentration
- C_A = airflow coefficient for automatic doors, cfm/[ft²·(in. of water)^{0.5}]
- C_D = discharge coefficient
- C_p = pressure coefficient
- C_s = stack flow coefficient, cfm²/(in⁴·°F) or (in. of water/°F) ^{n}
- C_v = effectiveness of openings
- C_w = wind flow coefficient, cfm²/(in⁴·mph²) or (in. of water/mph²) ^{n}
- E = system efficiency
- F = tracer gas injection rate, cfm
- \bar{F} = time-averaged contaminant source strength, cfm
- f = fractional on-time
- g = gravitational acceleration, ft/s²
- G = wind speed multiplier, Table 7
- h = specific enthalpy, Btu/lb_m
- H = height, ft
- i = hour of year
- I = air exchange rate, 1/time
- I_i = instantaneous air exchange rate, 1/time
- I_m = effective air exchange rate, 1/time
- IDD = infiltration degree-days, °F
- n = pressure exponent
- N = number of discrete time periods in period of interest
- p = pressure, in. of water
- P = parameter, or occupancy population
- q = heat rate, Btu/h
- \underline{Q} = volumetric flow rate, cfm
- \bar{Q} = effective volumetric flow rate, cfm
- R = outdoor airflow rate, cfm
- s = shelter factor
- S = source strength, cfm
- t = time [Equations (9) to (11)]; temperature, °F or °R
- U = wind speed, mph
- V = volume, ft³, or ventilation airflow rate, cfm
- W = humidity ratio, lb_m water/lb_m dry air
- ϵ_f = air change effectiveness
- θ = time
- θ_{age} = age of air
- ρ = air density, lb_m/ft³
- τ = time constant
- ϕ = wind angle, degrees

Subscripts

- a = area
- b = base
- ba = bypass air
- bz = breathing zone
- c = calculated
- ca = recirculated air

- e = effective
- ea = exhaust air
- f = floor
- i = indoor or time counter for summation (instantaneous)
- inf = infiltration
- H = building height, eaves or roof
- ka = makeup air
- l = latent
- la = relief air
- L = leakage or local
- ma = mixed air
- met = meteorological station location
- n = normalized
- N = nominal
- NPL = neutral pressure level
- o = outdoor, initial condition, or reference
- oa = outdoor air
- ot = adjusted outdoor air
- ou = uncorrected outdoor air
- oz = zone outdoor
- p = pressure, or primary
- r = reference
- s = sensible or stack
- sa = supply air
- S = space or source
- w = wind
- v = ventilation
- z = zone

CHAPTER 17

RESIDENTIAL COOLING AND HEATING LOAD CALCULATIONS

<i>Residential Features</i>	17.1	<i>Common Data and Procedures</i>	17.3
<i>Calculation Approach</i>	17.1	<i>Cooling Load</i>	17.8
<i>Other Methods</i>	17.2	<i>Heating Load</i>	17.11
<i>Residential Heat Balance (RHB) Method</i>	17.2	<i>Load Calculation Example</i>	17.12
<i>Residential Load Factor (RLF) Method</i>	17.2	<i>Symbols</i>	17.14

THIS chapter covers cooling and heating load calculation procedures for residential buildings, including detailed heat-balance methods that serve as the basis for cooling load calculation. Simple cooling-load procedures, suitable for hand calculations, are provided for typical cases. Straightforward heating load calculation procedures are also included.

Procedures in this chapter are based on the same fundamentals as the nonresidential methods in Chapter 18. However, many characteristics distinguish residential loads, and Chapter 18's procedures should be applied with care to residential applications.

Additional information about residential heating and cooling is found in Chapter 1 of the 2007 *ASHRAE Handbook—HVAC Applications* and Chapter 9 of the 2008 *ASHRAE Handbook—HVAC Systems and Equipment*.

RESIDENTIAL FEATURES

With respect to heating and cooling load calculation and equipment sizing, the following unique features distinguish residences from other types of buildings:

- **Smaller Internal Heat Gains.** Residential system loads are primarily imposed by heat gain or loss through structural components and by air leakage or ventilation. Internal heat gains, particularly those from occupants and lights, are small compared to those in commercial or industrial structures.
- **Varied Use of Spaces.** Use of spaces in residences is more flexible than in commercial buildings. Localized or temporary temperature excursions are often tolerable.
- **Fewer Zones.** Residences are generally conditioned as a single zone or, at most, a few zones. Typically, a thermostat located in one room controls unit output for multiple rooms, and capacity cannot be redistributed from one area to another as loads change over the day. This results in some hour-to-hour temperature variation or swing that has a significant moderating effect on peak loads, because of heat storage in building components.
- **Greater Distribution Losses.** Residential ducts are frequently installed in attics or other unconditioned buffer spaces. Duct leakage and heat gain or loss can require significant increases in unit capacity. Residential distribution gains and losses cannot be neglected or estimated with simple rules of thumb.
- **Partial Loads.** Most residential cooling systems use units of relatively small capacity (about 12,000 to 60,000 Btu/h cooling, 40,000 to 120,000 Btu/h heating). Because loads are largely determined by outside conditions, and few days each season are design days, the unit operates at partial load during most of the season; thus, an oversized unit is detrimental to good system performance, especially for cooling in areas of high wet-bulb temperature.

- **Dehumidification Issues.** Dehumidification occurs during cooling unit operation only, and space condition control is usually limited to use of room thermostats (sensible heat-actuated devices). Excessive sensible capacity results in short-cycling and severely degraded dehumidification performance.

In addition to these general features, residential buildings can be categorized according to their exposure:

- **Single-Family Detached.** A house in this category usually has exposed walls in four directions, often more than one story, and a roof. The cooling system is a single-zone, unitary system with a single thermostat. Two-story houses may have a separate cooling system for each floor. Rooms are reasonably open and generally have a centralized air return. In this configuration, both air and load from rooms are mixed, and a load-leveling effect, which requires a distribution of air to each room that is different from a pure commercial system, results. Because the amount of air supplied to each room is based on the load for that room, proper load calculation procedures must be used.
- **Multifamily.** Unlike single-family detached units, multifamily units generally do not have exposed surfaces facing in all directions. Rather, each unit typically has a maximum of three exposed walls and possibly a roof. Both east and west walls might not be exposed in a given living unit. Each living unit has a single unitary cooling system or a single fan-coil unit and the rooms are relatively open to one another. This configuration does not have the same load-leveling effect as a single-family detached house.
- **Other.** Many buildings do not fall into either of the preceding categories. Critical to the designation of a single-family detached building is well-distributed exposure so there is not a short-duration peak; however, if fenestration exposure is predominantly east or west, the cooling load profile resembles that of a multifamily unit. On the other hand, multifamily units with both east and west exposures or neither east nor west exposure exhibit load profiles similar to single-family detached.

CALCULATION APPROACH

Variations in the characteristics of residences can lead to surprisingly complex load calculations. Time-varying heat flows combine to produce a time-varying load. The relative magnitude and pattern of the heat flows depends on the building characteristics and exposure, resulting in a building-specific load profile. In general, an hour-by-hour analysis is required to determine that profile and find its peak.

In theory, cooling and heating processes are identical; a common analysis procedure should apply to either. Acceptable simplifications are possible for heating; however, for cooling, different approaches are used.

Heating calculations use simple worst-case assumptions: no solar or internal gains, and no heat storage (with all heat losses evaluated instantaneously). With these simplifications, the heating

The preparation of this chapter is assigned to TC 4.1, Load Calculation Data and Procedures.

problem is reduced to a basic $UA\Delta t$ calculation. The heating procedures in this chapter use this long-accepted approach, and thus differ only in details from prior methods put forth by ASHRAE and others.

In contrast, the cooling procedures in this edition are extensively revised, based on the results of ASHRAE research project RP-1199, also supported by the Air-Conditioning Contractors of America (ACCA) (Barnaby et al. 2004, 2005). Although the complexity of residential cooling load calculations has been understood for decades, prior methods used a cooling load temperature difference/cooling load factor (CLTD/CLF) form requiring only hand-tractable arithmetic. Without such simplification, the procedures would not have been used; an approximate calculation was preferable to none at all. The simplified approaches were developed using detailed computer models and/or empirical data, but only the simplifications were published. Now that computing power is routinely available, it is appropriate to promulgate 24 h, equation-based procedures.

OTHER METHODS

Several residential load calculation methods have been published in North America over the last 20 years. All use the $UA\Delta t$ heating formulation and some variation of the CLTD/CLF approach for cooling.

- **ACCA.** *Manual J*, 7th Edition (ACCA 1986) and 8th Edition (ACCA 2006) are widely used in the United States. Cooling loads are calculated using semiempirical heat gain factors derived from experimental data taken at the University of Illinois in the 1950s. These factors, associated overview, and references are found in the 1985 and earlier editions of the *ASHRAE Handbook—Fundamentals*. The 8th Edition retains the underlying factors but provides increased flexibility in their application, in addition to other extensions.
- **ASHRAE.** The 1989 to 2001 editions of the *ASHRAE Handbook—Fundamentals* contain an updated method based on ASHRAE research project RP-342 (McQuiston 1984). In this work, cooling factors were re-derived using a transfer-function building model that included temperature-swing effects.
- **F280.** This Canadian adaptation of the CLTD/CLF procedure (CAN/CSA-F280-M90 1990; HRAI 1996) also uses cooling methods based on ASHRAE RP-342. Heating procedures include detailed ground heat loss estimates.

A key common element of all cooling methods is attention to temperature swing, via empirical data or suitable models. Throughout the literature, it is repeatedly emphasized that direct application of nonresidential methods (based on a fixed set point) results in unrealistically high cooling loads for residential applications.

RESIDENTIAL HEAT BALANCE (RHB) METHOD

A 24 h procedure is required to accurately determine the cooling load profile of a residence. The heat balance (HB) method allows detailed simulation of space temperatures and heat flows. ASHRAE research project RP-1199 adapted HB to residential applications, resulting in the residential heat balance (RHB) method. Although RHB provides the technical basis for this chapter, it is a computer-only technique and is not documented here. HB is described in Chapter 18 and Pedersen et al. 1998; Barnaby et al. (2004, 2005) document RHB enhancements.

RP-1199 produced an implementation of the RHB method, called ResHB (Barnaby et al. 2004). This application is derived from the ASHRAE *Toolkit for Building Load Calculations* (Pedersen et al. 2001) and has the following features:

- **Multizone.** Whereas the original *Toolkit* code supported a single zone, ResHB can analyze projects that include multiple systems, zones, and rooms.

- **Temperature swing.** ResHB calculates cooling load with temperature swing. That is, the code searches for sensible capacity sufficient to hold the space temperature within a specified excursion above the set point.
- **Master/slave control.** ResHB allows control of cooling output in “slave” rooms based on the cooling requirements of a “master” room, where the thermostat is located. Rooms with incompatible load profiles will exhibit poor temperature control.
- **Residential defaults.** ResHB includes default values suitable for residential problems.

In its current form, ResHB is a research-oriented reference implementation of RHB. It is expected that ResHB will be incorporated into third-party software so the full RHB method will be available to practitioners. ResHB FORTRAN source code is available under license from ASHRAE.

RESIDENTIAL LOAD FACTOR (RLF) METHOD

The procedure presented in this chapter is the residential load factor (RLF) method. RLF is a simplified procedure derived from detailed ResHB analysis of prototypical buildings across a range of climates. The method is tractable by hand but is best applied using a spreadsheet. Two main applications are anticipated:

- **Education and training.** The transparency and simplicity of RLF make it suitable for use in introductory courses on building load calculations.
- **Quick load estimates.** In situations where detailed analysis is impractical, the RLF method is a possible alternative. For example, the method might be implemented as a spreadsheet on a handheld device and used for on-site sizing of replacement cooling equipment.

Note that, although room-by-room calculations are possible with the RLF method, computerized methods based on RHB are more suitable for performing full room-level calculations required for equipment selection and distribution system design.

RLF was derived from several thousand ResHB cooling load results (Barnaby and Spitler 2005; Barnaby et al. 2004). A range of climates and building types were analyzed. Statistical regression techniques were used to find values for the load factors tabulated in later sections. Factor values were validated by comparing ResHB versus RLF results for buildings not involved in the regression analysis. Within its range of applicability, RLF cooling loads are generally within 10% of those calculated with ResHB. The RLF derivation has been repeated for 2009 using the updated temperature profile and clear-sky model (see Chapter 14), resulting in minor revisions to load factors and other coefficients.

The RLF method should not be applied to situations outside the range of underlying cases, as shown in Table 1.

The RLF method appears more complex than the table-based procedure found in prior editions of this chapter. However, note that the RLF calculation sequence involves two distinct steps. First, the cooling and heating load factors (CFs and HFs) are derived for all project component types. These factors are then applied to the individual components by a single multiplication. (The two-step approach is clearly shown in the Load Calculation Example section.) For a specific location and representative constructions, CFs and HFs can be precalculated and used repeatedly. In essence, the structure of RLF allows assembling location-specific versions of the rigid tables found in prior editions. Further, this edition documents the equations used to generate tabulated values. Using these equations, a complete implementation of the RLF method, including CF and HF calculation, is well within the capabilities of current PC spreadsheet applications.

Table 1 RLF Limitations

Item	Valid Range	Notes
Latitude	20 to 60°N	Also approximately valid for 20 to 60°S with N and S orientations reversed for southern hemisphere.
Date	July 21	Application must be summer peaking. Buildings in mild climates with significant SE/S/SW glazing may experience maximum cooling load in fall or even winter. Use RHB if local experience indicates this is a possibility.
Elevation	Less than 6500 ft	RLF factors assume 164 ft elevation. With elevation-corrected C_s , method is acceptably accurate except at very high elevations.
Climate	Warm/hot	Design-day average outdoor temperature assumed to be above indoor design temperature.
Construction	Lightweight residential construction (wood or metal framing, wood or stucco siding)	May be applied to masonry veneer over frame construction; results are conservative. Use RHB for structural masonry or unconventional construction.
Fenestration area	0 to 15% of floor area on any façade, 0 to 30% of floor area total	Spaces with high fenestration fraction should be analyzed with RHB.
Fenestration tilt	Vertical or horizontal	Skylights with tilt less than 30° can be treated as horizontal. Buildings with significant sloped glazing areas should be analyzed with RHB.
Occupancy	Residential	Applications with high internal gains and/or high occupant density should be analyzed with RHB or nonresidential procedures.
Temperature swing	3°F	
Distribution losses	Typical	Applications with extensive duct runs in unconditioned spaces should be analyzed with RHB.

COMMON DATA AND PROCEDURES

The following guidelines, data requirements, and procedures apply to all load calculation approaches, whether heating or cooling, hand-tractable or computerized.

General Guidelines

Design for Typical Building Use. In general, residential systems should be designed to meet representative maximum-load conditions, not extreme conditions. Normal occupancy should be assumed, not the maximum that might occur during an occasional social function. Intermittently operated ventilation fans should be assumed to be off. These considerations are especially important for cooling-system sizing.

Building Codes and Standards. This chapter presentation is necessarily general. Codes and regulations take precedence; consult local authorities to determine applicable requirements.

Designer Judgment. Designer experience with local conditions, building practices, and prior projects should be considered when applying the procedures in this chapter. For equipment-replacement projects, occupant knowledge concerning performance of the existing system can often provide useful guidance in achieving a successful design.

Verification. Postconstruction commissioning and verification are important steps in achieving design performance. Designers should encourage pressurization testing and other procedures that allow identification and repair of construction shortcomings.

Uncertainty and Safety Allowances. Residential load calculations are inherently approximate. Many building characteristics are estimated during design and ultimately determined by construction quality and occupant behavior. These uncertainties apply to all calculation methods, including first-principles procedures such as RHB. It is therefore tempting to include safety allowances for each aspect of a calculation. However, this practice has a compounding effect and often produces oversized results. Typical conditions should be assumed; safety allowances, if applied at all, should be added to the final calculated loads rather than to intermediate components. In addition, temperature swing provides a built-in safety factor for sensible cooling: a 20% capacity shortfall typically results in a temperature excursion of at most about one or two degrees.

Basic Relationships

Common air-conditioning processes involve transferring heat via air transport or leakage. The sensible, latent, and total heat conveyed by air on a volumetric basis is

$$q_s = C_s Q \Delta t \quad (1)$$

$$q_l = C_l Q \Delta W \quad (2)$$

$$q_t = C_t Q \Delta h \quad (3)$$

$$q_t = q_s + q_l \quad (4)$$

where

q_s, q_l, q_t = sensible, latent, total heat transfer rates, Btu/h

C_s = air sensible heat factor, Btu/h · °F · cfm (1.1 at sea level)

C_l = air latent heat factor, Btu/h · cfm (4840 at sea level)

C_t = air total heat factor, Btu/h · cfm per Btu/lb enthalpy h (4.5 at sea level)

Q = air volumetric flow rate, cfm

Δt = air temperature difference across process, °F

ΔW = air humidity ratio difference across process, lb_w/lb_{da}

Δh = air enthalpy difference across process, Btu/lb

The heat factors C_s , C_l , and C_t are elevation dependent. The sea-level values in the preceding definitions are appropriate for elevations up to about 1000 ft. Procedures are provided in Chapter 18 for calculating adjusted values for higher elevations.

Design Conditions

The initial step in the load calculation is selecting indoor and outdoor design conditions.

Indoor Conditions. Indoor conditions assumed for design purposes depend on building use, type of occupancy, and/or code requirements. Chapter 9 and ASHRAE *Standard 55* define the relationship between indoor conditions and comfort.

Typical practice for cooling is to design for indoor conditions of 75°F db and a maximum of 50 to 65% rh. For heating, 68°F db and 30% rh are common design values. These conditions are the default values used throughout this chapter.

Outdoor Conditions. Outdoor design conditions for load calculations should be selected from location-specific climate data in Chapter 14, or according to local code requirements as applicable.

Cooling. The 1% design dry-bulb temperature and mean coincident wet bulb temperature from Chapter 14 climate data are generally appropriate. As previously emphasized, oversized cooling equipment results in poor system performance. Extremely hot events are necessarily of short duration (conditions always moderate each night); therefore, sacrificing comfort under typical conditions to meet occasional extremes is not recommended.

Load calculations also require the hottest-month dry-bulb temperature daily range, and wind speed. These values can also be found in Chapter 14, although wind speed is commonly assumed to be 7.5 mph.

Typical buildings in middle latitudes generally experience maximum cooling requirements in midsummer (July in the northern hemisphere and January in the southern hemisphere). For this reason, the RLF method is based on midsummer solar gains. However, this pattern does not always hold. Buildings at low latitudes or with significant south-facing glazing (north-facing in the southern hemisphere) should be analyzed at several times of the year using the RHB method. Local experience can provide guidance as to when maximum cooling is probable. For example, it is common for south-facing buildings in mild northern-hemisphere climates to have peak cooling loads in the fall because of low sun angles. Chapter 14 contains monthly temperature data to support calculations for any time of year.

Heating. General practice is to use the 99% design dry-bulb temperature from Chapter 14. Heating load calculations ignore solar and internal gains, providing a built-in safety factor. However, the designer should consider two additional factors:

- Many locations experience protracted (several-day) cold periods during which the outdoor temperature remains below the 99% value.
- Wind is a major determinant of infiltration. Residences with significant leakage (e.g., older houses) may have peak heating demand under conditions other than extreme cold, depending on site wind patterns.

Depending on the application and system type, the designer should consider using the 99.6% value or the mean minimum extreme as the heating design temperature. Alternatively, the heating load can be calculated at the 99% condition and a safety factor applied when equipment is selected. This additional capacity can also serve to meet pickup loads under nonextreme conditions.

Adjacent Buffer Spaces. Residential buildings often include unconditioned buffer spaces such as garages, attics, crawlspaces, basements, or enclosed porches. Accurate load calculations require the adjacent air temperature.

In many cases, a simple, conservative estimate is adequate, especially for heating calculations. For example, it is generally reasonable to assume that, under heating design conditions, adjacent uninsulated garages, porches, and attics are at outdoor temperature. Another reasonable assumption is that the temperature in an adjacent, unheated, *insulated* room is the mean of the indoor and outdoor temperatures.

In cases where a temperature estimate is required, a steady-state heat balance analysis yields the following:

$$t_b = \frac{C_s Q t_o + \sum A_x U_x t_x + q}{C_s Q + \sum A_x U_x} \quad (5)$$

where

- t_b = buffer space temperature, °F
- Q = buffer space infiltration/ventilation flow rate, cfm
- t_o = outdoor air temperature, °F
- A_x = area of x th buffer space surface, ft²
- U_x = U-factor of x th buffer space surface, Btu/h · ft² · °F
- t_x = air temperature at outside of x th buffer space surface, °F (typically, outdoor air temperature for exterior surfaces, conditioned space temperature for surfaces between buffer space and house, or ground temperature for below-grade surfaces)
- q = additional buffer space heat gains, Btu/h (e.g., solar gains or distribution system losses)

Building Data

Component Areas. To perform load calculations efficiently and reliably, standard methods must be used for determining building surface areas. For fenestration, the definition of component area must be consistent with associated ratings.

Gross area. It is both efficient and conservative to derive gross surface areas from outside building dimensions, ignoring wall and floor thicknesses. Thus, floor areas should be measured to the outside of adjacent exterior walls or to the center line of adjacent partitions. When apportioning to rooms, façade area should be divided at partition center lines. Wall height should be taken as floor-to-floor.

Using outside dimensions avoids separate accounting of floor edge and wall corner conditions. Further, it is standard practice in residential construction to define floor area in terms of outside dimensions, so outside-dimension takeoffs yield areas that can be readily checked against building plans (e.g., the sum of room areas should equal the plan floor area). Although outside-dimension procedures are recommended as expedient for load calculations, they are not consistent with rigorous definitions used in building-related standards [e.g., ASTM (1998)]. However, the inconsistencies are not significant in the load calculation context.

Fenestration area. Fenestration includes exterior windows, skylights, and doors. Fenestration U-factor and SHGC ratings (see Table 2) are based on the entire product area, including frames. Thus, for load calculations, fenestration area is the area of the rough opening in the wall or roof, less installation clearances (projected product area A_{pf}). Installation clearances can be neglected; it is acceptable to use the rough opening as an approximation of A_{pf} .

Net area. Net surface area is the gross surface area less fenestration area (rough opening or A_{pf}) contained within the surface.

Volume. Building volume is expediently calculated by multiplying floor area by floor-to-floor height. This produces a conservative estimate of enclosed air volume, because wall and floor volumes are included in the total. More precise calculations are possible but are generally not justified in this context.

Construction Characteristics.

U-factors. Except for fenestration, construction U-factors should be calculated using procedures in Chapter 27, or taken from manufacturer's data, if available. U-factors should be evaluated under heating (winter) conditions.

Fenestration. Fenestration is characterized by U-factor and solar heat gain coefficient (SHGC), which apply to the entire assembly (including frames). If available, rated values should be used, determined according to procedures set forth by National Fenestration Rating Council (NFRC), Canadian Standards Association (CSA), or other specifying body (see Chapter 15). Ratings can be obtained from product literature, product label, or published listings (NFRC 2009). For unrated products (e.g., in existing construction), the U-factor and SHGC can be estimated using Table 2 or tables in Chapter 15. Note that fenestration U-factors are evaluated under heating (winter) design conditions but are used in this chapter for both heating and cooling calculations.

Relatively few types of glazing are encountered in residential applications. Single-glazed clear, double-glazed clear, and double-glazed low-emissivity ("low-e") glass predominate. Single-glazed is now rare in new construction but common in older homes. Triple-glazing, reflective glass, and heat-absorbing glass are encountered occasionally. Acrylic or glass skylights are common. Multipane low-e insulated glazing is available in high- and low-solar-gain variants, as discussed in Chapter 15. Low-solar is now the more common for new construction in all parts of the United States.

Properties of windows equipped with storm windows should be estimated from data for a similar configuration with an additional pane. For example, data for clear, double-glazed should be used for a clear single-glazed window with a storm window.

Fenestration interior and exterior shading must be included in cooling load calculations, as discussed in the Cooling Load section.

Table 2 Typical Fenestration Characteristics

Glazing Type	Glazing Layers	ID ^b	Property ^{c,d}	Center of Glazing	Frame										
					Operable					Fixed

Table 2 shows representative window U-factor and SHGC values for common glazing and frame combinations. Consult Chapter 15 for skylight characteristics.

Load Components

Below-Grade Surfaces. For cooling calculations, heat flow into the ground is usually ignored because it is difficult to quantify. Surfaces adjacent to the ground are modeled as if well insulated on the outside, so there is no overall heat transfer, but diurnal heat storage effects are included. Heating calculations must include loss via slabs and basement walls and floors, as discussed in the Heating Load section.

Infiltration. Infiltration is generally a significant component of both cooling and heating loads. Refer to Chapter 16 for a detailed discussion of residential air leakage. The simplified residential models found in that chapter can be used to calculate infiltration rates for load calculations. Infiltration should be evaluated for the entire building, not individual rooms or zones.

Natural infiltration leakage rates are modified by mechanical pressurization caused by unbalanced ventilation or duct leakage. These effects are discussed in the section on Combined Ventilation and Infiltration Airflow.

Leakage rate. Air leakage rates are specified either as airflow rate Q_i , or air exchanges per hour (ACH), related as follows:

$$Q_i = \text{ACH}(V/60) \tag{6}$$

$$\text{ACH} = \frac{60Q_i}{V} \tag{7}$$

where

- Q_i = infiltration airflow rate, cfm
- ACH = air exchange rate, changes/h
- V = building volume, ft³

Infiltration airflow rate depends on two factors:

- Building effective leakage area (envelope leaks plus other air leakage paths, notably flues) and its distribution among ceilings, walls, floors, and flues.
- Driving pressure caused by buoyancy (stack effect) and wind.

Using the simplifying assumptions presented in Chapter 16, these factors can be evaluated separately and combined using Equation (8).

$$Q_i = A_L \text{IDF} \tag{8}$$

where

- A_L = building effective leakage area (including flue) at reference pressure difference = 0.016 in. of water, assuming discharge coefficient $C_D = 1$, in²
- IDF = infiltration driving force, cfm/in²

The following sections provide procedures for determining A_L and IDF.

Leakage area. As discussed in Chapter 16, there are several interconvertible ways to characterize building leakage, depending on reference pressure differences and assumed discharge coefficient. This formulation uses the effective leakage area at 0.016 in. of water, assuming $C_D = 1$, designated A_L (Sherman and Grimsrud 1980).

The only accurate procedure for determining A_L is by measurement using a pressurization test (commonly called a blower door test). Numerous field studies have shown that visual inspection is not adequate for obtaining even a crude estimate of leakage.

For buildings in design, a pressurization test is not possible and leakage area must be assumed for design purposes. Leakage can be estimated using tabulated component leakage areas found in Chapter 16. A simpler approach is based on an assumed average leakage per unit of building surface area:

$$A_L = A_{es}A_{ul} \tag{9}$$

where

- A_{es} = building exposed surface area, ft²
- A_{ul} = unit leakage area, in²/ft² (from Table 3)

A_{ul} is the leakage area per unit surface area; suitable design values are found in Table 3. Field experience indicates that the level of care applied to reducing leakage often depends on winter conditions, because cold-air leakage is readily detected. Thus, lower A_{ul} values are expected in colder climates.

In Equation (9), A_{es} is the total building surface area at the envelope pressure boundary, defined as all above-grade surface area that separates the outdoors from conditioned or semiconditioned space. Table 4 provides guidance for evaluating A_{es} .

IDF. To determine IDF, use the Chapter 16 methods cited previously. As a further simplification, Barnaby and Spitzer (2005) derived the following relationship that yields results approximately equal to the AIM-2 model (Walker and Wilson 1990, 1998; Chapter 16's enhanced model) at design conditions:

$$IDF = \frac{I_0 + H[\Delta t][I_1 + I_2(A_{L,flue}/A_L)]}{1000} \tag{10}$$

where

I_0, I_1, I_2 = coefficients, as follows:

	Cooling 7.5 mph	Heating 15 mph
I_0	343	698
I_1	0.88	0.81
I_2	0.28	0.53

H = building average stack height, ft (typically 8 to 10 ft per story)

Δt = difference between indoor and outdoor temperatures, °F

$A_{L,flue}$ = flue effective leakage area at reference pressure difference = 0.016 in. of water, assuming $C_D = 1$, in² (total for flues serving furnaces, domestic water heaters, fireplaces, or other vented equipment, evaluated assuming associated equipment is not operating and with dampers in closed position; see Chapter 16)

Building stack height H is the average height difference between the ceiling and floor (or grade, if the floor is below grade). Thus, for buildings with vented crawlspaces, the crawlspace height is not included. For basement or slab-on-grade construction, H is the average height of the ceiling above grade. Generally, there is significant leakage between basements and spaces above, so above-grade basement height should be included whether or not the basement is fully conditioned. With suitable adjustments for grade level, H can also be estimated as V/A_{cf} (conditioned floor area).

Table 3 Unit Leakage Areas

Construction	Description	A_{ul} (in ² /ft ²)
Tight	Construction supervised by air-sealing specialist	0.01
Good	Carefully sealed construction by knowledgeable builder	0.02
Average	Typical current production housing	0.04
Leaky	Typical pre-1970 houses	0.08
Very leaky	Old houses in original condition	0.15

Table 4 Evaluation of Exposed Surface Area

Situation	Include	Exclude
Ceiling/roof combination (e.g., cathedral ceiling without attic)	Gross surface area	
Ceiling or wall adjacent to attic	Ceiling or wall area	Roof area
Wall exposed to ambient	Gross wall area (including fenestration area)	
Wall adjacent to unconditioned buffer space (e.g., garage or porch)	Common wall area	Exterior wall area
Floor over open or vented crawlspace	Floor area	Crawlspace wall area
Floor over sealed crawlspace	Crawlspace wall area	Floor area
Floor over conditioned or semiconditioned basement	Above-grade basement wall area	Floor area
Slab floor		Slab area

Table 5 Typical IDF Values, cfm/in²

H , ft	Heating Design Temperature, °F					Cooling Design Temperature, °F		
	-40	-20	0	20	40	85	95	105
8	1.40	1.27	1.14	1.01	0.88	0.41	0.48	0.55
10	1.57	1.41	1.25	1.09	0.92	0.43	0.52	0.61
12	1.75	1.55	1.36	1.16	0.97	0.45	0.55	0.66
14	1.92	1.70	1.47	1.24	1.02	0.47	0.59	0.71
16	2.10	1.84	1.58	1.32	1.06	0.48	0.62	0.76
18	2.27	1.98	1.69	1.40	1.11	0.50	0.66	0.82
20	2.45	2.12	1.80	1.48	1.15	0.52	0.69	0.87
22	2.62	2.27	1.91	1.55	1.20	0.54	0.73	0.92
24	2.80	2.41	2.02	1.63	1.24	0.55	0.76	0.98

Equation (10) is valid for typical suburban residential wind sheltering, $A_{L,flue} < A_L/2$, and at any elevation. Table 5 shows IDF values derived with Equation (10), assuming $A_{L,flue} = 0$.

Verification of leakage. A postconstruction pressurization test is strongly recommended to verify that design leakage assumptions are actually achieved. Excess leaks can be located and repaired.

Allocation of infiltration to rooms. Total building infiltration should typically be allocated to rooms according to room volume; that is, it should be assumed that each room has the same air exchange rate as the whole building. In reality, leakage varies by room and over time, depending on outdoor temperature and wind conditions. These effects can either increase or decrease room leakage. In addition, system air mixing tends to redistribute localized leakage to all rooms. Thus, in most cases, there is no reasonable way to assign more or less leakage to specific rooms.

An exception is leaky, multistory houses. The preferable and cost-effective response is mitigation of the leakage. If repair is not possible, then for heating load calculation purposes, some leakage can be differentially assigned to lower story and/or windward rooms

in proportion to exposed surface area (i.e., adjustment using an “exposure factor”).

Multifamily buildings. Usually, the simplified methods in Chapter 16 and this section do not apply to multifamily residences. However, they can be used for row houses that are full building height and have more than one exposed façade. For apartment units subdivided within a former detached residence, the entire building should be analyzed and the resulting exchange rate applied to the apartment volume. In other multifamily structures, infiltration is determined by many factors, including overall building height and degree of sealing between apartments. For low-rise construction, an upper bound for the infiltration rate can be found by evaluating the entire building. As building height increases, leakage problems can be magnified, as discussed in Chapter 16. Estimating leakage rates may require advice from a high-rise infiltration specialist.

Ventilation.

Whole-building ventilation. Because of energy efficiency concerns, residential construction has become significantly tighter over the last several decades. Natural leakage rates are often insufficient to maintain acceptable indoor air quality. ASHRAE *Standard* 62.2-2004 specifies the required minimum whole-building ventilation rate as

$$Q_v = 0.01A_{cf} + 0.05A_{cf} + 7.5 \cdot 3.5(N_{br} + 1) \quad (11)$$

where

- Q_v = required ventilation flow rate, cfm
- A_{cf} = building conditioned floor area, ft²
- N_{br} = number of bedrooms (not less than 1)

Certain mild climates are exempted from this standard; local building authorities ultimately dictate actual requirements. Whole-building ventilation is expected to become more common because of a combination of regulation and consumer demand. The load effect of Q_v must be included in both cooling and heating calculations.

Heat recovery. Heat recovery devices should be considered part of mechanical ventilation systems. These appliances are variously called heat recovery ventilators (HRVs) or energy recovery ventilators (ERVs) and integrate with residential distribution systems, as described in Chapter 25 of the 2008 *ASHRAE Handbook—HVAC Systems and Equipment*. Either sensible heat or total heat (enthalpy) can be exchanged between the exhaust and intake airstreams. ERV/HRV units are characterized by their sensible and total effectiveness.

Local mechanical exhaust. Kitchen and bathroom exhaust fans are required by *Standard* 62.2 and are typically present. Exhaust fans that operate intermittently by manual control are generally not included in load calculations. Continuous systems should be included. Note that exhaust fans induce load only through enhanced infiltration because of building depressurization (see the section on Combined Ventilation and Infiltration Airflow for further discussion).

Combustion Air. Fuel-fired boilers, furnaces, and domestic water heaters require combustion air. If the combustion air source is within the building envelope (including in semiconditioned basements), additional infiltration and heating load are induced. Locating the equipment outside of conditioned space (e.g., in a garage or vented mechanical closet) or using sealed-combustion equipment eliminates this load.

Combustion air requirements for new forced-draft equipment can be estimated at 0.25 cfm per 1000 Btu/h or about 25 cfm for a 100,000 Btu/h heating appliance. The requirements for existing natural draft equipment should be estimated at twice that amount. In many cases, these quantities are relatively small and can be neglected.

For cooling load calculations, heating equipment is assumed to be not operating, leaving only any domestic water heaters, the combustion air requirements for which are generally neglected.

Combined Ventilation and Infiltration Airflow. Mechanical pressurization modifies the infiltration leakage rate. To assess this effect, overall supply and exhaust flow rates must be determined and then divided into “balanced” and “unbalanced” components.

$$Q_{bal} = \min(Q_{sup}, Q_{exh}) \quad (12)$$

$$Q_{unbal} = \max(Q_{sup}, Q_{exh}) - Q_{bal} \quad (13)$$

where

- Q_{bal} = balanced airflow rate, cfm
- Q_{sup} = total ventilation supply airflow rate, cfm
- Q_{exh} = total ventilation exhaust airflow rate (including any combustion air requirements), cfm
- Q_{unbal} = unbalanced airflow rate, cfm

Note that unbalanced duct leakage can produce additional pressurization or depressurization. This effect is discussed in the section on Distribution Losses.

Airflow components can be combined with infiltration leakage as follows (Palmiter and Bond 1991; Sherman 1992):

$$Q_{vi} = \max(Q_{unbal}, Q_i + 0.5Q_{unbal}) \quad (14)$$

where

- Q_{vi} = combined infiltration/ventilation flow rate (not including balanced component), cfm
- Q_i = infiltration leakage rate assuming no mechanical pressurization, cfm

Ventilation/infiltration load. The cooling or heating load from ventilation and infiltration is calculated as follows:

$$q_{vi,s} = C_s[Q_{vi} + (1 - \epsilon_s)Q_{bal,hr} + Q_{bal,oth}]\Delta t \quad (15)$$

$$q_{vi,l} = C_l(Q_{vi} + Q_{bal,oth})\Delta W \quad (\text{no HRV/ERV}) \quad (16)$$

$$q_{vi,t} = C_t[Q_{vi} + (1 - \epsilon_t)Q_{bal,hr} + Q_{bal,oth}]\Delta h \quad (17)$$

$$q_{vi,l} = q_{vi,t} - q_{vi,s} \quad (18)$$

where

- $q_{vi,s}$ = sensible ventilation/infiltration load, Btu/h
- ϵ_s = HRV/ERV sensible effectiveness
- $Q_{bal,hr}$ = balanced ventilation flow rate via HRV/ERV equipment, cfm
- $Q_{bal,oth}$ = other balanced ventilation supply airflow rate, cfm
- Δt = indoor/outdoor temperature difference, °F
- ΔW = indoor/outdoor humidity ratio difference
- $q_{vi,t}$ = total ventilation/infiltration load, Btu/h
- ϵ_t = HRV/ERV total effectiveness
- Δh = indoor/outdoor enthalpy difference, Btu/lb
- $q_{vnt,l}$ = latent ventilation/infiltration load, Btu/h

Distribution Losses. Air leakage and heat losses from duct systems frequently impose substantial equipment loads in excess of building requirements. The magnitude of losses depends on the location of duct runs, their surface areas, surrounding temperatures, duct wall insulation, and duct airtightness. These values are usually difficult to accurately determine at the time of preconstruction load calculations, and must be estimated using assumed values, so that selected equipment capacity is sufficient.

Good design and workmanship both reduce duct losses. In particular, locating duct runs within the conditioned envelope (above dropped hallway ceilings, for example) substantially eliminates duct losses. Specific recommendations are found in Chapter 9 of the 2008 *ASHRAE Handbook—HVAC Systems and Equipment*. Good workmanship and correct materials are essential to achieve low leakage. Many common sealing techniques, notably duct tape, have been shown to fail in a few years. Well-constructed duct systems show leakage rates of 5% of fan flow from supply and return runs, whereas 11% or more on each side is more typical. Because of the

Table 6 Typical Duct Loss/Gain Factors

Duct Location	Supply/Return Leakage Insulation ft ² ·h·°F/Btu	1 Story						2 or More Stories

Values calculated for ASHRAE *Standard* 152 default duct system surface area using model of Francisco and Palmiter (1999). Values are provided as guidance only; losses can differ substantially for other conditions and configurations. Assumed surrounding temperatures:

Cooling (C): $t_o = 95^\circ\text{F}$, $t_{attic} = 120^\circ\text{F}$, $t_b = 68^\circ\text{F}$, $t_{crawl} = 72^\circ\text{F}$ Heating/furnace (H/F) and heating/cooling pump (H/HP): $t_o = 32^\circ\text{F}$, $t_{attic} = 32^\circ\text{F}$, $t_b = 64^\circ\text{F}$, $t_{crawl} = 32^\circ\text{F}$

potentially large load impact of duct leakage, postconstruction verification of airtightness is strongly recommended.

Duct losses can be estimated using models specified in ASHRAE *Standard* 152, Francisco and Palmiter (1999), and Palmiter and Francisco (1997). The allowance for distribution losses is calculated as follows:

$$q_d = F_{dl} q_{bl} \quad (19)$$

where

q_d = distribution loss, Btu/h

F_{dl} = duct loss/gain factor, from Table 6 or ASHRAE *Standard* 152 design efficiencies or a detailed model

q_{bl} = total building load, Btu/h

Table 6 shows typical duct loss/gain factors calculated for the conditions indicated. These values can provide guidance for hand estimates, and illustrate the need for achieving low duct leakage. To the extent conditions differ from those shown, specific calculations should be made using a method cited previously. Note also that Table 6 cooling factors represent sensible gain only; duct leakage also introduces significant latent gain.

COOLING LOAD

A cooling load calculation determines total sensible cooling load from heat gain (1) through opaque surfaces (walls, floors, ceilings, and doors), (2) through transparent fenestration surfaces (windows, skylights, and glazed doors), (3) caused by infiltration and ventilation, and (4) because of occupancy. The latent portion of the cooling load is evaluated separately. Although the entire structure may be considered a single zone, equipment selection and system design should be based on room-by-room calculations. For proper design of the distribution system, the conditioned airflow required by each room must be known.

Peak Load Computation

To select a properly sized cooling unit, the peak or maximum load (block load) for each zone must be computed. The block load for a single-family detached house with one central system is the sum of all the room loads. If the house has a separate system for each zone, each zone block load is required. When a house is zoned with one central cooling system, the system size is based on the entire house block load, whereas zone components, such as distribution ducts, are sized using zone block loads.

In multifamily structures, each living unit has a zone load that equals the sum of the room loads. For apartments with separate

systems, the block load for each unit establishes the system size. Apartment buildings having a central cooling system with fan-coils in each apartment require a block load calculation for the complete structure to size the central system; each unit load establishes the size of the fan-coil and air distribution system for each apartment. One of the methods for nonresidential buildings discussed in Chapter 18 may be used to calculate the block load.

Opaque Surfaces

Heat gain through walls, floors, ceilings, and doors is caused by (1) the air temperature difference across such surfaces and (2) solar gains incident on the surfaces. The heat capacity of typical construction moderates and delays building heat gain. This effect is modeled in detail in the computerized RHB method, resulting in accurate simultaneous load estimates.

The RLF method uses the following to estimate cooling load:

$$q_{opq} = A \times CF_{opq} \quad (20)$$

$$CF_{opq} = U(OF_t \Delta t + OF_b + OF_r DR) \quad (21)$$

where

q_{opq} = opaque surface cooling load, Btu/h

A = net surface area, ft²

CF = surface cooling factor, Btu/h·ft²

U = construction U-factor, Btu/h·ft²·°F

Δt = cooling design temperature difference, °F

OF_t , OF_b , OF_r = opaque-surface cooling factors (see Table 7)

DR = cooling daily range, °F

OF factors, found in Table 7, represent construction-specific physical characteristics. OF_t values less than 1 capture the buffering effect of attics and crawlspaces, OF_b represents incident solar gain, and OF_r captures heat storage effects by reducing the effective temperature difference. Note also that CF can be viewed as $CF = U \times CLTD$, the formulation used in prior residential and nonresidential methods.

As shown in Table 7, roof solar absorptance has a significant effect on ceiling cooling load contribution. Table 8 shows typical values for solar absorptance of residential roofing materials. Note that low absorptance cannot be achieved with asphalt shingles.

Slab Floors

Slab floors produce a slight reduction in cooling load, as follows:

$$q_{opq} = A \times CF_{slab} \quad (22)$$

Table 7 Opaque Surface Cooling Factor Coefficients

Surface Type	OF _t	OF _b , °F	OF _r
Ceiling or wall adjacent to vented attic	0.62	25.7 α _{roof} - 8.1	-0.19
Ceiling/roof assembly	1	68.9 α _{roof} - 12.6	-0.36
Wall (wood frame) or door with solar exposure	1	14.8	-0.36
Wall (wood frame) or door (shaded)	1	0	-0.36
Floor over ambient	1	0	-0.06
Floor over crawlspace	0.33	0	-0.28
Slab floor (see Slab Floor section)			

α_{roof} = roof solar absorptance (see Table 8)

Source: Summarized from Parker et al. 2000

$$CF_{slab} = 0.59 - 2.5h_{srf} \quad (23)$$

where

- A = area of slab, ft²
- CF_{slab} = slab cooling factor, Btu/h·ft²
- h_{srf} = effective surface conductance, including resistance of slab covering material such as carpet = 1/(R_{cvr} + 0.68), Btu/h·ft²·°F. Representative R_{cvr} values are found in Chapter 6 of the 2008 ASHRAE Handbook—HVAC Systems and Equipment.
- 0.59 = constant, Btu/h·ft²
- 2.5 = factor, °F

Transparent Fenestration Surfaces

Cooling load associated with nondoor fenestration is calculated as follows:

$$q_{fen} = A \times CF_{fen} \quad (24)$$

$$CF_{fen} = U(\Delta t - 0.46DR) + PXI \times SHGC \times IAC \times FF_s \quad (25)$$

where

- q_{fen} = fenestration cooling load, Btu/h
- A = fenestration area (including frame), ft²
- CF_{fen} = surface cooling factor, Btu/h·ft²
- U = fenestration NFRC heating U-factor, Btu/h·ft²·°F
- Δt = cooling design temperature difference, °F
- PXI = peak exterior irradiance, including shading modifications, Btu/h·ft² [see Equations (26) or (27)]
- SHGC = fenestration rated or estimated NFRC solar heat gain coefficient
- IAC = interior shading attenuation coefficient, Equation (29)
- FF_s = fenestration solar load factor, Table 13

Peak Exterior Irradiance (PXI). Although solar gain occurs throughout the day, RP-1199 regression studies (Barnaby et al. 2004) showed that the cooling load contribution of fenestration correlates well with the peak-hour irradiance incident on the fenestration exterior. PXI is calculated as follows:

$$PXI = T_x E_t \text{ (unshaded fenestration)} \quad (26)$$

$$PXI = T_x [E_d + (1 - F_{shd})E_D] \text{ (shaded fenestration)} \quad (27)$$

where

- PXI = peak exterior irradiance, Btu/h·ft²
- E_t, E_d, E_D = peak total, diffuse, and direct irradiance (Table 9 or 10), Btu/h·ft²
- T_x = Transmission of exterior attachment (insect screen or shade screen)

Table 9 Peak Irradiance Equations

Table 11 Exterior Attachment Transmission

Attachment	T _x
None	1.0
Exterior insect screen	0.64 (see Chapter 15, Table 13G)
Shade screen	Manufacturer shading coefficient (SC) value, typically 0.4 to 0.6

F_{shd} = fraction of fenestration shaded by permanent overhangs, fins, or environmental obstacles

For horizontal or vertical surfaces, peak irradiance values can be obtained from Table 9 for primary exposures, or from Table 10 equations for any exposure. Skylights with slope less than 30° from horizontal should be treated as horizontal. Steeper, nonvertical slopes are not supported by the RLF method.

Exterior Attachments. Common window coverings can significantly reduce fenestration solar gain. Table 11 shows transmission values for typical attachments.

Permanent Shading. The shaded fraction F_{shd} can be taken as 1 for any fenestration shaded by adjacent structures during peak

hours. Simple overhang shading can be estimated using the following:

$$F_{shd} = \min \left[1, \max \left(0, \frac{SLF \times D_{oh} - X_{oh}}{h} \right) \right] \quad (28)$$

where

- SLF = shade line factor from Table 12
- D_{oh} = depth of overhang (from plane of fenestration), ft
- X_{oh} = vertical distance from top of fenestration to overhang, ft
- h = height of fenestration, ft

The shade line factor (SLF) is the ratio of the vertical distance a shadow falls beneath the edge of an overhang to the depth of the overhang, so the shade line equals the SLF times the overhang depth. Table 12 shows SLFs for July 21 averaged over the hours of greatest solar intensity on each exposure.

More complex shading situations should be analyzed with the RHB method.

Fenestration Solar Load Factors. Fenestration solar load factors FF_s depend on fenestration exposure and are found in Table 13. The values represent the fraction of transmitted solar gain that contributes to peak cooling load. It is thus understandable that morning (east) values are lower than afternoon (west) values. Higher values are included for multifamily buildings with limited exposure.

Interior Shading. Interior shading significantly reduces solar gain and is ubiquitous in residential buildings. Field studies show that a large fraction of windows feature some sort of shading; for

example, James et al. (1997) studied 368 houses and found interior shading in 80% of audited windows. Therefore, in all but special circumstances, interior shading should be assumed when calculating cooling loads. In the RLF method, the interior attenuation coefficient (IAC) model is used, as described in Chapter 15. Residential values from that chapter are consolidated in Table 14. IAC values for many other configurations are found in Chapter 15, Tables 13A to 13G.

In some cases, it is reasonable to assume that a shade is partially open. For example, drapes are often partially open to admit daylight. IAC values are computed as follows:

$$IAC = 1 + F_{cl}(IAC_{cl} - 1) \quad (29)$$

where

- IAC = interior attenuation coefficient of fenestration with partially closed shade
- F_{cl} = shade fraction closed (0 to 1)
- IAC_{cl} = interior attenuation coefficient of fully closed configuration (from Table 14 or Chapter 15, Tables 13A to 13G)

Infiltration and Ventilation

See the Common Data and Procedures section.

Internal Gain

The contributions of occupants, lighting, and appliance gains to peak sensible and latent loads can be estimated as

$$q_{ig,s} = 464 + 0.7A_{cf} + 75N_{oc} \quad (30)$$

$$q_{ig,l} = 68 + 0.07A_{cf} + 41N_{oc} \quad (31)$$

where

- $q_{ig,s}$ = sensible cooling load from internal gains, Btu/h
- $q_{ig,l}$ = latent cooling load from internal gains, Btu/h
- A_{cf} = conditioned floor area of building, ft²
- N_{oc} = number of occupants (unknown, estimate as $N_{br} + 1$)

Equations (30) and (31) and their coefficients are derived from Building America (2004) load profiles evaluated at 4:00 P.M., as documented by Barnaby and Spittler (2005). Predicted gains are typical for U.S. homes. Further allowances should be considered when unusual lighting intensities or other equipment are in continuous use during peak cooling hours. In critical situations where intermittent high occupant density or other internal gains are expected, a parallel cooling system should be considered.

For room-by-room calculations, $q_{ig,s}$ should be evaluated for the entire conditioned area, and allocated to kitchen and living spaces.

Air Distribution System: Heat Gain

See the Common Data and Procedures section.

Total Latent Load

The latent cooling load is the result of three predominant moisture sources: outdoor air (infiltration and ventilation), occupants,

Table 15 Summary of RLF Cooling Load Equations

Load Source	Equation	Tables and Notes
Exterior opaque surfaces	$q_{opq} = A \times CF$ $CF = U(OF_t \Delta t + OF_b + OF_{DR})$	OF factors from Table 7
Exterior transparent surfaces	$q_{fen} = A \times CF$ $CF = U(\Delta t - 0.46DR) + PXI \times SHGC \times IAC \times FF_s$	PXI from Table 9 plus adjustments FF _s from Table 13
Partitions to unconditioned space	$q = AU\Delta t$	Δt = temperature difference across partition
Ventilation/infiltration	$q_s = C_s Q \Delta t$	See Common Data and Procedures section
Occupants and appliances	$q_{ig,s} = 464 + 0.7A_{cf} + 75N_{oc}$	
Distribution	$q_d = F_{dl} \sum q$	F_{dl} from Table 6
Total sensible load	$q_s = q_d + \sum q$	
Latent load	$q_l = q_{vi,l} + q_{ig,l}$	
Ventilation/infiltration	$q_{vi,l} = C_l Q \Delta W$	
Internal gain	$q_{ig,l} = 68 + 0.07A_{cf} + 41N_{oc}$	

and miscellaneous sources, such as cooking, laundry, and bathing. These components, discussed in previous sections, combine to yield the total latent load:

$$q_l = q_{vi,l} + q_{ig,l} \quad (32)$$

where

q_l = total latent load, Btu/h

$q_{vi,l}$ = ventilation/infiltration latent gain, Btu/h, from Equation (16) or (18)

$q_{ig,l}$ = internal latent gain, Btu/h, from Equation (31)

Additional latent gains may be introduced through return duct leakage and specific atypical sources. These may be estimated and included. Lstiburek and Carmody (1993) provide data for household moisture sources; however, again note that Equation (31) adequately accounts for normal gains.

Because air conditioning systems are usually controlled by a thermostat, latent cooling is a side effect of equipment operation. During periods of significant latent gain but mild temperatures, there is little cooling operation, resulting in unacceptable indoor humidity. Multispeed equipment, combined temperature/humidity control, and dedicated dehumidification should be considered to address this condition.

Summary of RLF Cooling Load Equations

Table 15 contains a brief list of equations used in the cooling load calculation procedure described in this chapter.

HEATING LOAD

Calculating a residential heating load involves estimating the maximum heat loss of each room or space to be heated and the simultaneous maximum (block) heat loss for the building, while maintaining a selected indoor air temperature during periods of design outdoor weather conditions. As discussed in the section on Calculation Approach, heating calculations use conservative assumptions, ignoring solar and internal gains, and building heat storage. This leaves a simple steady-state heat loss calculation, with the only significant difficulty being surfaces adjacent to grade.

Exterior Surfaces Above Grade

All above-grade surfaces exposed to outdoor conditions (walls, doors, ceilings, fenestration, and raised floors) are treated identically, as follows:

$$q = A \times HF \quad (33)$$

$$HF = U\Delta t \quad (34)$$

where HF is the heating load factor in Btu/h·ft²

Two ceiling configurations are common:

- For **ceiling/roof combinations** (e.g., flat roof or cathedral ceiling), the U-factor should be evaluated for the entire assembly.
- For **well-insulated ceilings (or walls) adjacent to vented attic space**, the U-factor should be that of the insulated assembly only (the roof is omitted) and the attic temperature assumed to equal the heating design outdoor temperature. The effect of attic radiant barriers can be neglected. In cases where the ceiling or wall is not well insulated, the adjacent buffer space procedure (see the section on Surfaces Adjacent to Buffer Space) can be used.

Below-Grade and On-Grade Surfaces

The Heating Load Calculations section of Chapter 18 includes simplified procedures for estimating heat loss through below-grade walls and below- and on-grade floors. Those procedures are applicable to residential buildings. In more detailed work, Bahnfleth and Pedersen (1990) show a significant effect of the area-to-perimeter ratio. For additional generality and accuracy, see also methods described or cited in Beausoleil-Morrison and Mitalas (1997), CAN/CSA Standard F280-M90 (1990), HRAI (1996), and Krarti and Choi (1996).

Surfaces Adjacent to Buffer Space

Heat loss to adjacent unconditioned or semiconditioned spaces can be calculated using a heating factor based on the partition temperature difference:

$$HF = U(t_i - t_b) \quad (35)$$

Buffer space air temperature t_b can be estimated using procedures discussed in the section on Adjacent Buffer Spaces. Generally, simple approximations are sufficient except where the partition surface is poorly insulated.

Crawlspaces and basements are cases where the partition (the house floor) is often poorly insulated; they also involve heat transfer to the ground. Most codes require crawlspaces to be adequately vented year round. However, work highlighting problems with venting crawlspaces (DeWitt 2003) has led to application of sealed crawlspaces with insulated perimeter walls. Equation (5) may be applied to basements and crawlspace by including appropriate ground-related terms in the heat balance formulation. For example, when including below-grade walls, $A_x = A_{bw}$, $U_x = U_{avg,bw}$, and $t_x = t_{gr}$ should be included as applicable in the summations in Equation (5). Losses from piping or ducting should be included as additional buffer space heat gain. Determining the ventilation or infiltration rate for crawlspaces and basements is difficult. Latta and Boileau (1969) estimated the air exchange rate for an uninsulated basement at 0.67 ach under winter conditions. Field measurements of eight ventilated crawlspaces summarized in Palmiter and Francisco (1996) yielded a median flow rate of 4.6 ach. Clearly, crawlspace infiltration rates vary widely, depending on vent configuration and operation.

Ventilation and Infiltration

Infiltration of outside air causes both sensible and latent heat loss. The energy required to raise the temperature of outdoor infiltrating air to indoor air temperature is the sensible component; energy associated with net loss of moisture from the space is the latent component. Determining the volumetric flow Q of outdoor air entering the building is discussed in the Common Data and Procedures section and in Chapter 16. Determining the resulting sensible and latent loads is discussed in the Ventilation/Infiltration Load subsection.

Humidification

In many climates, humidification is required to maintain comfortable indoor relative humidity under heating conditions. The latent ventilation and infiltration load calculated, assuming desired indoor humidity conditions, equals the sensible heat needed to evaporate water at a rate sufficient to balance moisture losses from air leakage. Self-contained humidifiers provide this heat from internal sources. If the heat of evaporation is taken from occupied space or the distribution system, the heating capacity should be increased accordingly.

Pickup Load

For intermittently heated buildings and night thermostat setback, additional heat is required to raise the temperature of air, building materials, and material contents to the specified temperature. The rate at which this additional heat must be supplied is the pickup load, which depends on the structure's heat capacity, its material contents, and the time in which these are to be heated.

Because the design outdoor temperature is generally much lower than typical winter temperatures, under most conditions excess heating capacity is available for pickup. Therefore, many engineers make no pickup allowance except for demanding situations. If pickup capacity is justified, the following guidance can be used to estimate the requirement.

Relatively little rigorous information on pickup load exists. Building simulation programs can predict recovery times and required equipment capacities, but a detailed simulation study is rarely practical. Armstrong et al. (1992a, 1992b) developed a model for predicting recovery from setback and validated it for a church and two office buildings. Nelson and MacArthur (1978) studied the relationship between thermostat setback, furnace capacity, and recovery time. Hedrick et al. (1992) compared Nelson and MacArthur's results to tests for two test houses. They found that the furnace oversizing required for a 2 h recovery time ranges from 20 to 120%, depending on size of setback, building mass, and heating Δt (colder locations require less oversizing on a percentage basis).

The designer should be aware that there are tradeoffs between energy savings from thermostat setback and energy penalties incurred by oversizing equipment. Koenig (1978) studied a range of locations and suggested that 30% oversizing allows recovery times less than 4 h for nearly the entire heating season and is close to optimum from an energy standpoint.

The preceding guidance applies to residential buildings with fuel-fired furnaces. Additional considerations may be important for other types of heating systems. For air-source heat pumps with electric resistance auxiliary heat, thermostat setback may be undesirable (Bullock 1978).

Thermostats with optimum-start algorithms, designed to allow both energy savings and timely recovery to the daytime set point, are becoming routinely available and should be considered in all cases.

Summary of Heating Load Procedures

Table 16 lists equations used in the heating load calculation procedures described in this chapter.

Table 16 Summary of Heating Load Calculation Equations

Load Source	Equation	Tables and Notes
Exterior surfaces above grade	$q = UA\Delta t$	$\Delta t = t_i - t_o$
Partitions to unconditioned buffer space	$q = UA\Delta t$	$\Delta t = \text{temp. difference across partition}$
Walls below grade	$q = U_{\text{avg},bw}A(t_{in} - t_{gr})$	
Floors on grade	$q = F_p p \Delta t$	See Chapter 18, Equations (41) and (42)
Floors below grade	$q = U_{\text{avg},bf}A(t_{in} - t_{gr})$	See Chapter 18, Equations (37) and (38)
Ventilation/infiltration	$q_{vi} = C_s Q \Delta t$	From Common Data and Procedures section
Total sensible load	$q_s = \Sigma q$	

Fig. 1 Example House

LOAD CALCULATION EXAMPLE

A single-family detached house with floor plan shown in Figure 1 is located in Atlanta, GA, USA. Construction characteristics are documented in Table 17. Using the RLF method, find the block (whole-house) design cooling and heating loads. A furnace/air-conditioner forced-air system is planned with a well-sealed and well-insulated (R-8 wrap) attic duct system.

Solution

Design Conditions. Table 18 summarizes design conditions. Typical indoor conditions are assumed. Outdoor conditions are determined from Chapter 14.

Component Quantities. Areas and lengths required for load calculations are derived from plan dimensions (Figure 1). Table 19 summarizes these quantities.

Opaque Surface Factors. Heating and cooling factors are derived for each component condition. Table 20 shows the resulting factors and their sources.

Window Factors. Deriving cooling factors for windows requires identifying all unique glazing configurations in the house. Equation (25) input items indicate that the variations for this case are exposure, window height (with overhang shading), and frame type (which determines U-factor, SHGC, and the presence of insect screen). CF derivation for all configurations is summarized in Table 21.

For example, CF for operable 3 ft high windows facing west (the second row in Table 21) is derived as follows:

- U-factor and SHGC are found in Table 2.
- Each operable window is equipped with an insect screen. From Table 11, $T_x = 0.64$ for this arrangement.
- Overhang shading is evaluated with Equation (28). For west exposure and latitude 34° , Table 12 shows $SLF = 1.1$. Overhang depth (D_{oh}) is 2 ft and the window-overhang distance (X_{oh}) is 0 ft. With window height h of 3 ft, $F_s = 0.73$ (73% shaded).

Table 17 Example House Characteristics

Component	Description	Factors
Roof/ceiling	Flat wood frame ceiling (insulated with R-30 fiberglass) beneath vented attic with medium asphalt shingle roof	$U = 0.031 \text{ Btu/h}\cdot\text{ft}^2\cdot^\circ\text{F}$ $\alpha_{roof} = 0.85$ (Table 8)
Exterior walls	Wood frame, exterior wood sheathing, interior gypsum board, R-13 fiberglass insulation	$U = 0.090 \text{ Btu/h}\cdot\text{ft}^2\cdot^\circ\text{F}$
Doors	Wood, solid core	$U = 0.40 \text{ Btu/h}\cdot\text{ft}^2\cdot^\circ\text{F}$
Floor	Slab on grade with heavy carpet over rubber pad; R-5 edge insulation to 3 ft below grade	$R_{cvr} = 1.2 \text{ ft}^2\cdot\text{h}\cdot^\circ\text{F}/\text{Btu}$ (Table 3, Chapter 6, 2008 ASHRAE Handbook—HVAC Systems and Equipment) $F_p = 0.5 \text{ Btu/h}\cdot\text{ft}\cdot^\circ\text{F}$ (estimated from Chapter 18, Table 24)
Windows	Clear double-pane glass in wood frames. Half fixed, half operable with insect screens (except living room picture window, which is fixed). 2 ft eave overhang on east and west with eave edge at same height as top of glazing for all windows. Allow for typical interior shading, half closed.	Fixed: $U = 0.50 \text{ Btu/h}\cdot\text{ft}^2\cdot^\circ\text{F}$; SHGC = 0.67 (Table 2) Operable: $U = 0.51 \text{ Btu/h}\cdot\text{ft}^2\cdot^\circ\text{F}$; SHGC = 0.57 (Table 2); $T_x = 0.64$ (Table 11) IAC _{cl} = 0.6 (estimated from Table 14)
Construction	Good	$A_{ul} = 0.02 \text{ in}^2/\text{ft}^{22}$ (Table 3)

Table 18 Example House Design Conditions

Item	Heating	Cooling	Notes

Walls, garage	384 ft ²	
Floor area	2088 ft ²	
Floor perimeter	220 ft	Include perimeter adjacent to garage
Total exposed surface	3848 ft ²	Wall gross area (including garage wall) plus ceiling area
Volume	16,704 ft ³	

Table 20 Example House Opaque Surface Factors

Component	$U, \text{Btu/h}\cdot\text{ft}^2\cdot^\circ\text{F}$ or $F_p, \text{Btu/h}\cdot\text{ft}\cdot^\circ\text{F}$	Heating		Cooling				
		HF	Reference	OF _t	OF _b	OF _r	CF	Reference
Ceiling	0.031	1.30	Equation (34)	0.62	13.75	-0.19	0.65	Table 7 Equation (21)
Wall	0.090	3.78		1	14.80	-0.36	2.31	
Garage wall	0.090	3.78		1	0.00	-0.36	0.98	
Door	0.400	16.8		1	14.80	-0.36	10.27	
Floor perimeter	0.500	21.0	Chapter 18, Equation (42)					
Floor area				0.59	-2.5/(0.68 + 1.20) = -1.33		-0.74	Equation (23)

- PXI depends on peak irradiance and shading. Approximating site latitude as 35°N, Table 9 shows $E_D = 177$ and $E_d = 60 \text{ Btu/h}\cdot\text{ft}^2$ for west exposure. Equation (27) combines these values with T_x and F_s to find $PXI = 0.6[52 + (1 - 0.73)208] = 69 \text{ Btu/h}\cdot\text{ft}^2$.
- All windows are assumed to have some sort of interior shading in the half-closed position. Use Equation (29) with $F_{cl} = 0.5$ and $IAC_{cl} = 0.6$ (per Table 17) to derive $IAC = 0.8$.
- FF_s is taken from Table 13 for west exposure.
- Finally, inserting the preceding values into Equation (25) gives $CF = 0.51(17 - 0.46 \times 17) + 69 \times 0.57 \times 0.80 \times 0.56 = 22.3 \text{ Btu/h}\cdot\text{ft}^2$.

Envelope Loads. Given the load factors and component quantities, heating and cooling loads are calculated for each envelope element, as shown in Table 22.

Infiltration and Ventilation. From Table 3, A_{ul} for this house is $0.02 \text{ in}^2/\text{ft}^2$ of exposed surface area. Applying Equation (9) yields $A_L = A_{es} \times A_{ul} = 3848 \times 0.02 = 77 \text{ in}^2$. Using Table 5, estimate heating and cooling IDF to be 1.0 0.073 and 0.48 cfm/in², respectively [alternatively, Equation (10) could be used to find IDF values].

Apply Equation (8) to find the infiltration leakage rates and Equation (7) to convert the rate to air changes per hour:

$$Q_{i,h} = 77 \times 1.0 = 77 \text{ cfm (0.28 ach)}$$

$$Q_{i,c} = 77 \times 0.48 = 36 \text{ cfm (0.13 ach)}$$

Calculate the ventilation outside air requirement with Equation (11) using $A_{cf} = 2088 \text{ ft}^2$ and $N_{br} = 3$, resulting in $Q_v = 51 \text{ cfm}$. For design purposes, assume that this requirement is met by a mechanical system with balanced supply and exhaust flow rates ($Q_{unbal} = 0$).

Find the combined infiltration/ventilation flow rates with Equation (14):

$$Q_{vi,h} = 51 + \max(0, 77 + 0.5 \times 0) = 128 \text{ cfm}$$

$$Q_{vi,c} = 51 + \max(0, 36 + 0.5 \times 0) = 87 \text{ cfm}$$

At Atlanta's elevation of 1027 ft, elevation adjustment of heat factors results in a small (4%) reduction in air heat transfer; thus,

E-Fixed-3	21.0	22.5	4.5	95	101
E-Operable-3	21.4	14.4	4.5	96	65
E-Fixed-4	21.0	27.8	24	504	667
E-Operable-4	21.4	17.3	24	514	416
Envelope totals				17,207	9336

Table 23 Example House Total Sensible Loads

Item	Heating Load, Btu/h	Cooling Load, Btu/h
Envelope	17,207	9336
Infiltration/ventilation	5914	1627
Internal gain		2226
Subtotal	23,121	13,189
Distribution loss	3006	3561
Total sensible load	26,126	16,750

adjustment is unnecessary, resulting in C_s = 1.10 Btu/h·°F·cfm. Use Equation (15) with Q_{bal,hr} = 0 and Q_{bal,oth} = 0 to calculate the sensible infiltration/ventilation loads:

$$q_{vi,s,h} = 1.1 \times 128 \times 42 = 5914 \text{ Btu/h}$$

$$q_{vi,s,c} = 1.1 \times 87 \times 17 = 1627 \text{ Btu/h}$$

Internal Gain. Apply Equation (30) to find the sensible cooling load from internal gain:

$$q_{ig,s} = 464 + 0.7 \times 2088 + 75 (3 + 1) = 2226 \text{ Btu/h}$$

Distribution Losses and Total Sensible Load. Table 23 summarizes the sensible load components. Distribution loss factors F_{dl} are estimated (from Table 6) at 0.13 for heating and 0.27 for cooling.

Latent Load. Use Equation (16) with C_l = 4840 Btu/h·cfm, Q_{vi,c} = 87 cfm, Q_{bal,oth} = 0, and ΔW = 0.0052 to calculate the

infiltration/ventilation latent load = 2187 Btu/h. Use Equation (31) to find the latent load from internal gains = 378 Btu/h. Therefore, the total latent cooling load is 2565 Btu/h.

SYMBOLS

- A = area, ft²; ground surface temperature amplitude, °F
- A_L = building effective leakage area (including flue) at 0.016 in. of water, assuming C_D = 1, in²
- C_l = air latent heat factor, 4840 Btu/h·cfm at sea level
- C_s = air sensible heat factor, 1.1 Btu/h·cfm·°F at sea level
- C_t = air total heat factor, 4.5 Btu/h·cfm·(Btu/lb) at sea level
- CF = cooling load factor, Btu/h·ft²
- D_{oh} = depth of overhang (from plane of fenestration), ft
- DR = daily range of outdoor dry-bulb temperature, °F
- E = peak irradiance for exposure, Btu/h·ft²
- F_{dl} = distribution loss factor
- F_p = heat loss coefficient per unit length of perimeter, Btu/h·ft·°F
- F_{shd} = shaded fraction
- FF = coefficient for CF_{fen}
- G = internal gain coefficient
- h_{surf} = effective surface conductance, including resistance of slab covering material such as carpet, 1/(R_{cvr} + 0.68) Btu/h·ft²·°F
- Δh = indoor/outdoor enthalpy difference, Btu/lb
- H = height, ft
- HF = heating (load) factor, Btu/h·ft²
- I = infiltration coefficient
- IAC = interior shading attenuation coefficient
- IDF = infiltration driving force, cfm/in²
- k = conductivity, Btu/h·ft·°F
- LF = load factor, Btu/h·ft²
- OF = coefficient for CF_{opq}
- p = perimeter or exposed edge of floor, ft
- PXI = peak exterior irradiance, including shading modifications, Btu/h·ft²
- q = heating or cooling load, Btu/h
- Q = air volumetric flow rate, cfm
- R = insulation thermal resistance, ft²·h·°F/Btu
- SHGC = fenestration rated or estimated NFRC solar heat gain coefficient
- SLF = shade line factor
- t = temperature, °F
- T_x = solar transmission of exterior attachment
- Δt = design dry-bulb temperature difference (cooling or heating), °F
- U = construction U-factor, Btu/h·ft²·°F (for fenestration, NFRC rated heating U-factor)
- w = width, ft
- ΔW = indoor-outdoor humidity ratio difference, lb_w/lb_{da}
- V = building volume, ft³
- X_{oh} = vertical distance from top of fenestration to overhang, ft
- z = depth below grade, ft
- α_{roof} = roof solar absorptance
- ε = heat/energy recovery ventilation (HRV/ERV) effectiveness

Subscripts

- avg = average
- b = base (as in OF_b), basement, building, buffer

bal = balanced
bf = basement floor
bl = building load
bw = basement wall
br = bedrooms
ceil = ceiling
cf = conditioned floor
cl = closed
cvr = floor covering
d = diffuse, distribution

<i>Radiant Time Series (RTS) Method</i>	18.20	<i>Building Example Drawings</i>	18.55

HHEATING and cooling load calculations are the primary design basis for most heating and air-conditioning systems and components. These calculations affect the size of piping, ductwork, diffusers, air handlers, boilers, chillers, coils, compressors, fans, and every other component of systems that condition indoor environments. Cooling and heating load calculations can significantly affect first cost of building construction, comfort and productivity of occupants, and operating cost and energy consumption.

Simply put, heating and cooling loads are the rates of energy input (heating) or removal (cooling) required to maintain an indoor environment at a desired temperature and humidity condition. Heating and air conditioning systems are designed, sized, and controlled to accomplish that energy transfer. The amount of heating or cooling required at any particular time varies widely, depending on external (e.g., outside temperature) and internal (e.g., number of people occupying a space) factors.

Peak design heating and cooling load calculations, which are this chapter's focus, seek to determine the maximum rate of heating and cooling energy transfer needed at any point in time. Similar principles, but with different assumptions, data, and application, can be used to estimate building energy consumption, as described in Chapter 19.

This chapter discusses common elements of cooling load calculation (e.g., internal heat gain, ventilation and infiltration, moisture migration, fenestration heat gain) and two methods of heating and cooling load estimation: heat balance (HB) and radiant time series (RTS).

COOLING LOAD CALCULATION PRINCIPLES

Cooling loads result from many conduction, convection, and radiation heat transfer processes through the building envelope and from internal sources and system components. Building components or contents that may affect cooling loads include the following:

- **External:** Walls, roofs, windows, skylights, doors, partitions, ceilings, and floors
- **Internal:** Lights, people, appliances, and equipment
- **Infiltration:** Air leakage and moisture migration
- **System:** Outside air, duct leakage and heat gain, reheat, fan and pump energy, and energy recovery

TERMINOLOGY

The variables affecting cooling load calculations are numerous, often difficult to define precisely, and always intricately interrelated. Many cooling load components vary widely in magnitude,

and possibly direction, during a 24 h period. Because these cyclic changes in load components often are not in phase with each other, each component must be analyzed to establish the maximum cooling load for a building or zone. A **zoned system** (i.e., one serving several independent areas, each with its own temperature control) needs to provide no greater total cooling load capacity than the largest hourly sum of simultaneous zone loads throughout a design day; however, it must handle the peak cooling load for each zone at its individual peak hour. At some times of day during heating or intermediate seasons, some zones may require heating while others require cooling. The zones' ventilation, humidification, or dehumidification needs must also be considered.

Heat Flow Rates

In air-conditioning design, the following four related heat flow rates, each of which varies with time, must be differentiated.

Space Heat Gain. This instantaneous rate of heat gain is the rate at which heat enters into and/or is generated within a space. Heat gain is classified by its mode of entry into the space and whether it is sensible or latent. **Entry modes** include (1) solar radiation through transparent surfaces; (2) heat conduction through exterior walls and roofs; (3) heat conduction through ceilings, floors, and interior partitions; (4) heat generated in the space by occupants, lights, and appliances; (5) energy transfer through direct-with-space ventilation and infiltration of outdoor air; and (6) miscellaneous heat gains. **Sensible heat** is added directly to the conditioned space by conduction, convection, and/or radiation. **Latent heat** gain occurs when moisture is added to the space (e.g., from vapor emitted by occupants and equipment). To maintain a constant humidity ratio, water vapor must condense on the cooling apparatus and be removed at the same rate it is added to the space. The amount of energy required to offset latent heat gain essentially equals the product of the condensation rate and latent heat of condensation. In selecting cooling equipment, distinguish between sensible and latent heat gain: every cooling apparatus has different maximum removal capacities for sensible versus latent heat for particular operating conditions. In extremely dry climates, humidification may be required, rather than dehumidification, to maintain thermal comfort.

Radiant Heat Gain. Radiant energy must first be absorbed by surfaces that enclose the space (walls, floor, and ceiling) and objects in the space (furniture, etc.). When these surfaces and objects become warmer than the surrounding air, some of their heat transfers to the air by convection. The composite heat storage capacity of these surfaces and objects determines the rate at which their respective surface temperatures increase for a given radiant input, and thus governs the relationship between the radiant portion of heat gain and its corresponding part of the space cooling load (Figure 1). The thermal storage effect is critical in differentiating between instantaneous heat gain for a given space and its cooling load at that moment. Predicting the nature and magnitude of this phenomenon in order to estimate a realistic cooling load for a particular set of circumstances has long

The preparation of this chapter is assigned to TC 4.1, Load Calculation Data and Procedures.

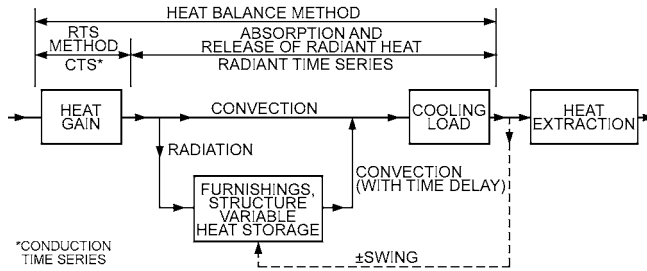

Fig. 1 Origin of Difference Between Magnitude of Instantaneous Heat Gain and Instantaneous Cooling Load

been of interest to design engineers; the Bibliography lists some early work on the subject.

Space Cooling Load. This is the rate at which sensible and latent heat must be removed from the space to maintain a constant space air temperature and humidity. The sum of all space instantaneous heat gains at any given time does not necessarily (or even frequently) equal the cooling load for the space at that same time.

Space Heat Extraction Rate. The rates at which sensible and latent heat are removed from the conditioned space equal the space cooling load only if the room air temperature and humidity are constant. Along with the intermittent operation of cooling equipment, control systems usually allow a minor cyclic variation or swing in room temperature; humidity is often allowed to float, but it can be controlled. Therefore, proper simulation of the control system gives a more realistic value of energy removal over a fixed period than using values of the space cooling load. However, this is primarily important for estimating energy use over time; it is not needed to calculate design peak cooling load for equipment selection.

Cooling Coil Load. The rate at which energy is removed at a cooling coil serving one or more conditioned spaces equals the sum of instantaneous space cooling loads (or space heat extraction rate, if it is assumed that space temperature and humidity vary) for all spaces served by the coil, plus any system loads. System loads include fan heat gain, duct heat gain, and outdoor air heat and moisture brought into the cooling equipment to satisfy the ventilation air requirement.

Time Delay Effect

Energy absorbed by walls, floor, furniture, etc., contributes to space cooling load only after a time lag. Some of this energy is still present and reradiating even after the heat sources have been switched off or removed, as shown in Figure 2.

There is always significant delay between the time a heat source is activated, and the point when reradiated energy equals that being instantaneously stored. This time lag must be considered when calculating cooling load, because the load required for the space can be much lower than the instantaneous heat gain being generated, and the space's peak load may be significantly affected.

Accounting for the time delay effect is the major challenge in cooling load calculations. Several methods, including the two presented in this chapter, have been developed to take the time delay effect into consideration.

COOLING LOAD CALCULATION METHODS

This chapter presents two load calculation methods that vary significantly from previous methods. The technology involved, however (the principle of calculating a heat balance for a given space) is not new. The first of the two methods is the **heat balance (HB) method**; the second is **radiant time series (RTS)**, which is a simplification of the HB procedure. Both methods are explained in their respective sections.

Fig. 2 Thermal Storage Effect in Cooling Load from Lights

Cooling load calculation of an actual, multiple-room building requires a complex computer program implementing the principles of either method.

Cooling Load Calculations in Practice

Load calculations should accurately describe the building. All load calculation inputs should be as accurate as reasonable, without using safety factors. Introducing compounding safety factors at multiple levels in the load calculation results in an unrealistic and oversized load.

Variation in heat transmission coefficients of typical building materials and composite assemblies, differing motivations and skills of those who construct the building, unknown filtration rates, and the manner in which the building is actually operated are some of the variables that make precise calculation impossible. Even if the designer uses reasonable procedures to account for these factors, the calculation can never be more than a good estimate of the actual load. Frequently, a cooling load must be calculated before every parameter in the conditioned space can be properly or completely defined. An example is a cooling load estimate for a new building with many floors of unleased spaces for which detailed partition requirements, furnishings, lighting, and layout cannot be pre-defined. Potential tenant modifications once the building is occupied also must be considered. Load estimating requires proper engineering judgment that includes a thorough understanding of heat balance fundamentals.

Perimeter spaces exposed to high solar heat gain often need cooling during sunlit portions of traditional heating months, as do completely interior spaces with significant internal heat gain. These spaces can also have significant heating loads during nonsunlit hours or after periods of nonoccupancy, when adjacent spaces have cooled below interior design temperatures. The heating loads involved can be estimated conventionally to offset or to compensate for them and prevent overheating, but they have no direct relationship to the spaces' design heating loads.

Correct design and sizing of air-conditioning systems require more than calculation of the cooling load in the space to be conditioned. The type of air-conditioning system, ventilation rate, reheat, fan energy, fan location, duct heat loss and gain, duct leakage, heat extraction lighting systems, type of return air system, and any sensible or latent heat recovery all affect system load and component sizing. Adequate system design and component sizing require that system performance be analyzed as a series of psychrometric processes.

System design could be driven by either sensible or latent load, and both need to be checked. When a space is sensible-load-driven, which is generally the case, the cooling supply air will have surplus capacity to dehumidify, but this is commonly permissible. For a space driven by latent load, (e.g., an auditorium), supply airflow based on sensible load is likely not have enough dehumidifying capability, so subcooling and reheating or some other dehumidification process is needed.

This chapter is primarily concerned with a given space or zone in a building. When estimating loads for a group of spaces (e.g., for an

air-handling system that serves multiple zones), the assembled zones must be analyzed to consider (1) the simultaneous effects taking place; (2) any diversification of heat gains for occupants, lighting, or other internal load sources; (3) ventilation; and/or (4) any other unique circumstances. With large buildings that involve more than a single HVAC system, simultaneous loads and any additional diversity also must be considered when designing the central equipment that serves the systems. Methods presented in this chapter are expressed as hourly load summaries, reflecting 24 h input schedules and profiles of the individual load variables. Specific systems and applications may require different profiles.

DATA ASSEMBLY

Calculating space cooling loads requires detailed building design information and weather data at design conditions. Generally, the following information should be compiled.

Building Characteristics. Building materials, component size, external surface colors, and shape are usually determined from building plans and specifications.

Configuration. Determine building location, orientation, and external shading from building plans and specifications. Shading from adjacent buildings can be determined from a site plan or by visiting the proposed site, but its probable permanence should be carefully evaluated before it is included in the calculation. The possibility of abnormally high ground-reflected solar radiation (e.g., from adjacent water, sand, or parking lots) or solar load from adjacent reflective buildings should not be overlooked.

Outdoor Design Conditions. Obtain appropriate weather data, and select outdoor design conditions. Chapter 14 provides information for many weather stations; note, however, that these design dry-bulb and mean coincident wet-bulb temperatures may vary considerably from data traditionally used in various areas. Use judgment to ensure that results are consistent with expectations. Also, consider prevailing wind velocity and the relationship of a project site to the selected weather station.

Recent research projects have greatly expanded the amount of available weather data (e.g., ASHRAE 2004). In addition to the conventional dry-bulb with mean coincident wet-bulb, data are now available for wet-bulb and dew point with mean coincident dry-bulb. Peak space load generally coincides with peak solar or peak dry-bulb, but peak system load often occurs at peak wet-bulb temperature. The relationship between space and system loads is discussed further in following sections of the chapter.

To estimate conductive heat gain through exterior surfaces and infiltration and outdoor air loads at any time, applicable outdoor dry- and wet-bulb temperatures must be used. Chapter 14 gives monthly cooling load design values of outdoor conditions for many locations. These are generally midafternoon conditions; for other times of day, the daily range profile method described in Chapter 14 can be used to estimate dry- and wet-bulb temperatures. Peak cooling load is often determined by solar heat gain through fenestration; this peak may occur in winter months and/or at a time of day when outside air temperature is not at its maximum.

Indoor Design Conditions. Select indoor dry-bulb temperature, indoor relative humidity, and ventilation rate. Include permissible variations and control limits. Consult ASHRAE *Standard* 90.1 for energy-savings conditions, and *Standard* 55 for ranges of indoor conditions needed for thermal comfort.

Internal Heat Gains and Operating Schedules. Obtain planned density and a proposed schedule of lighting, occupancy, internal equipment, appliances, and processes that contribute to the internal thermal load.

Areas. Use consistent methods for calculation of building areas. For fenestration, the definition of a component's area must be consistent with associated ratings.

Gross surface area. It is efficient and conservative to derive gross surface areas from outside building dimensions, ignoring wall and floor thicknesses and avoiding separate accounting of floor edge and wall corner conditions. Measure floor areas to the outside of adjacent exterior walls or to the center line of adjacent partitions. When apportioning to rooms, façade area should be divided at partition center lines. Wall height should be taken as floor-to-floor height.

The outside-dimension procedure is expedient for load calculations, but it is not consistent with rigorous definitions used in building-related standards. The resulting differences do not introduce significant errors in this chapter's procedures.

Fenestration area. As discussed in Chapter 15, fenestration ratings [U-factor and solar heat gain coefficient (SHGC)] are based on the entire product area, including frames. Thus, for load calculations, fenestration area is the area of the rough opening in the wall or roof.

Net surface area. Net surface area is the gross surface area less any enclosed fenestration area.

INTERNAL HEAT GAINS

Internal heat gains from people, lights, motors, appliances, and equipment can contribute the majority of the cooling load in a modern building. As building envelopes have improved in response to more restrictive energy codes, internal loads have increased because of factors such as increased use of computers and the advent of dense-occupancy spaces (e.g., call centers). Internal heat gain calculation techniques are identical for both heat balance (HB) and radiant time series (RTS) cooling-load calculation methods, so internal heat gain data are presented here independent of calculation methods.

PEOPLE

Table 1 gives representative rates at which sensible heat and moisture are emitted by humans in different states of activity. In high-density spaces, such as auditoriums, these sensible and latent heat gains comprise a large fraction of the total load. Even for short-term occupancy, the extra sensible heat and moisture introduced by people may be significant. See Chapter 9 for detailed information; however, Table 1 summarizes design data for common conditions.

The conversion of sensible heat gain from people to space cooling load is affected by the thermal storage characteristics of that space because some percentage of the sensible load is radiant energy. Latent heat gains are usually considered instantaneous, but research is yielding practical models and data for the latent heat storage of and release from common building materials.

LIGHTING

Because lighting is often a major space cooling load component, an accurate estimate of the space heat gain it imposes is needed. Calculation of this load component is not straightforward; the rate of cooling load from lighting at any given moment can be quite different from the heat equivalent of power supplied instantaneously to those lights, because of heat storage.

Instantaneous Heat Gain from Lighting

The primary source of heat from lighting comes from light-emitting elements, or lamps, although significant additional heat may be generated from ballasts and other appurtenances in the luminaires. Generally, the instantaneous rate of sensible heat gain from electric lighting may be calculated from

$$q_{el} = 3.41 WF_{ul} F_{sa} \quad (1)$$

where

q_{el} = heat gain, Btu/h

W = total light wattage, W

F_{ul} = lighting use factor

F_{sa} = lighting special allowance factor

3.41 = conversion factor

Table 1 Representative Rates at Which Heat and Moisture Are Given Off by Human Beings in Different States of Activity

Degree of Activity	Location	Total Heat, Btu/h		Sensible Heat, Btu/h	Latent Heat, Btu/h	% Sensible Heat that is Radiant ^b	
		Adult Male	Adjusted, M/F ^a			Low <i>V</i>	High <i>V</i>
		Seated at theater	Theater, matinee	390	330	225	105
Seated at theater, night	Theater, night	390	350	245	105	60	27
Seated, very light work	Offices, hotels, apartments	450	400	245	155

Notes:

1. Tabulated values are based on 75°F room dry-bulb temperature. For 80°F room dry bulb, total heat remains the same, but sensible heat values should be decreased by approximately 20%, and latent heat values increased accordingly.
2. Also see Table 4, Chapter 9, for additional rates of metabolic heat generation.
3. All values are rounded to nearest 5 Btu/h.
- ^aAdjusted heat gain is based on normal percentage of men, women, and children for the application listed, and assumes that gain from an adult female is

- 85% of that for an adult male, and gain from a child is 75% of that for an adult male.
- ^bValues approximated from data in Table 6, Chapter 9, where *V* is air velocity with limits shown in that table.
- ^cAdjusted heat gain includes 60 Btu/h for food per individual (30 Btu/h sensible and 30 Btu/h latent).
- ^dFigure one person per alley actually bowling, and all others as sitting (400 Btu/h) or standing or walking slowly (550 Btu/h).

The **total light wattage** is obtained from the ratings of all lamps installed, both for general illumination and for display use. Ballasts are not included, but are addressed by a separate factor. Wattages of magnetic ballasts are significant; the energy consumption of high-efficiency electronic ballasts might be insignificant compared to that of the lamps.

The **lighting use factor** is the ratio of wattage in use, for the conditions under which the load estimate is being made, to total installed wattage. For commercial applications such as stores, the use factor is generally 1.0.

The **special allowance factor** is the ratio of the lighting fixtures' power consumption, including lamps and ballast, to the nominal power consumption of the lamps. For incandescent lights, this factor is 1. For fluorescent lights, it accounts for power consumed by the ballast as well as the ballast's effect on lamp power consumption. The special allowance factor can be less than 1 for electronic ballasts that lower electricity consumption below the lamp's rated power consumption. Use manufacturers' values for system (lamps + ballast) power, when available.

For high-intensity-discharge lamps (e.g. metal halide, mercury vapor, high- and low-pressure sodium vapor lamps), the actual lighting system power consumption should be available from the manufacturer of the fixture or ballast. Ballasts available for metal halide and high pressure sodium vapor lamps may have special allowance factors from about 1.3 (for low-wattage lamps) down to 1.1 (for high-wattage lamps).

An alternative procedure is to estimate the lighting heat gain on a per square foot basis. Such an approach may be required when final lighting plans are not available. Table 2 shows the maximum lighting power density (LPD) (lighting heat gain per square foot) allowed by ASHRAE *Standard* 90.1-2007 for a range of space types.

In addition to determining the lighting heat gain, the fraction of lighting heat gain that enters the conditioned space may need to be distinguished from the fraction that enters an unconditioned space; of the former category, the distribution between radiative and convective heat gain must be established.

Fisher and Chantrasrisalai (2006) experimentally studied 12 luminaire types and recommended five different categories of luminaires,

as shown in Table 3. The table provides a range of design data for the conditioned space fraction, short-wave radiative fraction, and long-wave radiative fraction under typical operating conditions: airflow rate of 1 cfm/ft², supply air temperature between 59 and 62°F, and room air temperature between 72 and 75°F. The recommended fractions in Table 3 are based on lighting heat input rates range of 0.9 to 2.6 W/ft². For higher design power input, the lower bounds of the space and short-wave fractions should be used; for design power input below this range, the upper bounds of the space and short-wave fractions should be used. The **space fraction** in the table is the fraction of lighting heat gain that goes to the room; the fraction going to the plenum can be computed as 1 – the space fraction. The **radiative fraction** is the radiative part of the lighting heat gain that goes to the room. The convective fraction of the lighting heat gain that goes to the room is 1 – the radiative fraction. Using values in the middle of the range yields sufficiently accurate results. However, values that better suit a specific situation may be determined according to the notes for Table 3.

Table 3's data are applicable for both ducted and nonducted returns. However, application of the data, particularly the ceiling plenum fraction, may vary for different return configurations. For instance, for a room with a ducted return, although a portion of the lighting energy initially dissipated to the ceiling plenum is quantitatively equal to the plenum fraction, a large portion of this energy would likely end up as the conditioned space cooling load and a small portion would end up as the cooling load to the return air.

If the space airflow rate is different from the typical condition (i.e., about 1 cfm/ft²), Figure 3 can be used to estimate the lighting heat gain parameters. Design data shown in Figure 3 are only applicable for the recessed fluorescent luminaire without lens.

Although design data presented in Table 3 and Figure 3 can be used for a vented luminaire with side-slot returns, they are likely not applicable for a vented luminaire with lamp compartment returns, because in the latter case, all heat convected in the vented luminaire is likely to go directly to the ceiling plenum, resulting in zero convective fraction and a much lower space fraction. Therefore, the design data should only be used for a configuration where conditioned air is returned through the ceiling grille or luminaire side slots.

*In cases where both a common space type and a building-specific type are listed, the building-specific space type applies.

For other luminaire types, it may be necessary to estimate the heat gain for each component as a fraction of the total lighting heat gain by using judgment to estimate heat-to-space and heat-to-return percentages.

Because of the directional nature of downlight luminaires, a large portion of the short-wave radiation typically falls on the floor. When converting heat gains to cooling loads in the RTS method, the solar radiant time factors (RTF) may be more appropriate than non-solar RTF. (Solar RTF are calculated assuming most solar radiation is intercepted by the floor; nonsolar RTF assume uniform distribution by area over all interior surfaces.) This effect may be significant for rooms where lighting heat gain is high and for which solar RTF are significantly different from nonsolar RTF.

ELECTRIC MOTORS

Instantaneous sensible heat gain from equipment operated by electric motors in a conditioned space is calculated as

$$q_{em} = 2545(P/E_M)F_{UM}F_{LM} \tag{2}$$

where

- q_{em} = heat equivalent of equipment operation, Btu/h
- P = motor power rating, hp
- E_M = motor efficiency, decimal fraction <1.0
- F_{UM} = motor use factor, 1.0 or decimal fraction <1.0
- F_{LM} = motor load factor, 1.0 or decimal fraction <1.0
- 2545 = conversion factor, Btu/h·hp

Fig. 3 Lighting Heat Gain Parameters for Recessed Fluorescent Luminaire Without Lens
(Fisher and Chantrasrisalai 2006)

Table 3 Lighting Heat Gain Parameters for Typical Operating Conditions

Luminaire Category	Space Fraction	Radiative Fraction	Notes
Recessed fluorescent luminaire without lens	0.64 to 0.74	0.48 to 0.68	<ul style="list-style-type: none"> • Use middle values in most situations • May use higher space fraction, and lower radiative fraction for luminaire with side-slot returns • May use lower values of both fractions for direct/indirect luminaire • May use higher values of both fractions for ducted returns
Recessed fluorescent luminaire with lens	0.40 to 0.50	0.61 to 0.73	<ul style="list-style-type: none"> • May adjust values in the same way as for recessed fluorescent luminaire without lens
Downlight compact fluorescent luminaire	0.12 to 0.24	0.95 to 1.0	<ul style="list-style-type: none"> • Use middle or high values if detailed features are unknown • Use low value for space fraction and high value for radiative fraction if there are large holes in luminaire's reflector
Downlight incandescent luminaire	0.70 to 0.80	0.95 to 1.0	<ul style="list-style-type: none"> • Use middle values if lamp type is unknown • Use low value for space fraction if standard lamp (i.e. A-lamp) is used • Use high value for space fraction if reflector lamp (i.e. BR-lamp) is used
Non-in-ceiling fluorescent luminaire	1.0	0.5 to 0.57	<ul style="list-style-type: none"> • Use lower value for radiative fraction for surface-mounted luminaire • Use higher value for radiative fraction for pendant luminaire

The motor use factor may be applied when motor use is known to be intermittent, with significant nonuse during all hours of operation (e.g., overhead door operator). For conventional applications, its value is 1.0.

The motor load factor is the fraction of the rated load delivered under the conditions of the cooling load estimate. In Equation (2), it is assumed that both the motor and driven equipment are in the conditioned space. If the motor is outside the space or airstream,

$$q_{em} = 2545PF_{UM}F_{LM} \tag{3}$$

When the motor is inside the conditioned space or airstream but the driven machine is outside,

$$q_{em} = 2545P\left(\frac{1.0 - E_M}{E_M}\right)F_{UM}F_{LM} \tag{4}$$

Equation (4) also applies to a fan or pump in the conditioned space that exhausts air or pumps fluid outside that space.

Table 4 gives minimum efficiencies and related data representative of typical electric motors from ASHRAE Standard 90.1-2007. If electric motor load is an appreciable portion of cooling load, the motor efficiency should be obtained from the manufacturer. Also, depending on design, maximum efficiency might occur anywhere between 75 to 110% of full load; if under- or overloaded, efficiency could vary from the manufacturer's listing.

Overloading or Underloading

Heat output of a motor is generally proportional to motor load, within rated overload limits. Because of typically high no-load motor current, fixed losses, and other reasons, F_{LM} is generally assumed to be unity, and no adjustment should be made for underloading or overloading unless the situation is fixed and can be accurately established, and reduced-load efficiency data can be obtained from the motor manufacturer.

Radiation and Convection

Unless the manufacturer's technical literature indicates otherwise, motor heat gain normally should be equally divided between radiant and convective components for the subsequent cooling load calculations.

APPLIANCES

A cooling load estimate should take into account heat gain from all appliances (electrical, gas, or steam). Because of the variety of appliances, applications, schedules, use, and installations, estimates can be very subjective. Often, the only information available about

heat gain from equipment is that on its nameplate, which can overestimate actual heat gain for many types of appliances, as discussed in the section on Office Equipment.

Cooking Appliances

These appliances include common heat-producing cooking equipment found in conditioned commercial kitchens. Marn (1962) concluded that appliance surfaces contributed most of the heat to commercial kitchens and that when appliances were installed under an effective hood, the cooling load was independent of the fuel or energy used for similar equipment performing the same operations.

Gordon et al. (1994) and Smith et al. (1995) found that gas appliances may exhibit slightly higher heat gains than their electric counterparts under wall-canopy hoods operated at typical ventilation rates. This is because heat contained in combustion products exhausted from a gas appliance may increase the temperatures of the appliance and surrounding surfaces, as well as the hood above the appliance, more so than the heat produced by its electric counterpart. These higher-temperature surfaces radiate heat to the kitchen, adding moderately to the radiant gain directly associated with the appliance cooking surface.

Marn (1962) confirmed that, where appliances are installed under an effective hood, only radiant gain adds to the cooling load; convective and latent heat from cooking and combustion products are exhausted and do not enter the kitchen. Gordon et al. (1994) and Smith et al. (1995) substantiated these findings. Chapter 31 of the 2007 ASHRAE Handbook—HVAC Applications has more information on kitchen ventilation.

Sensible Heat Gain for Hooded Cooking Appliances. To establish a heat gain value, nameplate energy input ratings may be used with appropriate usage and radiation factors. Where specific rating data are not available (nameplate missing, equipment not yet purchased, etc.), representative heat gains listed in Tables 5A to E (Swierczyna et al. 2008, 2009) for a wide variety of commonly encountered equipment items. In estimating appliance load, probabilities of simultaneous use and operation for different appliances located in the same space must be considered.

Radiant heat gain from hooded cooking equipment can range from 15 to 45% of the actual appliance energy consumption (Gordon et al. 1994; Smith et al. 1995; Swierczyna et al. 2008; Talbert et al. 1973). This ratio of heat gain to appliance energy consumption may be expressed as a radiation factor, and it is a function of both appliance type and fuel source. The radiation factor F_R is applied to the average rate of appliance energy consumption, determined by applying usage factor F_U to the nameplate or rated energy input. Marn (1962) found that radiant heat temperature rise can be substantially reduced by shielding the fronts of cooking appliances. Although this approach may not always be practical in a commercial kitchen, radiant gains can also be reduced by adding side panels or partial enclosures that are integrated with the exhaust hood.

Heat Gain from Meals. For each meal served, approximately 50 Btu/h of heat, of which 75% is sensible and 25% is latent, is transferred to the dining space.

Heat Gain for Generic Appliances. The average rate of appliance energy consumption can be estimated from the nameplate or rated energy input q_{input} by applying a duty cycle or usage factor F_U . Thus, sensible heat gain q_s for generic electric, steam, and gas appliances installed under a hood can be estimated using one of the following equations:

$$q_s = q_{input} F_U F_R \tag{5}$$

or

$$q_s = q_{input} F_L \tag{6}$$

where F_L is the ratio of sensible heat gain to the manufacturer's rated energy input. However, recent ASHRAE research (Swierczyna et al. 2008, 2009) showed the design value for heat gain from a hooded appliance at idle (ready-to-cook) conditions based on its energy consumption rate is, at best, a rough estimate. When appliance heat gain measurements during idle conditions were regressed against energy consumption rates for gas and electric appliances, the appliances' emissivity, insulation, and surface cooling (e.g., through ventilation rates) scattered the data points widely, with large deviations from the average values. Because large errors could occur in the heat load calculation for specific appliance lines by using a general radiation factor, heat gain values in Table 5 should be applied in the HVAC design.

Table 5 lists usage factors, radiation factors, and load factors based on appliance energy consumption rate for typical electrical, steam, and gas appliances under standby or idle conditions, hooded and unhooded.

Recirculating Systems. Cooking appliances ventilated by recirculating systems or "ductless" hoods should be treated as unhooded appliances when estimating heat gain. In other words, all energy consumed by the appliance and all moisture produced by cooking is introduced to the kitchen as a sensible or latent cooling load.

Recommended Heat Gain Values. Table 5 lists recommended rates of heat gain from typical commercial cooking appliances. Data in the "hooded" columns assume installation under a properly designed exhaust hood connected to a mechanical fan exhaust system operating at an exhaust rate for complete capture and containment of the thermal and effluent plume. Improperly operating hood systems load the space with a significant convective component of the heat gain.

Table 5A Recommended Rates of Radiant and Convective Heat Gain from Unhooded Electric Appliances During Idle (Ready-to-Cook) Conditions

Appliance	Energy Rate, Btu/h		Rate of Heat Gain, Btu/h				Usage Factor F_u	Radiation Factor F_r

Hospital and Laboratory Equipment

Hospital and laboratory equipment items are major sources of sensible and latent heat gains in conditioned spaces. Care is needed in evaluating the probability and duration of simultaneous usage when many components are concentrated in one area, such as a laboratory, an operating room, etc. Commonly, heat gain from equipment in a laboratory ranges from 15 to 70 Btu/h·ft² or, in laboratories with outdoor exposure, as much as four times the heat gain from all other sources combined.

Medical Equipment. It is more difficult to provide generalized heat gain recommendations for medical equipment than for general office equipment because medical equipment is much more varied in type and in application. Some heat gain testing has been done, but the equipment included represents only a small sample of the type of equipment that may be encountered.

Data presented for medical equipment in Table 6 are relevant for portable and bench-top equipment. Medical equipment is very specific and can vary greatly from application to application. The data are presented to provide guidance in only the most general sense. For large equipment, such as MRI, heat gain must be obtained from the manufacturer.

Laboratory Equipment. Equipment in laboratories is similar to medical equipment in that it varies significantly from space to space. Chapter 14 of the 2007 *ASHRAE Handbook—HVAC Applications* discusses heat gain from equipment, which may range from 5 to 25 W/ft² in highly automated laboratories. Table 7 lists some values for laboratory equipment, but, with medical equipment, it is for general guidance only. Wilkins and Cook (1999) also examined laboratory equipment heat gains.

Office Equipment

Computers, printers, copiers, etc., can generate very significant heat gains, sometimes greater than all other gains combined. ASHRAE research project RP-822 developed a method to measure the actual heat gain from equipment in buildings and the radiant/convective percentages (Hosni et al. 1998; Jones et al. 1998). This methodology was then incorporated into ASHRAE research project RP-1055 and applied to a wide range of equipment (Hosni et al. 1999) as a follow-up to independent research by Wilkins and McGaffin (1994) and Wilkins et al. (1991). Komor (1997) found similar results. Analysis of measured data showed that results for office equipment could be generalized, but results from laboratory and hospital equipment proved too diverse. The following general guidelines for office equipment are a result of these studies.

Nameplate Versus Measured Energy Use. Nameplate data rarely reflect the actual power consumption of office equipment. Actual power consumption is assumed to equal total (radiant plus convective) heat gain, but its ratio to the nameplate value varies widely. ASHRAE research project RP-1055 (Hosni et al. 1999) found that, for general office equipment with nameplate power consumption of less than 1000 W, the actual ratio of total heat gain to nameplate ranged from 25% to 50%, but when all tested equipment is considered, the range is broader. Generally, if the nameplate value is the only information known and no actual heat gain data are available for similar equipment, it is conservative to use 50% of nameplate as heat gain and more nearly correct if 25% of nameplate is used. Much better results can be obtained, however, by considering heat gain to be predictable based on the type of equipment. However, if the device has a mainly resistive internal electric load (e.g.,

a space heater), the nameplate rating may be a good estimate of its peak energy dissipation.

Computers. Based on tests by Hosni et al. (1999) and Wilkins and McGaffin (1994), nameplate values on computers should be ignored when performing cooling load calculations. Table 8 presents typical heat gain values for computers with varying degrees of safety factor.

Monitors. Based on monitors tested by Hosni et al. (1999), heat gain for cathode ray tube (CRT) monitors correlates approximately with screen size as

$$q_{mon} = 5S - 20 \quad (7)$$

where

q_{mon} = sensible heat gain from monitor, W
 S = nominal screen size, in.

Table 8 shows typical values.

Flat-panel monitors have replaced CRT monitors in many workplaces. Power consumption, and thus heat gain, for flat-panel displays are significantly lower than for CRTs. Consult manufacturers' literature for average power consumption data for use in heat gain calculations.

Laser Printers. Hosni et al. (1999) found that power consumption, and therefore the heat gain, of laser printers depended largely on the level of throughput for which the printer was designed. Smaller printers tend to be used more intermittently, and larger printers may run continuously for longer periods.

Table 9 presents data on laser printers. These data can be applied by taking the value for continuous operation and then applying an appropriate diversity factor. This would likely be most appropriate for larger open office areas. Another approach, which may be appropriate for a single room or small area, is to take the value that most closely matches the expected operation of the printer with no diversity.

Copiers. Hosni et al. (1999) also tested five photocopy machines, including desktop and office (freestanding high-volume copiers) models. Larger machines used in production environments were not addressed. Table 9 summarizes the results. Desktop copiers rarely operate continuously, but office copiers frequently operate continuously for periods of an hour or more. Large, high-volume photocopiers often include provisions for exhausting air outdoors; if so equipped, the direct-to-space or system makeup air heat gain needs to be included in the load calculation. Also, when the air is dry, humidifiers are often operated near copiers to limit static electricity; if this occurs during cooling mode, their load on HVAC systems should be considered.

Miscellaneous Office Equipment. Table 10 presents data on miscellaneous office equipment such as vending machines and mailing equipment.

Diversity. The ratio of measured peak electrical load at equipment panels to the sum of the maximum electrical load of each individual item of equipment is the usage diversity. A small, one- or two-person office containing equipment listed in Tables 8 to 10 usually contributes heat gain to the space at the sum of the appropriate listed values. Progressively larger areas with many equipment items always experience some degree of usage diversity resulting from whatever percentage of such equipment is not in operation at any given time.

Wilkins and McGaffin (1994) measured diversity in 23 areas within five different buildings totaling over 275,000 ft². Diversity was found to range between 37 and 78%, with the average (normalized based on area) being 46%. Figure 4 illustrates the relationship between nameplate, sum of peaks, and actual electrical load with diversity accounted for, based on the average of the total area tested. Data on actual diversity can be used as a guide, but diversity varies

significantly with occupancy. The proper diversity factor for an office of mail-order catalog telephone operators is different from that for an office of sales representatives who travel regularly.

ASHRAE research project RP-1093 derived diversity profiles for use in energy calculations (Abushakra et al. 2004; Claridge et al. 2004). Those profiles were derived from available measured data sets for a variety of office buildings, and indicated a range of peak weekday diversity factors for lighting ranging from 70 to 85% and for receptacles (appliance load) between 42 and 89%.

Heat Gain per Unit Area. Wilkins and Hosni (2000) and Wilkins and McGaffin (1994) summarized research on a heat gain per unit area basis. Diversity testing showed that the actual heat gain per unit area, or load factor, ranged from 0.44 to 1.08 W/ft², with an average

Fig. 4 Office Equipment Load Factor Comparison (Wilkins and McGaffin 1994)

(normalized based on area) of 0.81 W/ft². Spaces tested were fully occupied and highly automated, comprising 21 unique areas in five buildings, with a computer and monitor at every workstation. Table 11 presents a range of load factors with a subjective description of the type of space to which they would apply. Table 12 presents more specific data that can be used to better quantify the amount of equipment in a space and expected load factor. The medium load density is likely to be appropriate for most standard office spaces. Medium/heavy or heavy load densities may be encountered but can

be considered extremely conservative estimates even for densely populated and highly automated spaces.

Radiant Convective Split. ASHRAE research project RP-1482 (Hosni and Beck 2008) is examining the radiant/convective split for common office equipment; the most important differentiating feature is whether the equipment had a cooling fan. Footnotes in Tables 8 and 9 summarizes those results.

INFILTRATION AND MOISTURE MIGRATION HEAT GAINS

Two other load components contribute to space cooling load directly without time delay from building mass: (1) infiltration, and (2) moisture migration through the building envelope.

INFILTRATION

Principles of estimating infiltration in buildings, with emphasis on the heating season, are discussed in Chapter 16. When economically feasible, somewhat more outdoor air should be introduced to a building than the total of that exhausted, to create a slight overall positive pressure in the building relative to the outdoors. Under

these conditions, air usually exfiltrates, rather than infiltrates, through the building envelope and thus effectively eliminates infiltration sensible and latent heat gains. However, there is concern, especially in some climates, that water may condense within the building envelope; actively managing space air pressures to reduce this condensation problem, as well as infiltration, may be needed.

When positive air pressure is assumed, most designers do not include infiltration in cooling load calculations for commercial buildings. However, including some infiltration for spaces such entry areas or loading docks may be appropriate, especially when those spaces are on the windward side of buildings. But the downward stack effect, as occurs when indoor air is denser than the outdoor,

^aPower consumption for newer desktop computers in operational mode varies from 50 to 100 W, but a conservative value of about 65 W may be used. Power consumption in sleep mode is negligible. Because of cooling fan, approximately 90% of load is by convection and 10% is by radiation. Actual power consumption is about 10 to 15% of nameplate value.

^bPower consumption of laptop computers is relatively small: depending on processor speed and screen size, it varies from about 15 to 40 W. Thus, differentiating between radiative and convective parts of the cooling load is unnecessary and the entire load may be classified as convective. Otherwise, a 75/25% split between convective and radiative components may be used. Actual power consumption for laptops is about 25% of nameplate values.

^cFlat-panel monitors have replaced cathode ray tube (CRT) monitors in many workplaces, providing better resolution and being much lighter. Power consumption depends on size and resolution, and ranges from about 20 W (for 15 in. size) to 90 W (for 30 in.). The most common sizes in workplaces are 19 and 22 in., for which an average 30 W power consumption value may be used. Use 60/40% split between convective and radiative components. In idle mode, monitors have negligible power consumption. Nameplate values should not be used.

Source: Hosni and Beck (2008).

^aVarious laser printers commercially available and commonly used in personal offices were tested for power consumption in print mode, which varied from 75 to 140 W, depending on model, print capacity, and speed. Average power consumption of 110 W may be used. Split between convection and radiation is approximately 70/30%.

^bSmall multifunction (copy, scan, print) systems use about 15 to 30 W; medium-sized ones use about 135 W. Power consumption in idle mode is negligible.

Nameplate values do not represent actual power consumption and should not be used. Small, single-sheet scanners consume less than 20 W and do not contribute significantly to building cooling load.

^cPower consumption for large copy machines in large offices and copy centers ranges from about 550 to 1100 W in copy mode. Consumption in idle mode varies from about 130 to 300 W. Count idle-mode power consumption as mostly convective in cooling load calculations.

might eliminate infiltration to these entries on lower floors of tall buildings; infiltration may occur on the upper floors during cooling conditions if makeup air is not sufficient.

Infiltration also depends on wind direction and magnitude, temperature differences, construction type and quality, and occupant

use of exterior doors and operable windows. As such, it is impossible to accurately predict infiltration rates. Designers usually predict overall rates of infiltration using the number of **air changes per hour (ach)**. A common guideline for climates and buildings typical of at least the central United States is to estimate the achs for winter

heating conditions, and then use half that value for the cooling load calculations.

Standard Air Volumes

Because the specific volume of air varies appreciably, calculations are more accurate when made on the basis of air mass instead of volume. However, volumetric flow rates are often required for selecting coils, fans, ducts, etc.; basing volumes on measurement at standard conditions may be used for accurate results. One standard value is 0.075 lb_{da}/ft³ (13.33 ft³/lb). This density corresponds to about 60°F at saturation and 69°F dry air (at 14.696 psia). Because

air usually passes through the equipment at a density close to standard for locations below about 1000 ft, the accuracy desired normally requires no correction. When airflow is to be measured at a particular condition or point, such as at a coil entrance or exit, the corresponding specific volume can be read from the sea-level psychrometric chart. For higher elevations, the mass flow rates of air must be adjusted and higher-elevation psychrometric charts or algorithms must be used.

Heat Gain Calculations Using Standard Air Values

Air-conditioning design often requires the following information:

1. Total heat

Total heat gain q_t corresponding to the change of a given standard flow rate Q_s through an enthalpy difference Δh is

$$q_t = 60 \times 0.075 Q_s \Delta h = 4.5 Q_s \Delta h \tag{8}$$

where 60 = min/h, 0.075 = lb_{da}/ft³.

This total heat equation can also be expressed as

$$q_t = C_t Q_s \Delta h$$

where $C_t = 4.5$ is the air total heat factor, in Btu/h·cfm per Btu/lb enthalpy h .

2. Sensible heat

Sensible heat gain q_s corresponding to the change of dry-bulb temperature Δt for given airflow (standard conditions) Q_s is

$$q_s = 60 \times 0.075(0.24 + 0.45W)Q_s \Delta t \quad (9)$$

where

0.24 = specific heat of dry air, Btu/lb·°F

W = humidity ratio, lb_w/lb_{da}

0.45 = specific heat of water vapor, Btu/lb·°F

The specific heats are for a range from about -100 to 200°F. When $W = 0$, the value of $60 \times 0.075(0.24 + 0.45W) = 1.08$; when $W = 0.01$, the value is 1.10; when $W = 0.02$, the value is 1.12; and when $W = 0.03$, the value is 1.14. Because a value of $W = 0.01$ approximates conditions found in many air-conditioning problems, the sensible heat change (in Btu/h) has traditionally been found as

$$q_s = 1.10Q_s \Delta t \quad (10)$$

This sensible heat equation can also be expressed as

$$q_s = C_s Q_s \Delta t$$

where $C_s = 1.1$ is the air sensible heat factor, in Btu/h·cfm·°F.

3. Latent heat

Latent heat gain q_l corresponding to the change of humidity ratio ΔW (in lb_{m,w}/lb_{m,da}) for given airflow (standard conditions) Q_s is

$$q_l = 60 \times 0.075 \times 1076 Q_s \Delta W = 4840 Q_s \Delta W \quad (11)$$

where 1076 Btu/lb is the approximate heat content of 50% rh vapor at 75°F less the heat content of water at 50°F. A common design condition for the space is 50% rh at 75°F, and 50°F is normal condensate temperature from cooling and dehumidifying coils.

This latent heat equation can also be expressed as

$$q_l = C_l Q_s \Delta W$$

where $C_l = 4840$ is the air latent heat factor, in Btu/h·cfm. When ΔW is in gr_w/lb_{m,da}, $C_l = 0.69$ Btu/h·cfm.

4. Altitude correction for total, sensible, and latent heat equations

The constants 4.5, 1.10, and 4840 are useful in air-conditioning calculations at sea level (14.696 psia) and for normal temperatures and moisture ratios. For other conditions, more precise values should be used. For an altitude of 5000 ft (12.2 psia), appropriate values are 3.74, 0.92, and 4027. Equations (9) to (11) can be corrected for altitudes other than sea level by multiplying them by the ratio of pressure at sea level divided by the pressure at actual altitude. This can be derived from Equation (3) in Chapter 1 as

$$C_{x,alt} = C_{x,0} P/P_0$$

where $C_{x,0}$ is any of the sea-level C values and $P/P_0 = [1 - \text{elevation} \times (6.8754 \times 10^{-6})]^{5.2559}$, where elevation is in feet.

LATENT HEAT GAIN FROM MOISTURE DIFFUSION

Diffusion of moisture through building materials is a natural phenomenon that is always present. Chapters 25 to 27 cover principles, materials, and specific methods used to control moisture. Moisture transfer through walls and roofs is often neglected in comfort air conditioning because the actual rate is quite small and the corresponding latent heat gain is insignificant. Permeability and permeance values for various building materials are given in Chapter 26. Vapor retarders should be specified and installed in the proper location to keep moisture transfer to a minimum, and to minimize condensation within the envelope. Moisture migration up through slabs-on-grade and basement floors has been found to be significant, but has historically not been addressed in cooling load calculations. Under-slab continuous moisture retarders and drainage can reduce upward moisture flow.

Some industrial applications require low moisture to be maintained in a conditioned space. In these cases, the latent heat gain accompanying moisture transfer through walls and roofs may be greater than any other latent heat gain. This gain is computed by

$$q_{l_m} = (M/7000)A\Delta p_v(h_g - h_f) \quad (12)$$

where

q_{l_m} = latent heat gain from moisture transfer, Btu/h

M = permeance of wall or roof assembly, perms or grains/(ft²·h·in. Hg)

7000 = grains/lb

A = area of wall or roof surface, ft²

Δp_v = vapor pressure difference, in. Hg

h_g = enthalpy at room conditions, Btu/lb

h_f = enthalpy of water condensed at cooling coil, Btu/lb

$h_g - h_f = 1076$ Btu/lb when room temperature is 75°F and condensate off coil is 50°F

OTHER LATENT LOADS

Moisture sources within a building (e.g., shower areas, swimming pools or natatoriums, arboretums) can also contribute to latent load. Unlike sensible loads, which correlate to supply air quantities required in a space, latent loads usually only affect cooling coils sizing or refrigeration load. Because air from showers and some other moisture-generating areas is exhausted completely, those airborne latent loads do not reach the cooling coil and thus do not contribute to cooling load. However, system loads associated with ventilation air required to make up exhaust air must be recognized, and any recirculated air's moisture must be considered when sizing the dehumidification equipment.

For natatoriums, occupant comfort and humidity control are critical. In many instances, size, location, and environmental requirements make complete exhaust systems expensive and ineffective. Where recirculating mechanical cooling systems are used, evaporation (latent) loads are significant. Chapter 4 of the 2007 *ASHRAE Handbook—HVAC Applications* provides guidance on natatorium load calculations.

FENESTRATION HEAT GAIN

For spaces with neutral or positive air pressurization, the primary weather-related variable affecting cooling load is solar radiation. The effect of solar radiation is more pronounced and immediate on exposed, nonopaque surfaces. Chapter 14 includes procedures for calculating clear-sky solar radiation intensity and incidence angles for weather conditions encountered at specific locations. That chapter also includes some useful solar equations. Calculation of solar heat gain and conductive heat transfer through various glazing materials and associated mounting frames, with or without interior and/or exterior shading devices, is discussed in Chapter 15. This chapter covers application of such data to overall heat gain evaluation, and conversion of calculated heat gain into a composite cooling load for the conditioned space.

FENESTRATION DIRECT SOLAR, DIFFUSE SOLAR, AND CONDUCTIVE HEAT GAINS

For fenestration heat gain, use the following equations:

Direct beam solar heat gain q_b :

$$q_b = AE_{t,b} \text{SHGC}(\theta) \text{IAC}(\theta, \Omega) \quad (13)$$

Diffuse solar heat gain q_d :

$$q_d = A(E_{t,d} + E_{t,r}) \text{SHGC}_D \text{IAC}_D \quad (14)$$

Conductive heat gain q_c :

$$q_c = UA(T_{out} - T_{in}) \quad (15)$$

Total fenestration heat gain Q :

$$Q = q_b + q_d + q_c \quad (16)$$

where

- A = window area, ft²
- $E_{t,b}$, $E_{t,d}$, and $E_{t,r}$ = beam, sky diffuse, and ground-reflected diffuse irradiance, calculated using equations in Chapter 14
- SHGC(θ) = beam solar heat gain coefficient as a function of incident angle θ ; may be interpolated between values in Table 10 of Chapter 15
- $\langle \text{SHGC} \rangle_D$ = diffuse solar heat gain coefficient (also referred to as hemispherical SHGC); from Table 10 of Chapter 15
- T_{in} = inside temperature, °F
- T_{out} = outside temperature, °F
- U = overall U-factor, including frame and mounting orientation from Table 4 of Chapter 15, Btu/h·ft²·°F
- IAC(θ, Ω) = indoor solar attenuation coefficient for beam solar heat gain coefficient; = 1.0 if no inside shading device. IAC(θ, Ω) is a function of shade type and, depending on type, may also be a function of beam solar angle of incidence θ and shade geometry
- IAC_D = indoor solar attenuation coefficient for diffuse solar heat gain coefficient; = 1.0 if not inside shading device. IAC_D is a function of shade type and, depending on type, may also be a function of shade geometry

If specific window manufacturer's SHGC and U-factor data are available, those should be used. For fenestration equipped with inside shading (blinds, drapes, or shades), the indoor solar attenuation coefficients IAC(θ, Ω) and IAC_D are listed in Tables 13A to 13G of Chapter 15.

Note that, as discussed in Chapter 15, fenestration ratings (U-factor and SHGC) are based on the entire product area, including frames. Thus, for load calculations, fenestration area is the area of the entire opening in the wall or roof.

EXTERIOR SHADING

Nonuniform exterior shading, caused by roof overhangs, side fins, or building projections, requires separate hourly calculations for the externally shaded and unshaded areas of the window in question, with the inside shading SHGC still used to account for any internal shading devices. The areas, shaded and unshaded, depend on the location of the shadow line on a surface in the plane of the glass. Sun (1968) developed fundamental algorithms for analysis of shade patterns. McQuiston and Spitler (1992) provide graphical data to facilitate shadow line calculation.

Equations for calculating shade angles [Chapter 15, Equations (39) to (42)] can be used to determine the shape and area of a moving shadow falling across a given window from external shading elements during the course of a design day. Thus, a subprofile of heat gain for that window can be created by separating its sunlit and shaded areas for each hour.

HEAT BALANCE METHOD

Cooling load estimation involves calculating a surface-by-surface conductive, convective, and radiative heat balance for each room surface and a convective heat balance for the room air. These principles form the foundation for all methods described in this chapter. The heat balance (HB) method solves the problem directly instead of introducing transformation-based procedures. The advantages are that it contains no arbitrarily set parameters, and no processes are hidden from view.

Some computations required by this rigorous approach require the use of computers. The heat balance procedure is not new. Many energy calculation programs have used it in some form for many years. The first implementation that incorporated all the elements to

form a complete method was NBSLD (Kusuda 1967). The heat balance procedure is also implemented in both the BLAST and TARP energy analysis programs (Walton 1983). Before ASHRAE research project RP-875, the method had never been described completely or in a form applicable to cooling load calculations. The papers resulting from RP-875 describe the heat balance procedure in detail (Liesen and Pedersen 1997; McClellan and Pedersen 1997; Pedersen et al. 1997).

The HB method is codified in the software called Hbfort that accompanies Cooling and Heating Load Calculation Principles (Pedersen et al. 1998).

ASHRAE research project RP-1117 constructed two model rooms for which cooling loads were physically measured using extensive instrumentation (Chantrasrisalai et al. 2003; Eldridge et al. 2003; Lu et al. 2003). HB calculations closely approximated measured cooling loads when provided with detailed data for the test rooms.

ASSUMPTIONS

All calculation procedures involve some kind of model; all models require simplifying assumptions and, therefore, are approximate. The most fundamental assumption is that air in the thermal zone can be modeled as **well mixed**, meaning its temperature is uniform throughout the zone. ASHRAE research project RP-664 (Fisher and Pedersen 1997) established that this assumption is valid over a wide range of conditions.

The next major assumption is that the surfaces of the room (walls, windows, floor, etc.) can be treated as having

- Uniform surface temperatures
- Uniform long-wave (LW) and short-wave (SW) irradiation
- Diffuse radiating surfaces
- One-dimensional heat conduction within

The resulting formulation is called the **heat balance (HB) model**. Note that the assumptions, although common, are quite restrictive and set certain limits on the information that can be obtained from the model.

ELEMENTS

Within the framework of the assumptions, the HB can be viewed as four distinct processes:

1. Outside-face heat balance
2. Wall conduction process
3. Inside-face heat balance
4. Air heat balance

Figure 5 shows the relationship between these processes for a single opaque surface. The top part of the figure, inside the shaded box, is repeated for each surface enclosing the zone. The process for transparent surfaces is similar, but the absorbed solar component appears in the conduction process block instead of at the outside face, and the absorbed component splits into inward- and outward-flowing fractions. These components participate in the surface heat balances.

Outside-Face Heat Balance

The heat balance on the outside face of each surface is

$$q''_{asol} + q''_{LWR} + q''_{conv} - q''_{ko} = 0 \quad (17)$$

where

- q''_{asol} = absorbed direct and diffuse solar radiation flux (q/A), Btu/h·ft²
- q''_{LWR} = net long-wave radiation flux exchange with air and surroundings, Btu/h·ft²
- q''_{conv} = convective exchange flux with outside air, Btu/h·ft²
- q''_{ko} = conductive flux (q/A) into wall, Btu/h·ft²

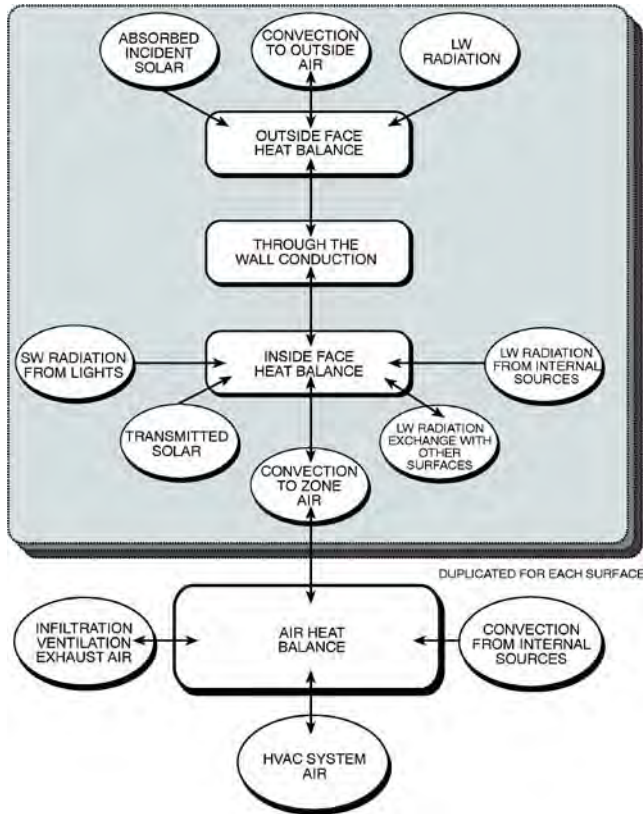

Fig. 5 Schematic of Heat Balance Processes in Zone

All terms are positive for net flux to the face except q''_{ko} , which is traditionally taken to be positive from outside to inside the wall.

Each term in Equation (17) has been modeled in several ways, and in simplified methods the first three terms are combined by using the sol-air temperature.

Wall Conduction Process

The wall conduction process has been formulated in more ways than any of the other processes. Techniques include

- Numerical finite difference
- Numerical finite element
- Transform methods
- Time series methods

This process introduces part of the time dependence inherent in load calculation. Figure 6 shows surface temperatures on the inside and outside faces of the wall element, and corresponding conductive heat fluxes away from the outside face and toward the inside face. All four quantities are functions of time. Direct formulation of the process uses temperature functions as input or known quantities, and heat fluxes as outputs or resultant quantities.

In some models, surface heat transfer coefficients are included as part of the wall element, making the temperatures in question the inside and outside air temperatures. This is not a desirable formulation, because it hides the heat transfer coefficients and prohibits changing them as airflow conditions change. It also prohibits treating the internal long-wave radiation exchange appropriately.

Because heat balances on both sides of the element induce both the temperature and heat flux, the solution must deal with this simultaneous condition. Two computational methods that have been used widely are finite difference and conduction transfer function methods. Because of the computational time advantage, the conduction

Fig. 6 Schematic of Wall Conduction Process

transfer function formulation has been selected for presentation here.

Inside-Face Heat Balance

The heart of the HB method is the internal heat balance involving the inside faces of the zone surfaces. This heat balance has many heat transfer components, and they are all coupled. Both long-wave (LW) and short-wave (SW) radiation are important, as well as wall conduction and convection to the air. The inside face heat balance for each surface can be written as follows:

$$q''_{LWX} + q''_{SW} + q''_{LWS} + q''_{ki} + q''_{sol} + q''_{conv} = 0 \quad (18)$$

where

q''_{LWX} = net long-wave radiant flux exchange between zone surfaces, Btu/h·ft²

q''_{SW} = net short-wave radiation flux to surface from lights, Btu/h·ft²

q''_{LWS} = long-wave radiation flux from equipment in zone, Btu/h·ft²

q''_{ki} = conductive flux through wall, Btu/h·ft²

q''_{sol} = transmitted solar radiative flux absorbed at surface, Btu/h·ft²

q''_{conv} = convective heat flux to zone air, Btu/h·ft²

These terms are explained in the following paragraphs.

LW Radiation Exchange Among Zone Surfaces. The limiting cases for modeling internal LW radiation exchange are

- Zone air is completely transparent to LW radiation
- Zone air completely absorbs LW radiation from surfaces in the zone

Most HB models treat air as completely transparent and not participating in LW radiation exchange among surfaces in the zone. The second model is attractive because it can be formulated simply using a combined radiative and convective heat transfer coefficient from each surface to the zone air and thus decouples radiant exchange among surfaces in the zone. However, because the transparent air model allows radiant exchange and is more realistic, the second model is inferior.

Furniture in a zone increases the amount of surface area that can participate in radiative and convective heat exchanges. It also adds thermal mass to the zone. These two changes can affect the time response of the zone cooling load.

SW Radiation from Lights. The short-wavelength radiation from lights is usually assumed to be distributed over the surfaces in the zone in some manner. The HB procedure retains this approach but allows the distribution function to be changed.

LW Radiation from Internal Sources. The traditional model for this source defines a radiative/convective split for heat introduced into a zone from equipment. The radiative part is then distributed over the zone's surfaces in some manner. This model is not completely realistic, and it departs from HB principles. In a true HB

model, equipment surfaces are treated just as other LW radiant sources within the zone. However, because information about the surface temperature of equipment is rarely known, it is reasonable to keep the radiative/convective split concept even though it ignores the true nature of the radiant exchange. ASHRAE research project RP-1055 (Hosni et al. 1999) determined radiative/convective splits for many additional equipment types, as listed in footnotes for Tables 8 and 9.

Transmitted Solar Heat Gain. Chapter 15’s calculation procedure for determining transmitted solar energy through fenestration uses the solar heat gain coefficient (SHGC) directly rather than relating it to double-strength glass, as is done when using a shading coefficient (SC). The difficulty with this plan is that the SHGC includes both transmitted solar and inward-flowing fraction of the solar radiation absorbed in the window. With the HB method, this latter part should be added to the conduction component so it can be included in the inside-face heat balance.

Transmitted solar radiation is also distributed over surfaces in the zone in a prescribed manner. It is possible to calculate the actual position of beam solar radiation, but this involves partial surface irradiation, which is inconsistent with the rest of the zone model, which assumes uniform conditions over an entire surface.

Using SHGC to Calculate Solar Heat Gain

The total solar heat gain through fenestration consists of directly transmitted solar radiation plus the inward-flowing fraction of solar radiation that is absorbed in the glazing system. Both parts contain beam and diffuse contributions. Transmitted radiation goes directly onto surfaces in the zone and is accounted for in the surface inside heat balance. The zone heat balance model accommodates the resulting heat fluxes without difficulty. The second part, the inward-flowing fraction of the absorbed solar radiation, interacts with other surfaces of the enclosure through long-wave radiant exchange and with zone air through convective heat transfer. As such, it is dependent both on geometric and radiative properties of the zone enclosure and convection characteristics inside and outside the zone. The solar heat gain coefficient (SHGC) combines the transmitted solar radiation and the inward-flowing fraction of the absorbed radiation. The SHGC is defined as

$$SHGC = \tau + \sum_{k=1}^n N_k \alpha_k \tag{19}$$

where

- τ = solar transmittance of glazing
- α_k = solar absorptance of the k th layer of the glazing system
- n = number of layers
- N_k = inward-flowing fraction of absorbed radiation in the k th layer

Note that Equation (19) is written generically. It can be written for a specific incidence angle and/or radiation wavelength and integrated over the wavelength and/or angle, but the principle is the same in each case. Refer to Chapter 15 for the specific expressions.

Unfortunately, the inward-flowing fraction N interacts with the zone in many ways. This interaction can be expressed as

$$N = f(\text{inside convection coefficient, outside convection coefficient, glazing system overall heat transfer coefficient, zone geometry, zone radiation properties})$$

The only way to model these interactions correctly is to combine the window model with the zone heat balance model and solve both simultaneously. This has been done recently in some energy analysis programs, but is not generally available in load calculation procedures. In addition, the SHGC used for rating glazing systems is based on specific values of the inside, outside, and overall heat transfer coefficients and does not include any zonal long-wavelength radiation considerations. So, the challenge is to devise a way to use SHGC values within the framework of heat balance calculation in the most accurate way possible, as discussed in the following paragraphs.

Using SHGC Data. The normal incidence SHGC used to rate and characterize glazing systems is not sufficient for determining solar heat gain for load calculations. These calculations require solar heat gain as a function of the incident solar angle in order to determine the hour-by-hour gain profile. Thus, it is necessary to use angular SHGC values and also diffuse SHGC values. These can be obtained from the WINDOW 5.2 program (LBL 2003). This program does a detailed optical and thermal simulation of a glazing system and, when applied to a single clear layer, produces the information shown in Table 13.

Table 13 shows the parameters as a function of incident solar angle and also the diffuse values. The specific parameters shown are

- V_{tc} = transmittance in visible spectrum
- R_{fv} and R_{bv} = front and back surface visible reflectances
- T_{sol} = solar transmittance [τ in Equations (19), (20), and (21)]
- R_f and R_b = front and back surface solar reflectances
- A_{bs1} = solar absorptance for layer 1, which is the only layer in this case [α in Equations (19), (20), and (21)]
- SHGC = solar heat gain coefficient at the center of the glazing

The parameters used for heat gain calculations are T_{sol} , A_{bs} , and SHGC. For the specific convective conditions assumed in WINDOW 5.2 program, the inward-flowing fraction of the absorbed solar can be obtained by rearranging Equation (19) to give

$$N_k \alpha_k = SHGC - \tau \tag{20}$$

This quantity, when multiplied by the appropriate incident solar intensity, provides the amount of absorbed solar radiation that flows

Table 13 Single-Layer Glazing Data Produced by WINDOW 5.2

Parameter	Incident Angle										Diffuse (Hemis.)
	0	10	20	30	40	50	60	70	80	90

Source: LBL (2003).

inward. In the heat balance formulation for zone loads, this heat flux is combined with that caused by conduction through glazing and included in the surface heat balance.

The outward-flowing fraction of absorbed solar radiation is used in the heat balance on the outside face of the glazing and is determined from

$$(1 - N_k) \alpha_k = \alpha_k - N_k \alpha_k = \alpha_k - (\text{SHGC} - \tau) \quad (21)$$

If there is more than one layer, the appropriate summation of absorptances must be done.

There is some potential inaccuracy in using the WINDOW 5.2 SHGC values because the inward-flowing fraction part was determined under specific conditions for the inside and outside heat transfer coefficients. However, the program can be run with inside and outside coefficients of one's own choosing. Normally, however, this effect is not large, and only in highly absorptive glazing systems might cause significant error.

For solar heat gain calculations, then, it seems reasonable to use the generic window property data that comes from WINDOW 5.2. Considering Table 13, the procedure is as follows:

1. Determine angle of incidence for the glazing.
2. Determine corresponding SHGC.
3. Evaluate $N_k \alpha_k$ using Equation (19).
4. Multiply T_{sol} by incident beam radiation intensity to get transmitted beam solar radiation.
5. Multiply $N_k \alpha_k$ by incident beam radiation intensity to get inward-flowing absorbed heat.
6. Repeat steps 2 to 5 with diffuse parameters and diffuse radiation.
7. Add beam and diffuse components of transmitted and inward-flowing absorbed heat.

This procedure is incorporated into the HB method so the solar gain is calculated accurately for each hour.

Table 10 in Chapter 15 contains SHGC information for many additional glazing systems. That table is similar to Table 13 but is slightly abbreviated. Again, the information needed for heat gain calculations is T_{sol} , SHGC, and A_{bs} .

The same caution about the inside and outside heat transfer coefficients applies to the information in Table 13 in Chapter 31. Those values were also obtained with specific inside and outside heat transfer coefficients, and the inward-flowing fraction N is dependent upon those values.

Convection to Zone Air. Inside convection coefficients presented in past editions of this chapter and used in most load calculation procedures and energy programs are based on very old, natural convection experiments and do not accurately describe heat transfer coefficients in a mechanically ventilated zone. In previous load calculation procedures, these coefficients were buried in the procedures and could not be changed. A heat balance formulation keeps them as working parameters. In this way, research results such as those from ASHRAE research project RP-664 (Fisher 1998) can be incorporated into the procedures. It also allows determining the sensitivity of the load calculation to these parameters.

Air Heat Balance

In HB formulations aimed at determining cooling loads, the capacitance of air in the zone is neglected and the air heat balance is done as a quasisteady balance in each time period. Four factors contribute to the air heat balance:

$$q_{conv} + q_{CE} + q_{IV} + q_{sys} = 0 \quad (22)$$

where

- q_{conv} = convective heat transfer from surfaces, Btu/h
- q_{CE} = convective parts of internal loads, Btu/h
- q_{IV} = sensible load caused by infiltration and ventilation air, Btu/h
- q_{sys} = heat transfer to/from HVAC system, Btu/h

Fig. 7 Schematic View of General Heat Balance Zone

Convection from zone surfaces q_{conv} is the sum of all the convective heat transfer quantities from the inside-surface heat balance. This comes to the air through the convective heat transfer coefficient on the surfaces.

The **convective parts of the internal loads q_{CE}** is the companion to q''_{LWS} , the radiant contribution from internal loads [Equation (18)]. It is added directly to the air heat balance. This also violates the tenets of the HB approach, because surfaces producing internal loads exchange heat with zone air through normal convective processes. However, once again, this level of detail is generally not included in the heat balance, so it is included directly into the air heat balance instead.

In keeping with the well-mixed model for zone air, any air that enters directly to a space through **infiltration or ventilation q_{IV}** is immediately mixed with the zone's air. The amount of infiltration or natural ventilation air is uncertain. Sometimes it is related to the indoor/outdoor temperature difference and wind speed; however it is determined, it is added directly to the air heat balance.

Conditioned air that enters the zone from the HVAC system and provides q_{sys} is also mixed directly with the zone air. For commercial HVAC systems, ventilation air is most often provided using outside air as part of this mixed-in conditioned air; ventilation air is thus normally a system load rather than a direct-to-space load. An exception is where infiltration or natural ventilation is used to provide all or part of the ventilation air, as discussed in Chapter 16.

GENERAL ZONE FOR LOAD CALCULATION

The HB procedure is tailored to a single thermal zone, shown in Figure 7. The definition of a thermal zone depends on how the fixed temperature is controlled. If air circulated through an entire building or an entire floor is uniformly well stirred, the entire building or floor could be considered a thermal zone. On the other hand, if each room has a different control scheme, each room may need to be considered as a separate thermal zone. The framework needs to be flexible enough to accommodate any zone arrangement, but the heat balance aspect of the procedure also requires that a complete zone be described. This zone consists of four walls, a roof or ceiling, a floor, and a "thermal mass surface" (described in the section on Input Required). Each wall and the roof can include a window (or skylight in the case of the roof). This makes a total of 12 surfaces, any of which may have zero area if it is not present in the zone to be modeled.

The heat balance processes for this general zone are formulated for a 24 h steady-periodic condition. The variables are the inside and outside temperatures of the 12 surfaces plus either the HVAC system energy required to maintain a specified air temperature or the air temperature, if system capacity is specified. This makes a total of $25 \times 24 = 600$ variables. Although it is possible to set up the problem

for a simultaneous solution of these variables, the relatively weak coupling of the problem from one hour to the next allows a double iterative approach. One iteration is through all the surfaces in each hour, and the other is through the 24 h of a day. This procedure automatically reconciles nonlinear aspects of surface radiative exchange and other heat flux terms.

MATHEMATICAL DESCRIPTION

Conduction Process

Because it links the outside and inside heat balances, the wall conduction process regulates the cooling load's time dependence. For the HB procedure presented here, wall conduction is formulated using **conduction transfer functions (CTFs)**, which relate conductive heat fluxes to current and past surface temperatures and past heat fluxes. The general form for the inside heat flux is

$$q''_{ki}(t) = -Z_o T_{si,\theta} - \sum_{j=1}^{nz} Z_j T_{si,\theta-j\delta} + Y_o T_{so,\theta} + \sum_{j=1}^{nz} Y_j T_{so,\theta-j\delta} + \sum_{j=1}^{nq} \Phi_j q''_{ki,\theta-j\delta} \quad (23)$$

For outside heat flux, the form is

$$q''_{ko}(t) = -Y_o T_{si,\theta} - \sum_{j=1}^{nz} Y_j T_{si,\theta-j\delta} + X_o T_{so,\theta} + \sum_{j=1}^{nz} X_j T_{so,\theta-j\delta} + \sum_{j=1}^{nq} \Phi_j q''_{ko,\theta-j\delta} \quad (24)$$

where

$$\begin{aligned} X_j &= \text{outside CTF, } j = 0, 1, \dots, nz \\ Y_j &= \text{cross CTF, } j = 0, 1, \dots, nz \\ Z_j &= \text{inside CTF, } j = 0, 1, \dots, nz \\ \Phi_j &= \text{flux CTF, } j = 1, 2, \dots, nq \\ \theta &= \text{time} \\ \delta &= \text{time step} \\ T_{si} &= \text{inside-face temperature, } ^\circ\text{F} \\ T_{so} &= \text{outside-face temperature, } ^\circ\text{F} \\ q''_{ki} &= \text{conductive heat flux on inside face, Btu/h} \cdot \text{ft}^2 \\ q''_{ko} &= \text{conductive heat flux on outside face, Btu/h} \cdot \text{ft}^2 \end{aligned}$$

The subscript following the comma indicates the time period for the quantity in terms of time step δ . Also, the first terms in the series have been separated from the rest to facilitate solving for the current temperature in the solution scheme.

The two summation limits nz and nq depend on wall construction and also somewhat on the scheme used for calculating the CTFs. If $nq = 0$, the CTFs are generally referred to as **response factors**, but then theoretically nz is infinite. Values for nz and nq are generally set to minimize the amount of computation. A development of CTFs can be found in Hittle and Pedersen (1981).

Heat Balance Equations

The primary variables in the heat balance for the general zone are the 12 inside face temperatures and the 12 outside face temperatures at each of the 24 h, assigning i as the surface index and j as the hour index, or, in the case of CTFs, the sequence index. Thus, the primary variables are

$$T_{so,j} = \text{outside face temperature, } i = 1, 2, \dots, 12; j = 1, 2, \dots, 24$$

$$T_{si,j} = \text{inside face temperature, } i = 1, 2, \dots, 12; j = 1, 2, \dots, 24$$

In addition, $q_{sys,j}$ = cooling load, $j = 1, 2, \dots, 24$

Equations (17) and (24) are combined and solved for T_{so} to produce 12 equations applicable in each time step:

$$T_{so,i,j} = \left(\sum_{k=1}^{nz} T_{si,i,j-k} Y_{i,k} - \sum_{k=1}^{nz} T_{so,i,j-k} Z_{i,k} - \sum_{k=1}^{nq} \Phi_{i,k} q''_{ko,i,j-k} + q''_{\alpha sol,i,j} + q''_{LWR,i,j} + T_{si,i,j} Y_{i,0} + T_{o,j} h_{co,i,j} \right) / (Z_{i,0} + h_{co,i,j}) \quad (25)$$

where

$$\begin{aligned} T_o &= \text{outside air temperature} \\ h_{co} &= \text{outside convection coefficient, introduced by using } q''_{conv} = h_{co}(T_o - T_{so}) \end{aligned}$$

Equation (25) shows the need to separate $Z_{i,0}$, because the contribution of current surface temperature to conductive flux can be collected with the other terms involving that temperature.

Equations (18) and (23) are combined and solved for T_{si} to produce the next 12 equations:

$$T_{si,i,j} = \left(T_{si,i,j} Y_{i,0} + \sum_{k=1}^{nz} T_{so,i,j-k} Y_{i,k} - \sum_{k=1}^{nz} T_{si,i,j-k} Z_{i,k} + \sum_{k=1}^{nq} \Phi_{i,k} q''_{ki,i,j-k} + T_{a,j} h_{ci,j} + q''_{LWS} + q''_{LWX} + q''_{SW} + q''_{sol} e \right) / (Z_{i,0} + h_{ci,i,j}) \quad (26)$$

where

$$\begin{aligned} T_a &= \text{zone air temperature} \\ h_{ci} &= \text{convective heat transfer coefficient on the inside, obtained from } q''_{conv} = h_{ci}(T_a - T_{si}) \end{aligned}$$

Note that in Equations (25) and (26), the opposite surface temperature at the current time appears on the right-hand side. The two equations could be solved simultaneously to eliminate those variables. Depending on the order of updating the other terms in the equations, this can have a beneficial effect on solution stability.

The remaining equation comes from the air heat balance, Equation (22). This provides the cooling load q_{sys} at each time step:

$$q_{sys,j} = \sum_{i=1}^{12} A_i h_{ci} (T_{si,i,j} - T_{a,j}) + q_{CE} + q_{IV} \quad (27)$$

In Equation (27), the convective heat transfer term is expanded to show the interconnection between the surface temperatures and the cooling load.

Overall HB Iterative Solution

The iterative HB procedure consists of a series of initial calculations that proceed sequentially, followed by a double iteration loop, as shown in the following steps:

1. Initialize areas, properties, and face temperatures for all surfaces, 24 h.
2. Calculate incident and transmitted solar flux for all surfaces and hours.
3. Distribute transmitted solar energy to all inside faces, 24 h.
4. Calculate internal load quantities for all 24 h.
5. Distribute LW, SW, and convective energy from internal loads to all surfaces for all hours.
6. Calculate infiltration and direct-to-space ventilation loads for all hours.
7. Iterate the heat balance according to the following scheme:

```

For Day = 1 to Maxdays
  For j = 1 to 24           {hours in the day}
    For Surfcelter = 1 to Maxlter
      For i = 1 to 12      {The twelve zone surfaces}
        Evaluate Equations (34) and (35)
      Next i
    Next Surfcelter
    Evaluate Equation (36)
  Next j
If not converged, Next Day

```

8. Display results.

Generally, four or six surface iterations are sufficient to provide convergence. The convergence check on the day iteration should be based on the difference between the inside and the outside conductive heat flux terms q_k . A limit, such as requiring the difference between all inside and outside flux terms to be less than 1% of either flux, works well.

INPUT REQUIRED

Previous methods for calculating cooling loads attempted to simplify the procedure by precalculating representative cases and grouping the results with various correlating parameters. This generally tended to reduce the amount of information required to apply the procedure. With heat balance, no precalculations are made, so the procedure requires a fairly complete description of the zone.

Global Information. Because the procedure incorporates a solar calculation, some global information is required, including latitude, longitude, time zone, month, day of month, directional orientation of the zone, and zone height (floor to floor). Additionally, to take full advantage of the flexibility of the method to incorporate, for example, variable outside heat transfer coefficients, things such as wind speed, wind direction, and terrain roughness may be specified. Normally, these variables and others default to some reasonable set of values, but the flexibility remains.

Wall Information (Each Wall). Because the walls are involved in three of the fundamental processes (external and internal heat balance and wall conduction), each wall of the zone requires a fairly large set of variables. They include

- Facing angle with respect to solar exposure
- Tilt (degrees from horizontal)
- Area
- Solar absorptivity outside
- Long-wave emissivity outside
- Short-wave absorptivity inside
- Long-wave emissivity inside
- Exterior boundary temperature condition (solar versus nonsolar)
- External roughness
- Layer-by-layer construction information

Again, some of these parameters can be defaulted, but they are changeable, and they indicate the more fundamental character of the HB method because they are related to true heat transfer processes.

Window Information (Each Window). The situation for windows is similar to that for walls, but the windows require some additional information because of their role in the solar load. Necessary parameters include

- Area
- Normal solar transmissivity
- Normal SHGC
- Normal total absorptivity
- Long-wave emissivity outside
- Long-wave emissivity inside
- Surface-to-surface thermal conductance
- Reveal (for solar shading)

- Overhang width (for solar shading)
- Distance from overhang to window (for solar shading)

Roof and Floor Details. The roof and floor surfaces are specified similarly to walls. The main difference is that the ground outside boundary condition will probably be specified more often for a floor.

Thermal Mass Surface Details. An “extra” surface, called a thermal mass surface, can serve several functions. It is included in radiant heat exchange with the other surfaces in the space but is only exposed to the inside air convective boundary condition. As an example, this surface would be used to account for movable partitions in a space. Partition construction is specified layer by layer, similar to specification for walls, and those layers store and release heat by the same conduction mechanism as walls. As a general definition, the extra thermal mass surface should be sized to represent all surfaces in the space that are exposed to the air mass, except the walls, roof, floor, and windows. In the formulation, both sides of the thermal mass participate in the exchange.

Internal Heat Gain Details. The space can be subjected to several internal heat sources: people, lights, electrical equipment, and infiltration. Infiltration energy is assumed to go immediately into the air heat balance, so it is the least complicated of the heat gains. For the others, several parameters must be specified. These include the following fractions:

- Sensible heat gain
- Latent heat gain
- Short-wave radiation
- Long-wave radiation
- Energy that enters the air immediately as convection
- Activity level of people
- Lighting heat gain that goes directly to the return air

Radiant Distribution Functions. As mentioned previously, the generally accepted assumptions for the HB method include specifying the distribution of radiant energy from several sources to surfaces that enclose the space. This requires a distribution function that specifies the fraction of total radiant input absorbed by each surface. The types of radiation that require distribution functions are

- Long-wave, from equipment and lights
- Short-wave, from lights
- Transmitted solar

Other Required Information. Additional flexibility is included in the model so that results of research can be incorporated easily. This includes the capability to specify such things as

- Heat transfer coefficients/convection models
- Solar coefficients
- Sky models

The amount of input information required may seem extensive, but many parameters can be set to default values in most routine applications. However, all parameters listed can be changed when necessary to fit unusual circumstances or when additional information is obtained.

RADIANT TIME SERIES (RTS) METHOD

The radiant time series (RTS) method is a simplified method for performing design cooling load calculations that is derived from the heat balance (HB) method. It effectively replaces all other simplified (non-heat-balance) methods, such as the transfer function method (TFM), the cooling load temperature difference/cooling load factor (CLTD/CLF) method, and the total equivalent temperature difference/time averaging (TETD/TA) method.

This method was developed to offer a method that is rigorous, yet does not require iterative calculations, and that quantifies each component’s contribution to the total cooling load. In addition, it is

desirable for the user to be able to inspect and compare the coefficients for different construction and zone types in a form illustrating their relative effect on the result. These characteristics of the RTS method make it easier to apply engineering judgment during cooling load calculation.

The RTS method is suitable for peak design load calculations, but it should not be used for annual energy simulations because of its inherent limiting assumptions. Although simple in concept, RTS involves too many calculations for practical use as a manual method, although it can easily be implemented in a simple computerized spreadsheet, as illustrated in the examples. For a manual cooling load calculation method, refer to the CLTD/CLF method in Chapter 28 of the 1997 *ASHRAE Handbook—Fundamentals*.

ASSUMPTIONS AND PRINCIPLES

Design cooling loads are based on the assumption of **steady-periodic conditions** (i.e., the design day’s weather, occupancy, and heat gain conditions are identical to those for preceding days such that the loads repeat on an identical 24 h cyclical basis). Thus, the heat gain for a particular component at a particular hour is the same as 24 h prior, which is the same as 48 h prior, etc. This assumption is the basis for the RTS derivation from the HB method.

Cooling load calculations must address two time-delay effects inherent in building heat transfer processes:

- (1) Delay of conductive heat gain through opaque massive exterior surfaces (walls, roofs, or floors)
- (2) Delay of radiative heat gain conversion to cooling loads.

Exterior walls and roofs conduct heat because of temperature differences between outdoor and indoor air. In addition, solar energy on exterior surfaces is absorbed, then transferred by conduction to the building interior. Because of the mass and thermal capacity of the wall or roof construction materials, there is a substantial time delay in heat input at the exterior surface becoming heat gain at the interior surface.

As described in the section on Cooling Load Principles, most heat sources transfer energy to a room by a combination of convection and radiation. The convective part of heat gain immediately

becomes cooling load. The radiative part must first be absorbed by the finishes and mass of the interior room surfaces, and becomes cooling load only when it is later transferred by convection from those surfaces to the room air. Thus, radiant heat gains become cooling loads over a delayed period of time.

OVERVIEW

Figure 8 gives an overview of the RTS method. When calculating solar radiation, transmitted solar heat gain through windows, sol-air temperature, and infiltration, RTS is exactly the same as previous simplified methods (TFM and TETD/TA). Important areas that differ from previous simplified methods include

- Computation of conductive heat gain
- Splitting of all heat gains into radiant and convective portions
- Conversion of radiant heat gains into cooling loads

The RTS method accounts for both conduction time delay and radiant time delay effects by multiplying hourly heat gains by 24 h time series. The time series multiplication, in effect, distributes heat gains over time. Series coefficients, which are called **radiant time factors** and **conduction time factors**, are derived using the HB method. Radiant time factors reflect the percentage of an earlier radiant heat gain that becomes cooling load during the current hour. Likewise, conduction time factors reflect the percentage of an earlier heat gain at the exterior of a wall or roof that becomes heat gain at the inside during the current hour. By definition, each radiant or conduction time series must total 100%.

These series can be used to easily compare the time-delay effect of one construction versus another. This ability to compare choices is of particular benefit during design, when all construction details may not have been decided. Comparison can illustrate the magnitude of difference between the choices, allowing the engineer to apply judgment and make more informed assumptions in estimating the load.

Figure 9 illustrates CTS values for three walls with similar U-factors but with light to heavy construction. Figure 10 illustrates CTS for three walls with similar construction but with different

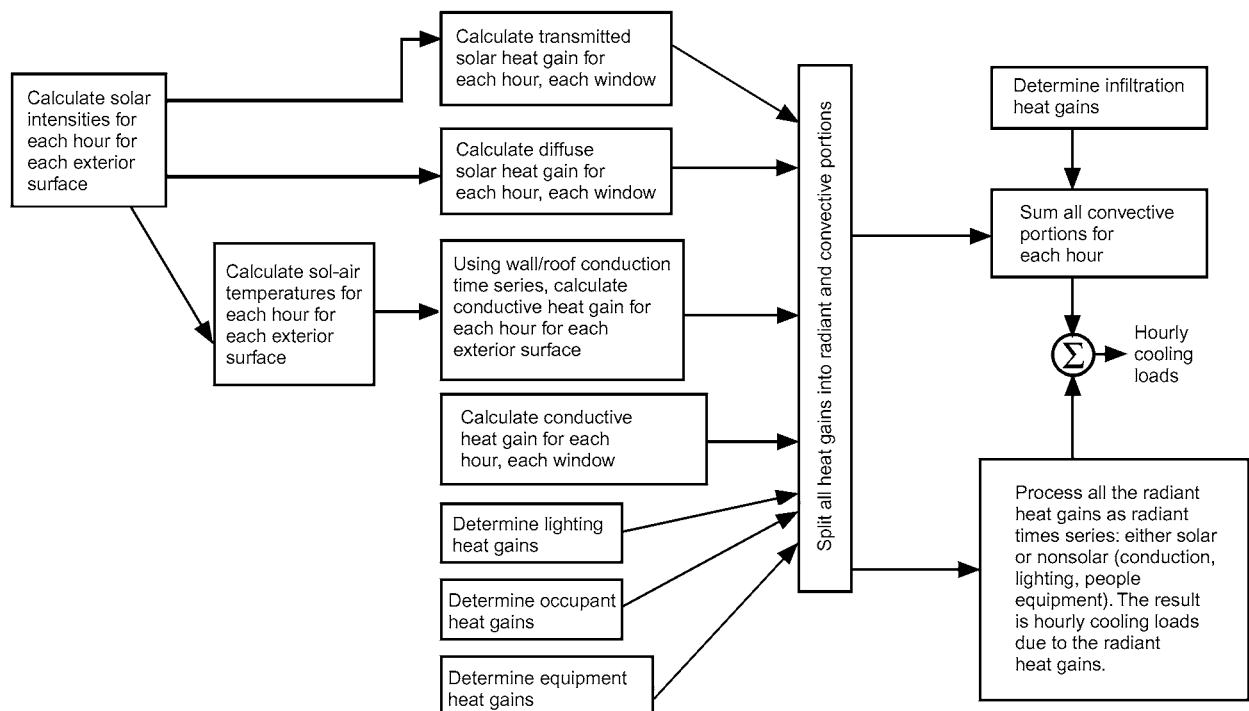

Fig. 8 Overview of Radiant Time Series Method

Fig. 9 CTS for Light to Heavy Walls

Fig. 10 CTS for Walls with Similar Mass and Increasing Insulation

amounts of insulation, thus with significantly different U-factors. Figure 11 illustrates RTS values for zones varying from light to heavy construction.

RTS PROCEDURE

The general procedure for calculating cooling load for each load component (lights, people, walls, roofs, windows, appliances, etc.) with RTS is as follows:

1. Calculate 24 h profile of component heat gains for design day (for conduction, first account for conduction time delay by applying conduction time series).
2. Split heat gains into radiant and convective parts (see Table 14 for radiant and convective fractions).
3. Apply appropriate radiant time series to radiant part of heat gains to account for time delay in conversion to cooling load.
4. Sum convective part of heat gain and delayed radiant part of heat gain to determine cooling load for each hour for each cooling load component.

After calculating cooling loads for each component for each hour, sum those to determine the total cooling load for each hour and select the hour with the peak load for design of the air-conditioning system. Repeat this process for multiple design months to determine the month when the peak load occurs, especially with windows on

Fig. 11 RTS for Light to Heavy Construction

southern exposures (northern exposure in southern latitudes), which can result in higher peak room cooling loads in winter months than in summer.

HEAT GAIN THROUGH EXTERIOR SURFACES

Heat gain through exterior opaque surfaces is derived from the same elements of solar radiation and thermal gradient as that for fenestration areas. It differs primarily as a function of the mass and nature of the wall or roof construction, because those elements affect the rate of conductive heat transfer through the composite assembly to the interior surface.

Sol-Air Temperature

Sol-air temperature is the outdoor air temperature that, in the absence of all radiation changes gives the same rate of heat entry into the surface as would the combination of incident solar radiation, radiant energy exchange with the sky and other outdoor surroundings, and convective heat exchange with outdoor air.

Heat Flux into Exterior Sunlit Surfaces. The heat balance at a sunlit surface gives the heat flux into the surface q/A as

$$\frac{q}{A} = \alpha E_t + h_o(t_o - t_s) - \varepsilon \Delta R \tag{28}$$

where

- α = absorptance of surface for solar radiation
- E_t = total solar radiation incident on surface, Btu/h · ft²
- h_o = coefficient of heat transfer by long-wave radiation and convection at outer surface, Btu/h · ft² · °F
- t_o = outdoor air temperature, °F
- t_s = surface temperature, °F
- ε = hemispherical emittance of surface
- ΔR = difference between long-wave radiation incident on surface from sky and surroundings and radiation emitted by blackbody at outdoor air temperature, Btu/h · ft²

Assuming the rate of heat transfer can be expressed in terms of the sol-air temperature t_e ,

$$\frac{q}{A} = h_o(t_e - t_s) \tag{29}$$

and from Equations (28) and (29),

$$t_e = t_o + \frac{\alpha E_t}{h_o} - \frac{\varepsilon \Delta R}{h_o} \tag{30}$$

For **horizontal surfaces** that receive long-wave radiation from the sky only, an appropriate value of ΔR is about 20 Btu/h · ft², so that if $\varepsilon = 1$ and $h_o = 3.0$ Btu/h · ft² · °F, the long-wave correction term is about 7°F (Bliss 1961).

Table 14 Recommended Radiative/Convective Splits for Internal Heat Gains

Heat Gain Type	Recommended Radiative Fraction	Recommended Convective Fraction	Comments
Occupants, typical office conditions	0.6	0.4	See Table 1 for other conditions.
Equipment	0.1 to 0.8	0.9 to 0.2	See Tables 6 to 12 for details of equipment heat gain and recommended radiative/convective splits for motors, cooking appliances, laboratory equipment, medical equipment, office equipment, etc. Varies; see Table 3.
Office, with fan	0.10	0.9

^aIncropera and DeWitt (1990).

^bParker et al. (2000).

^cMiller (1971).

Because **vertical surfaces** receive long-wave radiation from the ground and surrounding buildings as well as from the sky, accurate ΔR values are difficult to determine. When solar radiation intensity is high, surfaces of terrestrial objects usually have a higher temperature than the outdoor air; thus, their long-wave radiation compensates to some extent for the sky's low emittance. Therefore, it is common practice to assume $\epsilon\Delta R = 0$ for vertical surfaces.

Tabulated Temperature Values. The sol-air temperatures in Example Cooling and Heating Load Calculations section have been calculated based on $\epsilon\Delta R/h_o$ values of 7°F for horizontal surfaces and 0°F for vertical surfaces; total solar intensity values used for the calculations were calculated using equations in Chapter 14.

Surface Colors. Sol-air temperature values are given in the Example Cooling and Heating Load Calculations section for two values of the parameter α/h_o ; the value of 0.15 is appropriate for a light-colored surface, whereas 0.30 represents the usual maximum value for this parameter (i.e., for a dark-colored surface or any surface for which the permanent lightness cannot reliably be anticipated). Solar absorptance values of various surfaces are included in Table 15.

This procedure was used to calculate the sol-air temperatures included in the Examples section. Because of the tedious solar angle and intensity calculations, using a simple computer spreadsheet or other software for these calculations can reduce the effort involved.

Calculating Conductive Heat Gain Using Conduction Time Series

In the RTS method, conduction through exterior walls and roofs is calculated using conduction time series (CTS). Wall and roof conductive heat input at the exterior is defined by the familiar conduction equation as

$$q_{i,0-n} = UA(t_{e,0-n} - t_{rc}) \tag{31}$$

where

- $q_{i,0-n}$ = conductive heat input for the surface n hours ago, Btu/h
- U = overall heat transfer coefficient for the surface, Btu/h · ft² · °F
- A = surface area, ft²
- $t_{e,0-n}$ = sol-air temperature n hours ago, °F
- t_{rc} = presumed constant room air temperature, °F

Conductive heat gain through walls or roofs can be calculated using conductive heat inputs for the current hours and past 23 h and conduction time series:

$$q_0 = c_0q_{i,0} + c_1q_{i,0-1} + c_2q_{i,0-2} + c_3q_{i,0-3} + \dots + c_{23}q_{i,0-23} \tag{32}$$

where

- q_0 = hourly conductive heat gain for the surface, Btu/h
- $q_{i,0}$ = heat input for the current hour
- $q_{i,0-n}$ = heat input n hours ago
- c_0, c_1, \dots = conduction time factors

Conduction time factors for representative wall and roof types are included in Tables 16 and 17. Those values were derived by first calculating conduction transfer functions for each example wall and roof construction. Assuming steady-periodic heat input conditions for design load calculations allows conduction transfer functions to be reformulated into periodic response factors, as demonstrated by Spittle and Fisher (1999a). The periodic response factors were further simplified by dividing the 24 periodic response factors by the respective overall wall or roof U-factor to form the conduction time series (CTS). The conduction time factors can then be used in Equation (32) and provide a way to compare time delay characteristics between different wall and roof constructions. Construction material

data used in the calculations for walls and roofs in Tables 16 and 17 are listed in Table 18.

Heat gains calculated for walls or roofs using periodic response factors (and thus CTS) are identical to those calculated using conduction transfer functions for the steady periodic conditions assumed in design cooling load calculations. The methodology for calculating periodic response factors from conduction transfer functions was originally developed as part of ASHRAE research project RP-875 (Spitler and Fisher 1999b; Spitler et al. 1997). For walls and roofs that are not reasonably close to the representative constructions in Tables 16 and 17, CTS coefficients may be computed with a computer program such as that described by Iu and

Fisher (2004). For walls and roofs with thermal bridges, the procedure described by Karambakkam et al. (2005) may be used to determine an equivalent wall construction, which can then be used as the basis for finding the CTS coefficients. When considering the level of detail needed to make an adequate approximation, remember that, for buildings with windows and internal heat gains, the conduction heat gains make up a relatively small part of the cooling load. For heating load calculations, the conduction heat loss may be more significant.

The tedious calculations involved make a simple computer spreadsheet or other computer software a useful labor saver.

HEAT GAIN THROUGH INTERIOR SURFACES

Whenever a conditioned space is adjacent to a space with a different temperature, heat transfer through the separating physical section must be considered. The heat transfer rate is given by

$$q = UA(t_b - t_i) \tag{33}$$

where

- q = heat transfer rate, Btu/h
- U = coefficient of overall heat transfer between adjacent and conditioned space, Btu/h·ft²·°F
- A = area of separating section concerned, ft²
- t_b = average air temperature in adjacent space, °F
- t_i = air temperature in conditioned space, °F

U-values can be obtained from Chapter 27. Temperature t_b may differ greatly from t_i. The temperature in a kitchen or boiler room, for

example, may be as much as 15 to 50°F above the outdoor air temperature. Actual temperatures in adjoining spaces should be measured, when possible. Where nothing is known except that the adjacent space is of conventional construction, contains no heat sources, and itself receives no significant solar heat gain, t_b - t_i may be considered the difference between the outdoor air and conditioned space design dry-bulb temperatures minus 5°F. In some cases, air temperature in the adjacent space corresponds to the outdoor air temperature or higher.

Floors

For floors directly in contact with the ground or over an underground basement that is neither ventilated nor conditioned, sensible heat transfer may be neglected for cooling load estimates because usually there is a heat loss rather than a gain. An exception is in hot climates (i.e., where average outdoor air temperature exceeds

indoor design condition), where the positive soil-to-indoor temperature difference causes sensible heat gains (Rock 2005). In many climates and for various temperatures and local soil conditions, moisture transport up through slabs-on-grade and basement floors is also significant, and contributes to the latent heat portion of the cooling load.

CALCULATING COOLING LOAD

The **instantaneous cooling load** is the rate at which heat energy is convected to the zone air at a given point in time. Computation of cooling load is complicated by the radiant exchange between

surfaces, furniture, partitions, and other mass in the zone. Most heat gain sources transfer energy by both convection and radiation. Radiative heat transfer introduces a time dependency to the process that is not easily quantified. Radiation is absorbed by thermal masses in the zone and then later transferred by convection into the space. This process creates a time lag and dampening effect. The convective portion, on the other hand, is assumed to immediately become cooling load in the hour in which that heat gain occurs.

Heat balance procedures calculate the radiant exchange between surfaces based on their surface temperatures and emissivities, but they typically rely on estimated "radiative/convective splits" to determine the contribution of internal loads, including people, lighting,

appliances, and equipment, to the radiant exchange. RTS further simplifies the HB procedure by also relying on an estimated radiative/convective split of wall and roof conductive heat gain instead of simultaneously solving for the instantaneous convective and radiative heat transfer from each surface, as is done in the HB procedure.

Thus, the cooling load for each load component (lights, people, walls, roofs, windows, appliances, etc.) for a particular hour is the sum of the convective portion of the heat gain for that hour plus the time-delayed portion of radiant heat gains for that hour and the previous 23 h. Table 14 contains recommendations for splitting each of the heat gain components into convective and radiant portions.

RTS converts the radiant portion of hourly heat gains to hourly cooling loads using radiant time factors, the coefficients of the radiant time series. Radiant time factors are used to calculate the cooling load for the current hour on the basis of current and past heat gains. The radiant time series for a particular zone gives the time-dependent response of the zone to a single pulse of radiant energy. The series shows the portion of the radiant pulse that is convected to zone air for each hour. Thus, r_0 represents the fraction of the radiant pulse convected to the zone air in the current hour r_1 in the previous hour, and so on. The radiant time series thus generated is used to convert the radiant portion of hourly heat gains to hourly cooling loads according to the following equation:

$$Q_{r,\theta} = r_0 q_{r,\theta} + r_1 q_{r,\theta-1} + r_2 q_{r,\theta-2} + r_3 q_{r,\theta-3} + \dots + r_{23} q_{r,\theta-23} \quad (34)$$

where

$Q_{r,\theta}$ =radiant cooling load Q_r for current hour θ , Btu/h

$q_{r,\theta}$ =radiant heat gain for current hour, Btu/h

$q_{r,\theta-n}$ =radiant heat gain n hours ago, Btu/h

r_0, r_1, \dots =radiant time factors

The radiant cooling load for the current hour, which is calculated using RTS and Equation (34), is added to the convective portion to determine the total cooling load for that component for that hour.

Radiant time factors are generated by a heat balance based procedure. A separate series of radiant time factors is theoretically required for each unique zone and for each unique radiant energy distribution function assumption. For most common design applications, RTS variation depends primarily on the overall massiveness of the construction and the thermal responsiveness of the surfaces the radiant heat gains strike.

One goal in developing RTS was to provide a simplified method based directly on the HB method; thus, it was deemed desirable to generate RTS coefficients directly from a heat balance. A heat balance computer program was developed to do this: Hbfort, which is included as part of *Cooling and Heating Load Calculation Principles* (Pedersen et al. 1998). The RTS procedure is described by Spitler et al. (1997). The procedure for generating RTS coefficients may be thought of as analogous to the custom weighting factor generation procedure used by DOE 2.1 (Kerrisk et al. 1981; Sowell 1988a, 1988b). In both cases, a zone model is pulsed with a heat gain. With DOE 2.1, the resulting loads are used to estimate the best values of the transfer function method weighting factors to most closely match the load profile. In the procedure described here, a unit periodic heat gain pulse is used to generate loads for a 24 h period. As long as the heat gain pulse is a unit pulse, the resulting loads are equivalent to the RTS coefficients.

Two different radiant time series are used: **Solar**, for direct transmitted solar heat gain (radiant energy assumed to be distributed to the floor and furnishings only) and **nonsolar**, for all other types of heat gains (radiant energy assumed to be uniformly distributed on all internal surfaces). Nonsolar RTS apply to radiant heat gains from people, lights, appliances, walls, roofs, and floors. Also, for diffuse solar heat gain and direct solar heat gain from fenestration with inside shading (blinds, drapes, etc.), the nonsolar RTS should be used. Radiation from those sources is assumed to be more uniformly

distributed onto all room surfaces. Effect of beam solar radiation distribution assumptions is addressed by Hittle (1999).

Representative solar and nonsolar RTS data for light, medium, and heavyweight constructions are provided in Tables 19 and 20. Those were calculated using the Hbfort computer program (Pedersen et al. 1998) with zone characteristics listed in Table 21. Customized RTS values may be calculated using the HB method where the zone is not reasonably similar to these typical zones or where more precision is desired.

ASHRAE research project RP-942 compared HB and RTS results over a wide range of zone types and input variables (Rees et al. 2000; Spitler et al. 1998). In general, total cooling loads calculated using RTS closely agreed with or were slightly higher than those of the HB method with the same inputs. The project examined more than 5000 test cases of varying zone parameters. The dominating variable was overall thermal mass, and results were grouped into lightweight, U.S. medium-weight, U.K. medium-weight, and heavyweight construction. Best agreement between RTS and HB results was obtained for light- and medium-weight construction. Greater differences occurred in heavyweight cases, with RTS generally predicting slightly higher peak cooling loads than HB. Greater differences also were observed in zones with extremely high internal radiant loads and large glazing areas or with a very lightweight exterior envelope. In this case, heat balance calculations predict that some of the internal radiant load will be transmitted to the outdoor environment and never becomes cooling load within the space. RTS does not account for energy transfer out of the space to the environment, and thus predicted higher cooling loads.

ASHRAE research project RP-1117 constructed two model rooms for which cooling loads were physically measured using extensive instrumentation. The results agreed with previous simulations (Chantrasrisalai et al. 2003; Eldridge et al. 2003; Iu et al. 2003). HB calculations closely approximated the measured cooling loads when provided with detailed data for the test rooms. RTS overpredicted measured cooling loads in tests with large, clear, single-glazed window areas with bare concrete floor and no furnishings or internal loads. Tests under more typical conditions (venetian blinds, carpeted floor, office-type furnishings, and normal internal loads) provided good agreement between HB, RTS, and measured loads.

HEATING LOAD CALCULATIONS

Techniques for estimating design heating load for commercial, institutional, and industrial applications are essentially the same as for those estimating design cooling loads for such uses, with the following exceptions:

- Temperatures outside conditioned spaces are generally lower than maintained space temperatures.
- Credit for solar or internal heat gains is not included
- Thermal storage effect of building structure or content is ignored.
- Thermal bridging effects on wall and roof conduction are greater for heating loads than for cooling loads, and greater care must be taken to account for bridging effects on U-factors used in heating load calculations.

Heat losses (negative heat gains) are thus considered to be instantaneous, heat transfer essentially conductive, and latent heat treated only as a function of replacing space humidity lost to the exterior environment.

This simplified approach is justified because it evaluates worst-case conditions that can reasonably occur during a heating season. Therefore, the near-worst-case load is based on the following:

- Design interior and exterior conditions
- Including infiltration and/or ventilation
- No solar effect (at night or on cloudy winter days)
- Before the periodic presence of people, lights, and appliances has an offsetting effect

Table 21 RTS Representative Zone Construction for Tables 19 and 20

Construction Class	Exterior Wall	Roof/Ceiling	Partitions	Floor	Furnishings

Heavy	4 in. face brick, 8 in. HW concrete air space, 2 in. insulation, 3/4 in. gyp	8 in. HW concrete, ceiling air space, acoustic tile	3/4 in. gyp, 8 in. HW concrete block, 3/4 in. gyp	acoustic tile, ceiling air space, 8 in. HW concrete	1 in. wood @ 50% of floor area

Typical commercial and retail spaces have nighttime unoccupied periods at a setback temperature where little to no ventilation is required, building lights and equipment are off, and heat loss is primarily through conduction and infiltration. Before being occupied, buildings are warmed to the occupied temperature (see the following discussion). During occupied time, building lights, equipment, and people cooling loads can offset conduction heat loss, although some perimeter heat may be required, leaving the infiltration and ventilation loads as the primary heating loads. Ventilation heat load may be offset with heat recovery equipment. These loads (conduction loss, warm-up load, and ventilation load) may not be additive when sizing building heating equipment, and it is prudent to analyze each load and their interactions to arrive at final equipment sizing for heating.

HEAT LOSS CALCULATIONS

The general procedure for calculation of design heat losses of a structure is as follows:

1. Select outdoor design conditions: temperature, humidity, and wind direction and speed.
2. Select indoor design conditions to be maintained.
3. Estimate temperature in any adjacent unheated spaces.
4. Select transmission coefficients and compute heat losses for walls, floors, ceilings, windows, doors, and foundation elements.
5. Compute heat load through infiltration and any other outdoor air introduced directly to the space.
6. Sum the losses caused by transmission and infiltration.

Outdoor Design Conditions

The ideal heating system would provide enough heat to match the structure's heat loss. However, weather conditions vary considerably from year to year, and heating systems designed for the worst weather conditions on record would have a great excess of capacity most of the time. A system's failure to maintain design conditions during brief periods of severe weather usually is not critical. However, close regulation of indoor temperature may be critical for some occupancies or industrial processes. Design temperature data and discussion of their application are given in Chapter 14. Generally, the 99% temperature values given in the tabulated weather data be used. However, caution should be used, and local conditions always investigated. In some locations, outdoor temperatures are commonly much lower and wind velocities higher than those given in the tabulated weather data.

Indoor Design Conditions

The main purpose of the heating system is to maintain indoor conditions that make most of the occupants comfortable. It should be kept in mind, however, that the purpose of heating load calculations is to obtain data for sizing the heating system components. In many cases, the system will rarely be called upon to operate at the design conditions. Therefore, the use and occupancy of the space are general considerations from the design temperature point of view. Later, when the building's energy requirements are computed, the actual conditions in the space and outdoor environment, including internal heat gains, must be considered.

Fig. 12 Heat Flow from Below-Grade Surface

The indoor design temperature should be selected at the lower end of the acceptable temperature range, so that the heating equipment will not be oversized. Even properly sized equipment operates under partial load, at reduced efficiency, most of the time; therefore, any oversizing aggravates this condition and lowers overall system efficiency. A maximum design dry-bulb temperature of 70°F is recommended for most occupancies. The indoor design value of relative humidity should be compatible with a healthful environment and the thermal and moisture integrity of the building envelope. A minimum relative humidity of 30% is recommended for most situations.

Calculation of Transmission Heat Losses

Exterior Surface Above Grade. All above-grade surfaces exposed to outdoor conditions (walls, doors, ceilings, fenestration, and raised floors) are treated identically, as follows:

$$q = A \times HF \quad (35)$$

$$HF = U \Delta t \quad (36)$$

where HF is the heating load factor in Btu/h · ft².

Below-Grade Surfaces. An approximate method for estimating below-grade heat loss [based on the work of Latta and Boileau (1969)] assumes that the heat flow paths shown in Figure 12 can be used to find the steady-state heat loss to the ground surface, as follows:

$$HF = U_{avg}(t_{in} - t_{gr}) \quad (37)$$

where

U_{avg} = average U-factor for below-grade surface from Equation (39) or (40), Btu/h · ft² · °F

t_{in} = below-grade space air temperature, °F

t_{gr} = design ground surface temperature from Equation (38), °F

Fig. 13 Ground Temperature Amplitude

Fig. 14 Below-Grade Parameters

The effect of soil heat capacity means that none of the usual external design air temperatures are suitable values for t_{gr} . Ground surface temperature fluctuates about an annual mean value by amplitude A , which varies with geographic location and surface cover. The minimum ground surface temperature, suitable for heat loss estimates, is therefore

$$t_{gr} = \bar{t}_{gr} - A \quad (38)$$

where

\bar{t}_{gr} = mean ground temperature, °F, estimated from the annual average air temperature or from well-water temperatures, shown in Figure 17 of Chapter 32 in the 2007 ASHRAE Handbook—HVAC Applications

A = ground surface temperature amplitude, °F, from Figure 13 for North America

Figure 14 shows depth parameters used in determining U_{avg} . For walls, the region defined by z_1 and z_2 may be the entire wall or any portion of it, allowing partially insulated configurations to be analyzed piecewise.

The below-grade wall average U-factor is given by

$$U_{avg,bw} = \frac{2k_{soil}}{\pi(z_1 - z_2)} \times \left[\ln \left(z_2 + \frac{2k_{soil}R_{other}}{\pi} \right) - \ln \left(z_1 + \frac{2k_{soil}R_{other}}{\pi} \right) \right] \quad (39)$$

where

$U_{avg,bw}$ = average U-factor for wall region defined by z_1 and z_2 , Btu/h·ft²·°F

k_{soil} = soil thermal conductivity, Btu/h·ft·°F

R_{other} = total resistance of wall, insulation, and inside surface resistance, h·ft²·°F/Btu

z_1, z_2 = depths of top and bottom of wall segment under consideration, ft (Figure 14)

Table 22 Average U-Factor for Basement Walls with Uniform Insulation

Depth, ft	$U_{avg,bw}$ from Grade to Depth, Btu/h·ft ² ·°F			
	Uninsulated	R-5	R-10	R-15
1	0.432	0.135	0.080	0.057
2.6	0.331	0.121	0.075	0.054
3	0.273	0.110	0.070	0.052
4	0.235	0.101	0.066	0.050
5	0.208	0.094	0.063	0.048
6	0.187	0.088	0.060	0.046
7	0.170	0.083	0.057	0.044
8	0.157	0.078	0.055	0.043

Soil conductivity = 0.8 Btu/h·ft·°F; insulation is over entire depth. For other soil conductivities and partial insulation, use Equation (39).

Table 23 Average U-Factor for Basement Floors

z_f (Depth of Floor Below Grade), ft	$U_{avg,bf}$, Btu/h·ft ² ·°F			
	w_b (Shortest Width of Basement), ft			
	20	24	28	32
1	0.064	0.057	0.052	0.047
2	0.054	0.048	0.044	0.040
3	0.047	0.042	0.039	0.036
4	0.042	0.038	0.035	0.033
5	0.038	0.035	0.032	0.030
6	0.035	0.032	0.030	0.028
7	0.032	0.030	0.028	0.026

Soil conductivity is 0.8 Btu/h·ft·°F; floor is uninsulated. For other soil conductivities and insulation, use Equation (39).

The value of soil thermal conductivity k varies widely with soil type and moisture content. A typical value of 0.8 Btu/h·ft·°F has been used previously to tabulate U-factors, and R_{other} is approximately 1.47 h·ft²·°F/Btu for uninsulated concrete walls. For these parameters, representative values for $U_{avg,bw}$ are shown in Table 22.

The average below-grade floor U-factor (where the entire basement floor is uninsulated or has uniform insulation) is given by

$$U_{avg,bf} = \frac{2k_{soil}}{\pi w_b} \times \left[\ln \left(\frac{w_b}{2} + \frac{z_f}{2} + \frac{k_{soil}R_{other}}{\pi} \right) - \ln \left(\frac{k_{soil}R_{other}}{\pi} \right) \right] \quad (40)$$

where

w_b = basement width (shortest dimension), ft

z_f = floor depth below grade, ft (see Figure 14)

Representative values of $U_{avg,bf}$ for uninsulated basement floors are shown in Table 23.

At-Grade Surfaces. Concrete slab floors may be (1) unheated, relying for warmth on heat delivered above floor level by the heating system, or (2) heated, containing heated pipes or ducts that constitute a radiant slab or portion of it for complete or partial heating of the house.

The simplified approach that treats heat loss as proportional to slab perimeter allows slab heat loss to be estimated for both unheated and heated slab floors:

$$q = p \times HF \quad (41)$$

$$HF = F_p \Delta t \quad (42)$$

where

q = heat loss through perimeter, Btu/h

F_p = heat loss coefficient per foot of perimeter, Btu/h·ft·°F, Table 24

p = perimeter (exposed edge) of floor, ft

Table 24 Heat Loss Coefficient F_p of Slab Floor Construction

Construction	Insulation	F_p , Btu/h·ft·°F
8 in. block wall, brick facing	Uninsulated	0.68
	R-5.4 from edge to footer	0.50
4 in. block wall, brick facing	Uninsulated	0.84
	R-5.4 from edge to footer	0.49
Metal stud wall, stucco	Uninsulated	1.20
	R-5.4 from edge to footer	0.53
Poured concrete wall with duct near perimeter*	Uninsulated	2.12
	R-5.4 from edge to footer	0.72

*Weighted average temperature of heating duct was assumed at 110°F during heating season (outdoor air temperature less than 65°F).

Surfaces Adjacent to Buffer Space. Heat loss to adjacent unconditioned or semiconditioned spaces can be calculated using a heating factor based on the partition temperature difference:

$$HF = U(t_{in} - t_b) \quad (43)$$

Infiltration

All structures have some air leakage or infiltration. This means a heat loss because the cold, dry outdoor air must be heated to the inside design temperature and moisture must be added to increase the humidity to the design value. Procedures for estimating the infiltration rate are discussed in Chapter 16.

Once the infiltration rate has been calculated, the resulting sensible heat loss, equivalent to the sensible heating load from infiltration, is given by

$$q_s = 60(\text{cfm}/v) c_p (t_{in} - t_o) \quad (44)$$

where

- cfm = volume flow rate of infiltrating air
- c_p = specific heat capacity of air, Btu/lb_m·°F
- v = specific volume of infiltrating air, ft³/lb_m

Assuming standard air conditions (59°F and sea-level conditions) for v and c_p , Equation (44) may be written as

$$q_s = 1.10(\text{cfm})(t_{in} - t_o) \quad (45)$$

The infiltrating air also introduces a latent heating load given by

$$q_l = 60(\text{cfm}/v)(W_{in} - W_o)D_h \quad (46)$$

where

- W_{in} = humidity ratio for inside space air, lb_w/lb_a
- W_o = humidity ratio for outdoor air, lb_w/lb_a
- D_h = change in enthalpy to convert 1 lb water from vapor to liquid, Btu/lb_w

For standard air and nominal indoor comfort conditions, the latent load may be expressed as

$$q_l = 4840(\text{cfm})(W_{in} - W_o) \quad (47)$$

The coefficients 1.10 in Equation (45) and 4840 in Equation (47) are given for standard conditions. They depend on temperature and altitude (and, consequently, pressure).

HEATING SAFETY FACTORS AND LOAD ALLOWANCES

Before mechanical cooling became common in the second half of the 1900s, and when energy was less expensive, buildings included much less insulation; large, operable windows; and generally more

Table 25 Common Sizing Calculations in Other Chapters

Subject	Volume/Chapter	Equation(s)
Duct heat transfer	ASTM <i>Standard</i> C680

infiltration-prone assemblies than the energy-efficient and much tighter buildings typical of today. Allowances of 10 to 20% of the net calculated heating load for piping losses to unheated spaces, and 10 to 20% more for a warm-up load, were common practice, along with other occasional safety factors reflecting the experience and/or concern of the individual designer. Such measures are less conservatively applied today with newer construction. A combined warm-up/safety allowance of 20 to 25% is fairly common but varies depending on the particular climate, building use, and type of construction. Engineering judgment must be applied for the particular project. Armstrong et al. (1992a, 1992b) provide a design method to deal with warm-up and cooldown load.

OTHER HEATING CONSIDERATIONS

Calculation of design heating load estimates has essentially become a subset of the more involved and complex estimation of cooling loads for such spaces. Chapter 19 discusses using the heating load estimate to predict or analyze energy consumption over time. Special provisions to deal with particular applications are covered in the 2007 *ASHRAE Handbook—HVAC Applications* and the 2008 *ASHRAE Handbook—HVAC Systems and Equipment*.

The 1989 *ASHRAE Handbook—Fundamentals* was the last edition to contain a chapter dedicated only to heating load. Its contents were incorporated into this volume's Chapter 17, which describes steady-state conduction and convection heat transfer and provides, among other data, information on losses through basement floors and slabs.

SYSTEM HEATING AND COOLING LOAD EFFECTS

The heat balance (HB) or radiant time series (RTS) methods are used to determine cooling loads of rooms within a building, but they do not address the plant size necessary to reject the heat. Principal factors to consider in determining the plant size are ventilation, heat transport equipment, and air distribution systems. Some of these factors vary as a function of room load, ambient temperature, and control strategies, so it is often necessary to evaluate the factors and strategies dynamically and simultaneously with the heat loss or gain calculations.

The detailed analysis of system components and methods calculating their contribution to equipment sizing are beyond the scope of this chapter, which is general in nature. Table 25 lists the most frequently used calculations in other chapters and volumes.

ZONING

The organization of building rooms as defined for load calculations into zones and air-handling units has no effect on room cooling loads. However, specific grouping and ungrouping of rooms into

zones may cause peak system loads to occur at different times during the day or year and may significantly affected heat removal equipment sizes.

For example, if each room is cooled by a separate heat removal system, the total capacity of the heat transport systems equals the sum of peak room loads. Conditioning all rooms by a single heat transport system (e.g., a variable-volume air handler) requires less capacity (equal to the simultaneous peak of the combined rooms load, which includes some rooms at off-peak loads). This may significantly reduce equipment capacity, depending on the configuration of the building.

VENTILATION

Consult ASHRAE *Standard* 62.1 and building codes to determine the required quantity of ventilation air for an application, and the various methods of achieving acceptable indoor air quality. The following discussion is confined to the effect of mechanical ventilation on sizing heat removal equipment. Where natural ventilation is used, through operable windows or other means, it is considered as infiltration and is part of the direct-to-room heat gain. Where ventilation air is conditioned and supplied through the mechanical system its sensible and latent loads are applied directly to heat transport and central equipment, and do not affect room heating and cooling loads. If the mechanical ventilation rate sufficiently exceeds exhaust airflows, air pressure may be positive and infiltration from envelope openings and outside wind may not be included in the load calculations. Chapter 16 includes more information on ventilating commercial buildings.

AIR HEAT TRANSPORT SYSTEMS

Heat transport equipment is usually selected to provide adequate heating or cooling for the peak load condition. However, selection must also consider maintaining desired inside conditions during all occupied hours, which requires matching the rate of heat transport to room peak heating and cooling loads. Automatic control systems normally vary the heating and cooling system capacity during these off-peak hours of operation.

On/Off Control Systems

On/off control systems, common in residential and light commercial applications, cycle equipment on and off to match room load. They are adaptable to heating or cooling because they can cycle both heating and cooling equipment. In their purest form, their heat transport matches the combined room and ventilation load over a series of cycles.

Variable-Air-Volume Systems

Variable-air-volume (VAV) systems have airflow controls that adjust cooling airflow to match the room cooling load. Damper leakage or minimum airflow settings may cause overcooling, so most VAV systems are used in conjunction with separate heating systems. These may be duct-mounted heating coils, or separate radiant or convective heating systems.

The amount of heat added by the heating systems during cooling becomes part of the room cooling load. Calculations must determine the minimum airflow relative to off-peak cooling loads. The quantity of heat added to the cooling load can be determined for each terminal by Equation (9) using the minimum required supply airflow rate and the difference between supply air temperature and the room inside heating design temperature.

Constant-Air-Volume Reheat Systems

In constant-air-volume (CAV) reheat systems, all supply air is cooled to remove moisture and then heated to avoid overcooling rooms. *Reheat* refers to the amount of heat added to cooling supply air to raise the supply air temperature to the temperature necessary

for picking up the sensible load. The quantity of heat added can be determined by Equation (9).

With a constant-volume reheat system, heat transport system load does not vary with changes in room load, unless the cooling coil discharge temperature is allowed to vary. Where a minimum circulation rate requires a supply air temperature greater than the available design supply air temperature, reheat adds to the cooling load on the heat transport system. This makes the cooling load on the heat transport system larger than the room peak load.

Mixed Air Systems

Mixed air systems change the supply air temperature to match the cooling capacity by mixing airstreams of different temperatures; examples include multizone and dual-duct systems. Systems that cool the entire airstream to remove moisture and to reheat some of the air before mixing with the cooling airstream influence load on the heat transport system in the same way a reheat system does. Other systems separate the air paths so that mixing of hot- and cold-deck airstreams does not occur. For systems that mix hot and cold airstreams, the contribution to the heat transport system load is determined as follows.

1. Determine the ratio of cold-deck flow to hot-deck flow from

$$\frac{Q_h}{Q_c} = (T_c - T_r)/(T_r - T_h)$$

2. From Equation (10), the hot-deck contribution to room load during off-peak cooling is

$$q_{rh} = 1.1Q_h(T_h - T_r)$$

where

- Q_h = heating airflow, cfm
- Q_c = cooling airflow, cfm
- T_c = cooling air temperature, °F
- T_h = heating air temperature, °F
- T_r = room or return air temperature, °F
- q_{rh} = heating airflow contribution to room load at off-peak hours, Btu/h

Heat Gain from Fans

Fans that circulate air through HVAC systems add energy to the system through the following processes:

- Increasing velocity and static pressure adds kinetic and potential energy
- Fan inefficiency in producing airflow and static pressure adds sensible heat (fan heat) to the airflow
- Inefficiency of motor and drive dissipates sensible heat

The power required to provide airflow and static pressure can be determined from the first law of thermodynamics with the following equation:

$$P_A = 0.000157Vp$$

where

- P_A = air power, hp
- V = flow rate, cfm
- p = pressure, in. of water

at standard air conditions with air density = 0.075 lb/ft³ built into the multiplier 0.000157. The power necessary at the fan shaft must account for fan inefficiencies, which may vary from 50 to 70%. This may be determined from

$$P_F = P_A/\eta_F$$

where

- P_F = power required at fan shaft, hp
- η_F = fan efficiency, dimensionless

The power necessary at the input to the fan motor must account for fan motor inefficiencies and drive losses. Fan motor efficiencies generally vary from 80 to 95%, and drive losses for a belt drive are 3% of the fan power. This may be determined from

$$P_M = (1 + DL) P_F / E_M E_D$$

where

- P_M = power required at input to motor, hp
- E_D = belt drive efficiency, dimensionless
- E_M = fan motor efficiency, dimensionless
- P_F = power required at fan shaft, hp
- DL = drive loss, dimensionless

Almost all the energy required to generate airflow and static pressure is ultimately dissipated as heat within the building and HVAC system; a small portion is discharged with any exhaust air. Generally, it is assumed that all the heat is released at the fan rather than dispersed to the remainder of the system. The portion of fan heat released to the airstream depends on the location of the fan motor and drive: if they are within the airstream, all the energy input to the fan motor is released to the airstream. If the fan motor and drive are outside the airstream, the energy is split between the airstream and the room housing the motor and drive. Therefore, the following equations may be used to calculate heat generated by fans and motors:

If motor and drive are **outside** the airstream,

$$q_{fs} = 2545P_F$$

$$q_{fr} = 2545(P_M - P_F)$$

If motor and drive are **inside** the airstream,

$$q_{fs} = 2545P_M$$

$$q_{fr} = 0.0$$

where

- P_F = power required at fan shaft, hp
- P_M = power required at input to motor, hp
- q_{fs} = heat release to airstream, Btu/h
- q_{fr} = heat release to room housing motor and drive, Btu/h
- 2545 = conversion factor, Btu/h · hp

Supply airstream temperature rise may be determined from psychrometric formulas or Equation (9).

Variable- or adjustable-frequency drives (VFDs or AFDs) often drive fan motors in VAV air-handling units. These devices release heat to the surrounding space. Refer to manufacturers' data for heat released or efficiencies. The disposition of heat released is determined by the drive's location: in the conditioned space, in the return air path, or in a nonconditioned equipment room. These drives, and other electronic equipment such as building control, data processing, and communications devices, are temperature sensitive, so the rooms in which they are housed require cooling, frequently year-round.

Duct Surface Heat Transfer

Heat transfer across the duct surface is one mechanism for energy transfer to or from air inside a duct. It involves conduction through the duct wall and insulation, convection at inner and outer surfaces, and radiation between the duct and its surroundings. Chapter 4 presents a rigorous analysis of duct heat loss and gain, and Chapter 23 addresses application of analysis to insulated duct systems.

The effect of duct heat loss or gain depends on the duct routing, duct insulation, and its surrounding environment. Consider the following conditions:

- For duct run within the area cooled or heated by air in the duct, heat transfer from the space to the duct has no effect on heating or cooling load, but beware of the potential for condensation on cold ducts.
- For duct run through unconditioned spaces or outdoors, heat transfer adds to the cooling or heating load for the air transport system but not for the conditioned space.
- For duct run through conditioned space not served by the duct, heat transfer affects the conditioned space as well as the air transport system serving the duct.
- For an extensive duct system, heat transfer reduces the effective supply air differential temperature, requiring adjustment through air balancing to increase airflow to extremities of the distribution system.

Duct Leakage

Air leakage from supply ducts can considerably affect HVAC system energy use. Leakage reduces cooling and/or dehumidifying capacity for the conditioned space, and must be offset by increased airflow (sometimes reduced supply air temperatures), unless leaked air enters the conditioned space directly. Supply air leakage into a ceiling return plenum or leakage from unconditioned spaces into return ducts also affects return air temperature and/or humidity.

Determining leakage from a duct system is complex because of the variables in paths, fabrication, and installation methods. Refer to Chapter 21 and publications from the Sheet Metal and Air Conditioning Contractors' National Association (SMACNA) for methods of determining leakage. In general, good-quality ducts and post-installation duct sealing provide highly cost-effective energy savings, with improved thermal comfort and delivery of ventilation air.

Ceiling Return Air Plenum Temperatures

The space above a ceiling, when used as a return air path, is a ceiling return air plenum, or simply a **return plenum**. Unlike a traditional ducted return, the plenum may have multiple heat sources in the air path. These heat sources may be radiant and convective loads from lighting and transformers; conduction loads from adjacent walls, roofs, or glazing; or duct and piping systems within the plenum.

As heat from these sources is picked up by the unducted return air, the temperature differential between the ceiling cavity and conditioned space is small. Most return plenum temperatures do not rise more than 1 to 3°F above space temperature, thus generating only a relatively small thermal gradient for heat transfer through plenum surfaces, except to the outdoors. This yields a relatively large-percentage reduction in space cooling load by shifting plenum loads to the system. Another reason plenum temperatures do not rise more is leakage into the plenum from supply air ducts, and, if exposed to the roof, increasing levels of insulation.

Where the ceiling space is used as a return air plenum, energy balance requires that heat picked up from the lights into the return air (1) become part of the cooling load to the return air (represented by a temperature rise of return air as it passes through the ceiling space), (2) be partially transferred back into the conditioned space through the ceiling material below, and/or (3) be partially lost from the space through floor surfaces above the plenum. If the plenum has one or more exterior surfaces, heat gains through them must be considered; if adjacent to spaces with different indoor temperatures, partition loads must be considered, too. In a multistory building, the conditioned space frequently gains heat through its floor from a similar plenum below, offsetting the floor loss. The radiant component of heat leaving the ceiling or floor surface of a plenum is normally so small, because of relatively small temperature differences, that all such heat transfer is considered convective for calculation purposes (Rock and Wolfe 1997).

Figure 15 shows a schematic of a typical return air plenum. The following equations, using the heat flow directions shown in Figure

Fig. 15 Schematic Diagram of Typical Return Air Plenum

15, represent the heat balance of a return air plenum design for a typical interior room in a multifloor building:

$$q_1 = U_c A_c (t_p - t_r) \quad (48)$$

$$q_2 = U_f A_f (t_p - t_{fa}) \quad (49)$$

$$q_3 = 1.1 Q (t_p - t_r) \quad (50)$$

$$q_{lp} - q_2 - q_1 - q_3 = 0 \quad (51)$$

$$Q = \frac{q_r + q_1}{1.1(t_r - t_s)} \quad (52)$$

where

- q_1 = heat gain to space from plenum through ceiling, Btu/h
- q_2 = heat loss from plenum through floor above, Btu/h
- q_3 = heat gain "pickup" by return air, Btu/h
- Q = return airflow, cfm
- q_{lp} = light heat gain to plenum via return air, Btu/h
- q_{lr} = light heat gain to space, Btu/h
- q_f = heat gain from plenum below, through floor, Btu/h
- q_w = heat gain from exterior wall, Btu/h
- q_r = space cooling load, including appropriate treatment of q_{lr} , q_f , and/or q_w , Btu/h
- t_p = plenum air temperature, °F
- t_r = space air temperature, °F
- t_{fa} = space air temperature of floor above, °F
- t_s = supply air temperature, °F

By substituting Equations (48), (49), (50), and (52) into heat balance Equation (51), t_p can be found as the resultant return air temperature or plenum temperature. The results, although rigorous and best solved by computer, are important in determining the cooling load, which affects equipment size selection, future energy consumption, and other factors.

Equations (48) to (52) are simplified to illustrate the heat balance relationship. Heat gain into a return air plenum is not limited to heat from lights. Exterior walls directly exposed to the ceiling space can transfer heat directly to or from return air. For single-story buildings or the top floor of a multistory building, roof heat gain or loss enters or leaves the ceiling plenum rather than the conditioned space directly. The supply air quantity calculated by Equation (52) is only for the conditioned space under consideration, and is assumed to equal the return air quantity.

The amount of airflow through a return plenum above a conditioned space may not be limited to that supplied into the space; it will, however, have no noticeable effect on plenum temperature if the surplus comes from an adjacent plenum operating under similar conditions. Where special conditions exist, Equations (48) to (52) must be modified appropriately. Finally, although the building's thermal storage has some effect, the amount of heat entering the

return air is small and may be considered as convective for calculation purposes.

Ceiling Plenums with Ducted Returns

Compared to those in unducted plenum returns, temperatures in ceiling plenums that have well-sealed return or exhaust air ducts float considerably. In cooling mode, heat from lights and other equipment raises the ceiling plenum's temperature considerably. Solar heat gain through a poorly insulated roof can drive the ceiling plenum temperature to extreme levels, so much so that heat gains to uninsulated supply air ducts in the plenum can dramatically decrease available cooling capacity to the rooms below. In cold weather, much heat is lost from warm supply ducts. Thus, insulating supply air ducts and sealing them well to minimize air leaks are highly desirable, if not essential. Appropriately insulating roofs and plenums' exterior walls and minimizing infiltration are also key to lowering total building loads and improving HVAC system performance.

Floor Plenum Distribution Systems

Underfloor air distribution (UFAD) systems are designed to provide comfort conditions in the occupied level and allow stratification to occur above this level of the space. In contrast, room cooling loads determined by methods in this chapter assume uniform temperatures and complete mixing of air within the conditioned space, typically by conventional overhead air distribution systems. Ongoing research projects have identified several factors relating to the load calculation process:

- Heat transfer from a conditioned space with a conventional air distribution system is by convection; radiant loads are converted to convection and transferred to the airstream within the conditioned space.
- A significant fraction of heat transfer with a UFAD system is by radiation directly to the floor surface and, from there, by convection to the airstream in the supply plenum.
- Load at the cooling coil is similar for identical spaces with alternative distribution systems.

Plenums in Load Calculations

Currently, most designers include ceiling and floor plenums within neighboring occupied spaces when thermally zoning a building. However, temperatures in these plenums, and the way that they behave, are significantly different from those of occupied spaces. Thus, they should be defined as a separate thermal zone. However, most hand and computer-based load calculation routines currently do not allow floating air temperatures or humidities; assuming a constant air temperature in plenums, attics, and other unconditioned spaces is a poor, but often necessary, assumption. The heat balance method does allow floating space conditions, and when fully implemented in design load software, should allow more accurate modeling of plenums and other complex spaces.

CENTRAL PLANT

Piping

Losses must be considered for piping systems that transport heat. For water or hydronic piping systems, heat is transferred through the piping and insulation (see Chapter 23 for ways to determine this transfer). However, distribution of this transferred heat depends on the fluid in the pipe and the surrounding environment.

Consider a heating hot-water pipe. If the pipe serves a room heater and is routed through the heated space, any heat loss from the pipe adds heat to the room. Heat transfer to the heated space and heat loss from the piping system is null. If the piping is exposed to ambient conditions en route to the heater, the loss must be considered when selecting the heating equipment; if the pipe is routed

through a space requiring cooling, heat loss from the piping also becomes a load on the cooling system.

In summary, the designer must evaluate both the magnitude of the pipe heat transfer and the routing of the piping.

Pumps

Calculating heat gain from pumps is addressed in the section on Electric Motors. For pumps serving hydronic systems, disposition of heat from the pumps depends on the service. For chilled-water systems, energy applied to the fluid to generate flow and pressure becomes a chiller load. For condenser water pumps, pumping energy must be rejected through the cooling tower. The magnitude of pumping energy relative to cooling load is generally small.

EXAMPLE COOLING AND HEATING LOAD CALCULATIONS

To illustrate the cooling and heating load calculation procedures discussed in this chapter, an example problem has been developed based on building located in Atlanta, Georgia. This example is a two-story office building of approximately 30,000 ft², including a variety of common office functions and occupancies. In addition to demonstrating calculation procedures, a hypothetical design/construction process is discussed to illustrate (1) application of load calculations and (2) the need to develop reasonable assumptions when specific data is not yet available, as often occurs in everyday design processes.

SINGLE-ROOM EXAMPLE

Calculate the peak heating and cooling loads for the conference room shown in Figure 16, for Atlanta, Georgia. The room is on the second floor of a two-story building and has two vertical exterior exposures, with a flat roof above.

Room Characteristics

Area: 274 ft²

Floor: Carpeted 5 in. concrete slab on metal deck above a conditioned space.

Roof: Flat metal deck topped with rigid mineral fiber insulation and perlite board ($R = 12.5$), felt, and light-colored membrane roofing. Space above 9 ft suspended acoustical tile ceiling is used as a return air plenum. Assume 30% of the cooling load from the roof is directly absorbed in the return airstream without becoming room load. Use roof $U = 0.07 \text{ Btu/h} \cdot \text{ft}^2 \cdot ^\circ\text{F}$.

Spandrel wall: Spandrel bronze-tinted glass, opaque, backed with air space, rigid mineral fiber insulation ($R = 5.0$), mineral fiber batt insulation ($R = 5.0$), and 5/8 in. gypsum wall board. Use spandrel wall $U = 0.08 \text{ Btu/h} \cdot \text{ft}^2 \cdot ^\circ\text{F}$.

Brick wall: Light-brown-colored face brick (4 in.), mineral fiber batt insulation ($R = 10$), lightweight concrete block (6 in.) and gypsum wall board (5/8 in.). Use brick wall $U = 0.08 \text{ Btu/h} \cdot \text{ft}^2 \cdot ^\circ\text{F}$.

Windows: Double glazed, 1/4 in. bronze-tinted outside pane, 1/2 in. air space and 1/4 in. clear inside pane with light-colored interior miniblinds. Window normal solar heat gain coefficient (SHGC) = 0.49. Windows are nonoperable and mounted in aluminum frames with thermal breaks having overall combined $U = 0.56 \text{ Btu/h} \cdot \text{ft}^2 \cdot ^\circ\text{F}$ (based on Type 5d from Tables 4 and 10 of Chapter 15). Inside attenuation coefficients (IACs) for inside miniblinds are based on light venetian blinds (assumed louver reflectance = 0.8 and louvers positioned at 45° angle) with heat-absorbing double glazing (Type 5d from Table 13B of Chapter 15), $\text{IAC}(0) = 0.74$, $\text{IAC}(60) = 0.65$, $\text{IAD}(\text{diff}) = 0.79$, and radiant fraction = 0.54. Each window is 6.25 ft wide by 6.4 ft tall for an area per window = 40 ft².

South exposure: Orientation = 30° east of true south
Window area = 40 ft²

Fig. 16 Single-Room Example Conference Room

	Spandrel wall area	= 60 ft ²
	Brick wall area	= 60 ft ²
<i>West exposure:</i>	Orientation	= 60° west of south
	Window area	= 80 ft ²
	Spandrel wall area	= 120 ft ²
	Brick wall area	= 75 ft ²

Occupancy: 12 people from 8:00 AM to 5:00 PM.

Lighting: Four 3-lamp recessed fluorescent 2 by 4 ft parabolic reflector (without lens) type with side slot return-air-type fixtures. Each fixture has three 32 W T-8 lamps plus electronic ballasts, for a total of 110 W per fixture or 440 W total for the room. Operation is from 7:00 AM to 7:00 PM. Assume 26% of the cooling load from lighting is directly absorbed in the return air stream without becoming room load, per Table 3.

Equipment: Several computers and a video projector may be used, for which an allowance of 1 W/ft² is to be accommodated by the cooling system, for a total of 274 W for the room. Operation is from 8:00 AM to 5:00 PM.

Infiltration: For purposes of this example, assume the building is maintained under positive pressure during peak cooling conditions and therefore has no infiltration. Assume that infiltration during peak heating conditions is equivalent to one air change per hour.

Weather data: Per Chapter 14, for Atlanta, Georgia, latitude = 33.64, longitude = 84.43, elevation = 1027 ft above sea level, 99.6% heating design dry-bulb temperature = 20.7°F. For cooling load calculations, use 5% dry-bulb/coincident wet-bulb monthly design day profile calculated per Chapter 14. See Table 26 for temperature profiles used in these examples.

Inside design conditions: 72°F for heating; 75°F with 50% rh for cooling.

Cooling Loads Using RTS Method

Traditionally, simplified cooling load calculation methods have estimated the total cooling load at a particular design condition by independently calculating and then summing the load from each component (walls, windows, people, lights, etc.). Although the actual heat transfer processes for each component do affect each other, this simplification is appropriate for design load calculations and useful

to the designer in understanding the relative contribution of each component to the total cooling load.

Cooling loads are calculated with the RTS method on a component basis similar to previous methods. The following example parts illustrate cooling load calculations for individual components of this single room for a particular hour and month.

Part 1. Internal cooling load using radiant time series. Calculate the cooling load from lighting at 3:00 PM for the previously described conference room.

Solution: First calculate the 24 h heat gain profile for lighting, then split those heat gains into radiant and convective portions, apply the appropriate RTS to the radiant portion, and sum the convective and radiant cooling load components to determine total cooling load at the designated time. Using Equation (1), the lighting heat gain profile, based on the occupancy schedule indicated is

$$\begin{aligned}
 q_1 &= (440 \text{ W})3.41(0\%) = 0 & q_{13} &= (440 \text{ W})3.41(100\%) = 1500 \\
 q_2 &= (440 \text{ W})3.41(0\%) = 0 & q_{14} &= (440 \text{ W})3.41(100\%) = 1500 \\
 q_3 &= (440 \text{ W})3.41(0\%) = 0 & q_{15} &= (440 \text{ W})3.41(100\%) = 1500 \\
 q_4 &= (440 \text{ W})3.41(0\%) = 0 & q_{16} &= (440 \text{ W})3.41(100\%) = 1500 \\
 q_5 &= (440 \text{ W})3.41(0\%) = 0 & q_{17} &= (440 \text{ W})3.41(100\%) = 1500 \\
 q_6 &= (440 \text{ W})3.41(0\%) = 0 & q_{18} &= (440 \text{ W})3.41(100\%) = 1500 \\
 q_7 &= (440 \text{ W})3.41(100\%) = 1500 & q_{19} &= (440 \text{ W})3.41(0\%) = 0 \\
 q_8 &= (440 \text{ W})3.41(100\%) = 1500 & q_{20} &= (440 \text{ W})3.41(0\%) = 0 \\
 q_9 &= (440 \text{ W})3.41(100\%) = 1500 & q_{21} &= (440 \text{ W})3.41(0\%) = 0 \\
 q_{10} &= (440 \text{ W})3.41(100\%) = 1500 & q_{22} &= (440 \text{ W})3.41(0\%) = 0 \\
 q_{11} &= (440 \text{ W})3.41(100\%) = 1500 & q_{23} &= (440 \text{ W})3.41(0\%) = 0 \\
 q_{12} &= (440 \text{ W})3.41(100\%) = 1500 & q_{24} &= (440 \text{ W})3.41(0\%) = 0
 \end{aligned}$$

The convective portion is simply the lighting heat gain for the hour being calculated times the convective fraction for recessed fluorescent lighting fixtures without lens and with side slot return air, from Table 3:

$$Q_{c,15} = (1500)(52\%) = 780 \text{ Btu/h}$$

The radiant portion of the cooling load is calculated using lighting heat gains for the current hour and past 23 h, the radiant fraction from Table 3 (48%), and radiant time series from Table 19, in accordance with Equation (34). From Table 19, select the RTS for medium-weight construction, assuming 50% glass and carpeted floors as representative of the described construction. Thus, the radiant cooling load for lighting is

$$\begin{aligned}
 Q_{r,15} &= r_0(0.48)q_{15} + r_1(0.48)q_{14} + r_2(0.48)q_{13} + r_3(0.48)q_{12} \\
 &\quad + \dots + r_{23}(0.48)q_{16} \\
 &= (0.49)(0.48)(1500) + (0.17)(0.48)(1500) \\
 &+ (0.09)(0.48)(1500) + (0.05)(0.48)(1500) + (0.03)(0.48)(1500) \\
 &+ (0.02)(0.48)(1500) + (0.02)(0.48)(1500) + (0.01)(0.48)(1500) \\
 &\quad + (0.01)(0.48)(1500) + (0.01)(0.48)(0) + (0.01)(0.48)(0) \\
 &\quad + (0.01)(0.48)(0) + (0.01)(0.48)(0) + (0.01)(0.48)(0) \\
 &\quad + (0.01)(0.48)(0) + (0.01)(0.48)(0) + (0.01)(0.48)(0) \\
 &\quad + (0.00)(0.48)(0) + (0.00)(0.48)(1500) + (0.00)(0.48)(1500) \\
 &\quad + (0.00)(0.48)(1500) = 641 \text{ Btu/h}
 \end{aligned}$$

The total lighting cooling load at the designated hour is thus

$$Q_{light} = Q_{c,15} + Q_{r,15} = 780 + 641 = 1421 \text{ Btu/h}$$

As noted in the example definition, if it is assumed that 26% of the total lighting load is absorbed by the return air stream, the net lighting cooling load to the room is

$$Q_{light-room, 15} = Q_{light,15} (74\%) = 1421(0.74) = 1052 \text{ Btu/h}$$

See Table 27 for the conference room's lighting usage, heat gain, and cooling load profiles.

Part 2. Wall cooling load using sol-air temperature, conduction time series and radiant time series. Calculate the cooling load contribution from the spandrel wall section facing 60° west of south at 3:00 PM local standard time in July for the previously described conference room.

Solution: Determine the wall cooling load by calculating (1) sol-air temperatures at the exterior surface, (2) heat input based on sol-air temperature, (3) delayed heat gain through the mass of the wall to the interior surface using conduction time series, and (4) delayed space cooling load from heat gain using radiant time series.

First, calculate the sol-air temperature at 3:00 PM local standard time (LST) (4:00 PM daylight saving time) on July 21 for a vertical, dark-colored wall surface, facing 60° west of south, located in Atlanta, Georgia (latitude = 33.64, longitude = 84.43), solar taub = 0.556 and taud = 1.779 from monthly Atlanta weather data for July (Table 1 in Chapter 14). From Table 26, the calculated outdoor design temperature for that month and time is 92°F. The ground reflectivity is assumed $\rho_g = 0.2$.

Sol-air temperature is calculated using Equation (30). For the dark-colored wall, $\alpha/h_o = 0.30$, and for vertical surfaces, $\epsilon\Delta R/h_o = 0$. The solar irradiance E_t on the wall must be determined using the equations in Chapter 14:

Solar Angles:

$$\psi = \text{southwest orientation} = +60^\circ$$

Σ = surface tilt from horizontal (where horizontal = 0°) = 90° for vertical wall surface

$$3:00 \text{ PM LST} = \text{hour } 15$$

Calculate solar altitude, solar azimuth, surface solar azimuth, and incident angle as follows:

From Table 2 in Chapter 14, solar position data and constants for July 21 are

$$ET = -6.4 \text{ min}$$

$$\delta = 20.4^\circ$$

$$E_o = 419.8 \text{ Btu/h} \cdot \text{ft}^2$$

Local standard meridian (LSM) for Eastern Time Zone = 75°.

Apparent solar time AST

$$\begin{aligned}
 \text{AST} &= \text{LST} + ET/60 + (\text{LSM} - \text{LON})/15 \\
 &= 15 + (-6.4/60) + [(75 - 84.43)/15] \\
 &= 14.2647
 \end{aligned}$$

Hour angle H , degrees

$$\begin{aligned}
 H &= 15(\text{AST} - 12) \\
 &= 15(14.2647 - 12) \\
 &= 33.97^\circ
 \end{aligned}$$

Solar altitude β

$$\begin{aligned}
 \sin \beta &= \cos L \cos \delta \cos H + \sin L \sin \delta \\
 &= \cos (33.64) \cos (20.4) \cos (33.97) + \sin (33.64) \sin (20.4) \\
 &= 0.841 \\
 \beta &= \sin^{-1}(0.841) = 57.2^\circ
 \end{aligned}$$

Solar azimuth ϕ

$$\begin{aligned}
 \cos \phi &= (\sin \beta \sin L - \sin \delta) / (\cos \beta \cos L) \\
 &= [(\sin (57.2) \sin (33.64) - \sin (20.4))] / [\cos (57.2) \cos (33.64)] \\
 &= 0.258 \\
 \phi &= \cos^{-1}(0.253) = 75.05^\circ
 \end{aligned}$$

Surface-solar azimuth γ

$$\begin{aligned}
 \gamma &= \phi - \psi \\
 &= 75.05 - 60 \\
 &= 15.05^\circ
 \end{aligned}$$

Incident angle θ

$$\begin{aligned}
 \cos \theta &= \cos \beta \cos \gamma \sin \Sigma + \sin \beta \cos \Sigma \\
 &= \cos (57.2) \cos (15.05) \sin (90) + \sin (57.2) \cos (90) \\
 &= 0.523 \\
 \theta &= \cos^{-1}(0.523) = 58.5^\circ
 \end{aligned}$$

Beam normal irradiance E_b

$$\begin{aligned}
 E_b &= E_o \exp(-\tau_b m^{ab}) \\
 m &= \text{relative air mass} \\
 &= 1/[\sin \beta + 0.50572(6.07995 + \beta)^{-1.6364}], \beta \text{ expressed in degrees} \\
 &= 1.18905
 \end{aligned}$$

Table 26 Monthly/Hourly Design Temperatures (5% Conditions) for Atlanta, GA, °F

$$\begin{aligned}
 ab &= \text{beam air mass exponent} \\
 &= 1.219 - 0.043\tau_b - 0.151\tau_d - 0.204\tau_b\tau_d \\
 &= 0.72468 \\
 E_b &= 419.8 \exp[-0.556(1.8905^{0.72468})] \\
 &= 223.5 \text{ Btu/h}\cdot\text{ft}^2
 \end{aligned}$$

Surface beam irradiance $E_{t,b}$

$$\begin{aligned}
 E_{t,b} &= E_b \cos \theta \\
 &= (223.5) \cos(58.5) \\
 &= 117 \text{ Btu/h}\cdot\text{ft}^2
 \end{aligned}$$

Ratio Y of sky diffuse radiation on vertical surface to sky diffuse radiation on horizontal surface

$$\begin{aligned}
 Y &= 0.55 + 0.437 \cos \theta + 0.313 \cos^2 \theta \\
 &= 0.55 + 0.437 \cos(58.5) + 0.313 \cos^2(58.5) \\
 &= 0.864
 \end{aligned}$$

Diffuse irradiance E_d – Horizontal surfaces

$$\begin{aligned}
 E_d &= E_o \exp(-\tau_d m^{ad}) \\
 ad &= \text{diffuse air mass exponent} \\
 &= 0.202 + 0.852\tau_b - 0.007\tau_d - 0.357\tau_b\tau_d \\
 &= 0.3101417 \\
 E_d &= E_o \exp(-\tau_d m^{ad}) \\
 &= 419.8 \exp(-1.779(1.8905^{0.3101417})) \\
 &= 64.24 \text{ Btu/h}\cdot\text{ft}^2
 \end{aligned}$$

Diffuse irradiance E_{d} – Vertical surfaces

$$\begin{aligned}
 E_{i,d} &= E_d Y \\
 &= (64.24)(0.864) \\
 &= 55.5 \text{ Btu/h}\cdot\text{ft}^2
 \end{aligned}$$

Ground reflected irradiance $E_{t,r}$

$$\begin{aligned}
 E_{t,r} &= (E_b \sin \beta + E_d) \rho_g (1 - \cos \Sigma) / 2 \\
 &= [223.5 \sin(57.2) + 64.24](0.2)[1 - \cos(90)] / 2 \\
 &= 25.2 \text{ Btu/h}\cdot\text{ft}^2
 \end{aligned}$$

Total surface irradiance E_t

$$\begin{aligned}
 E_t &= E_D + E_d + E_r \\
 &= 117 + 55.5 + 25.2 \\
 &= 197.7 \text{ Btu/h}\cdot\text{ft}^2
 \end{aligned}$$

Sol-air temperature [from Equation (30)]:

$$\begin{aligned}
 T_e &= t_o + \alpha E_t / h_o - \varepsilon \Delta R / h_o \\
 &= 92 + (0.30)(197.7) - 0 \\
 &= 151^\circ\text{F}
 \end{aligned}$$

This procedure is used to calculate the sol-air temperatures for each hour on each surface. Because of the tedious solar angle and intensity calculations, using a simple computer spreadsheet or other computer software can reduce the effort involved. A spreadsheet was used to calculate a 24 h sol-air temperature profile for the data of this example. See Table 28A for the solar angle and intensity calculations and Table 28B for the sol-air temperatures for this wall surface and orientation.

Conductive heat gain is calculated using Equations (31) and (32). First, calculate the 24 h heat input profile using Equation (31) and the sol-air temperatures for a southwest-facing wall with dark exterior color:

$$\begin{aligned}
 q_{i,1} &= (0.08)(120)(73.8 - 75) &= -12 \text{ Btu/h} \\
 q_{i,2} &= (0.08)(120)(73 - 75) &= -19 \\
 q_{i,3} &= (0.08)(120)(72.3 - 75) &= -26 \\
 q_{i,4} &= (0.08)(120)(71.7 - 75) &= -32 \\
 q_{i,5} &= (0.08)(120)(71.3 - 75) &= -36 \\
 q_{i,6} &= (0.08)(120)(72.7 - 75) &= -22 \\
 q_{i,7} &= (0.08)(120)(78.4 - 75) &= 33 \\
 q_{i,8} &= (0.08)(120)(85.9 - 75) &= 104 \\
 q_{i,9} &= (0.08)(120)(93.1 - 75) &= 174 \\
 q_{i,10} &= (0.08)(120)(99.3 - 75) &= 234 \\
 q_{i,11} &= (0.08)(120)(104.5 - 75) &= 283 \\
 q_{i,12} &= (0.08)(120)(109.2 - 75) &= 328 \\
 q_{i,13} &= (0.08)(120)(125.4 - 75) &= 484 \\
 q_{i,14} &= (0.08)(120)(141.4 - 75) &= 638 \\
 q_{i,15} &= (0.08)(120)(151.3 - 75) &= 733 \\
 q_{i,16} &= (0.08)(120)(152.7 - 75) &= 746 \\
 q_{i,17} &= (0.08)(120)(144.8 - 75) &= 670 \\
 q_{i,18} &= (0.08)(120)(126.6 - 75) &= 495 \\
 q_{i,19} &= (0.08)(120)(98 - 75) &= 221 \\
 q_{i,20} &= (0.08)(120)(81.7 - 75) &= 64 \\
 q_{i,21} &= (0.08)(120)(79.8 - 75) &= 46 \\
 q_{i,22} &= (0.08)(120)(77.9 - 75) &= 28
 \end{aligned}$$

$$\begin{aligned}
 q_{i,23} &= (0.08)(120)(76.3 - 75) &= 12 \\
 q_{i,24} &= (0.08)(120)(75 - 75) &= 0
 \end{aligned}$$

Next, calculate wall heat gain using conduction time series. The preceding heat input profile is used with conduction time series to calculate the wall heat gain. From Table 16, the most similar wall construction is wall number 1. This is a spandrel glass wall that has similar mass and thermal capacity. Using Equation (32), the conduction time factors for wall 1 can be used in conjunction with the 24 h heat input profile to determine the wall heat gain at 3:00 PM LST:

$$\begin{aligned}
 q_{15} &= c_0 q_{i,15} + c_1 q_{i,14} + c_2 q_{i,13} + c_3 q_{i,12} + \dots + c_{23} q_{i,14} \\
 &= (0.18)(733) + (0.58)(638) + (0.20)(484) + (0.04)(328) \\
 &\quad + (0.00)(283) + (0.00)(234) + (0.00)(174) + (0.00)(104) \\
 &\quad + (0.00)(33) + (0.00)(-22) + (0.00)(-36) + (0.00)(-32) \\
 &\quad + (0.00)(-26) + (0.00)(-19) + (0.00)(-12) + (0.00)(0) \\
 &\quad + (0.00)(12) + (0.00)(28) + (0.00)(46) + (0.00)(64) \\
 &\quad + (0.00)(221) + (0.00)(495) + (0.00)(670) + (0.00)(746) \\
 &= 612 \text{ Btu/h}
 \end{aligned}$$

Because of the tedious calculations involved, a spreadsheet is used to calculate the remainder of a 24 h heat gain profile indicated in Table 28B for the data of this example.

Finally, calculate wall cooling load using radiant time series. Total cooling load for the wall is calculated by summing the convective and radiant portions. The convective portion is simply the wall heat gain for the hour being calculated times the convective fraction for walls from Table 14 (54%):

$$Q_c = (612)(0.54) = 330 \text{ Btu/h}$$

The radiant portion of the cooling load is calculated using conductive heat gains for the current and past 23 h, the radiant fraction for walls from Table 14 (46%), and radiant time series from Table 19, in accordance with Equation (34). From Table 19, select the RTS for medium-weight construction, assuming 50% glass and carpeted floors as representative for the described construction. Use the wall heat gains from Table 28B for 24 h design conditions in July. Thus, the radiant cooling load for the wall at 3:00 PM is

$$\begin{aligned}
 Q_{r,15} &= r_0(0.46)q_{i,15} + r_1(0.46)q_{i,14} + r_2(0.46)q_{i,13} + r_3(0.46)q_{i,12} \\
 &\quad + \dots + r_{23}(0.46)q_{i,16} \\
 &= (0.49)(0.46)(612) + (0.17)(0.46)(472) + (0.09)(0.46)(344) \\
 &\quad + (0.05)(0.46)(277) + (0.03)(0.46)(225) + (0.02)(0.46)(165) \\
 &\quad + (0.02)(0.46)(97) + (0.01)(0.46)(32) + (0.01)(0.46)(-15) \\
 &\quad + (0.01)(0.46)(-32) + (0.01)(0.46)(-31) + (0.01)(0.46)(-25) \\
 &\quad + (0.01)(0.46)(-18) + (0.01)(0.46)(-10) + (0.01)(0.46)(2) \\
 &\quad + (0.01)(0.46)(15) + (0.01)(0.46)(30) + (0.01)(0.46)(53) \\
 &\quad + (0.01)(0.46)(110) + (0.01)(0.46)(266) + (0.00)(0.46)(491) \\
 &\quad + (0.00)(0.46)(656) + (0.00)(0.46)(725) + (0.00)(0.46)(706) \\
 &= 203 \text{ Btu/h}
 \end{aligned}$$

The total wall cooling load at the designated hour is thus

$$Q_{wall} = Q_c + Q_{r15} = 330 + 203 = 533 \text{ Btu/h}$$

Again, a simple computer spreadsheet or other software is necessary to reduce the effort involved. A spreadsheet was used with the heat gain profile to split the heat gain into convective and radiant portions, apply RTS to the radiant portion, and total the convective and radiant loads to determine a 24 h cooling load profile for this example, with results in Table 28B.

Part 3. Window cooling load using radiant time series. Calculate the cooling load contribution, with and without inside shading (venetian blinds) for the window area facing 60° west of south at 3:00 PM in July for the conference room example.

Solution: First, calculate the 24 h heat gain profile for the window, then split those heat gains into radiant and convective portions, apply the appropriate RTS to the radiant portion, then sum the convective and radiant cooling load components to determine total window cooling load for the time. The window heat gain components are calculated using Equations (13) to (15). From Part 2, at hour 15 LST (3:00 PM):

$$\begin{aligned}
 E_{t,b} &= 117 \text{ Btu/h}\cdot\text{ft}^2 \\
 E_{i,d} &= 55.5 \text{ Btu/h}\cdot\text{ft}^2 \\
 E_r &= 25.2 \text{ Btu/h}\cdot\text{ft}^2 \\
 \theta &= 58.5^\circ
 \end{aligned}$$

From Chapter 15, Table 10, for glass type 5d,

$$SHGC(\theta) = SHGC(58.5) = 0.3978 \text{ (interpolated)}$$

$$\langle SHGC \rangle_D = 0.41$$

From Chapter 15, Table 13B, for light-colored blinds (assumed louver reflectance = 0.8 and louvers positioned at 45° angle) on double-glazed, heat-absorbing windows (Type 5d from Table 13B of Chapter 15), IAC(0) = 0.74, IAC(60) = 0.65, IAC(diff) = 0.79, and radiant fraction = 0.54. Without blinds, IAC = 1.0. Therefore, window heat gain components for hour 15, without blinds, are

$$q_{b15} = AE_{t,b} SHGC(\theta) IAC = (80)(117)(0.3978)(1.00) = 3722 \text{ Btu/h}$$

$$q_{d15} = A(E_{t,d} + E_r) \langle SHGC \rangle_D IAC = (80)(55.5 + 25.2)(0.41)(1.00) = 2648 \text{ Btu/h}$$

$$q_{c15} = UA(t_{out} - t_{in}) = (0.56)(80)(92 - 75) = 762 \text{ Btu/h}$$

This procedure is repeated to determine these values for a 24 h heat gain profile, shown in Table 29.

Total cooling load for the window is calculated by summing the convective and radiant portions. For windows with inside shading (blinds, drapes, etc.), the direct beam, diffuse, and conductive heat gains may be summed and treated together in calculating cooling loads. However, in this example, the window does not have inside shading, and the direct beam solar heat gain should be treated separately from the diffuse and conductive heat gains. The direct beam heat gain, without inside shading, is treated as 100% radiant, and solar RTS factors from Table 20 are used to convert the beam heat gains to cooling loads. The diffuse and conductive heat gains can be totaled and split into radiant and convective portions according to Table 14, and nonsolar RTS factors from Table 19 are used to convert the radiant portion to cooling load.

The solar beam cooling load is calculated using heat gains for the current hour and past 23 h and radiant time series from Table 20, in accordance with Equation (39). From Table 20, select the solar RTS for medium-weight construction, assuming 50% glass and carpeted floors

for this example. Using Table 29 values for direct solar heat gain, the radiant cooling load for the window direct beam solar component is

$$\begin{aligned} Q_{b,15} &= r_0 q_{b,15} + r_1 q_{b,14} + r_2 q_{b,13} + r_3 q_{b,12} + \dots + r_{23} q_{b,14} \\ &= (0.54)(3722) + (0.16)(2183) + (0.08)(537) + (0.04)(0) \\ &\quad + (0.03)(0) + (0.02)(0) + (0.01)(0) + (0.01)(0) + (0.01)(0) \\ &\quad + (0.01)(0) + (0.01)(0) + (0.01)(0) + (0.01)(0) + (0.01)(0) \\ &\quad + (0.01)(0) + (0.01)(0) + (0.01)(0) + (0.01)(0) + (0.01)(0) \\ &\quad + (0.00)(0) + (0.00)(1017) + (0.00)(3177) + (0.00)(4392) \\ &\quad + (0.00)(4583) = 2402 \text{ Btu/h} \end{aligned}$$

This process is repeated for other hours; results are listed in Table 30.

For diffuse and conductive heat gains, the radiant fraction according to Table 14 is 46%. The radiant portion is processed using nonsolar RTS coefficients from Table 19. The results are listed in Tables 29 and 30. For 3:00 PM, the diffuse and conductive cooling load is 3144 Btu/h. The total window cooling load at the designated hour is thus

$$Q_{window} = Q_b + Q_{diff+cond} = 2402 + 3144 = 5546 \text{ Btu/h}$$

Again, a computer spreadsheet or other software is commonly used to reduce the effort involved in calculations. The spreadsheet illustrated in Table 29 is expanded in Table 30 to include splitting the heat gain into convective and radiant portions, applying RTS to the radiant portion, and totaling the convective and radiant loads to determine a 24 h cooling load profile for a window without inside shading.

If the window has an inside shading device, it is accounted for with the inside attenuation coefficients (IAC), the radiant fraction, and the RTS type used. If a window has no inside shading, 100% of the direct beam energy is assumed to be radiant and solar RTS factors are used. However, if an inside shading device is present, the direct beam is assumed to be interrupted by the shading device, and a portion immediately becomes cooling load by convection. Also, the energy is assumed to be radiated to all surfaces of the room, therefore nonsolar RTS values are used to convert the radiant load into cooling load.

IAC values depend on several factors: (1) type of shading device, (2) position of shading device relative to window, (3) reflectivity of shading device, (4) angular adjustment of shading device, as well as (5) solar position relative to the shading device. These factors are discussed

Table 30 Window Component of Cooling Load (No Blinds or Overhang)

in detail in Chapter 15. For this example with venetian blinds, the IAC for beam radiation is treated separately from the diffuse solar gain. The direct beam IAC must be adjusted based on the profile angle of the sun. At 3:00 PM in July, the profile angle of the sun relative to the window surface is 58°. Calculated using Equation (45) from Chapter 15, the beam IAC = 0.653. The diffuse IAC is 0.79. Thus, the window heat gains, with light-colored blinds, at 3:00 PM are

$$q_{b15} = AE_D \text{SHGC}(\theta)(\text{IAC}) = (80)(117)(0.3978)(0.653) = 2430 \text{ Btu/h}$$

$$q_{d15} = A(E_d + E_r)(\text{SHGC})_D(\text{IAC})_D = (80)(55.5 + 25.2)(0.41)(0.79) = 2092 \text{ Btu/h}$$

$$q_{c15} = UA(t_{out} - t_{in}) = (0.56)(80)(92 - 75) = 762 \text{ Btu/h}$$

Because the same radiant fraction and nonsolar RTS are applied to all parts of the window heat gain when inside shading is present, those loads can be totaled and the cooling load calculated after splitting the radiant portion for processing with nonsolar RTS. This is illustrated by the spreadsheet results in Table 31. The total window cooling load with venetian blinds at 3:00 PM = 4500 Btu/h.

Part 4. Window cooling load using radiant time series for window with overhang shading. Calculate the cooling load contribution for the previous example with the addition of a 10 ft overhang shading the window.

Solution: In Chapter 15, methods are described and examples provided for calculating the area of a window shaded by attached vertical or horizontal projections. For 3:00 PM LST in July, the solar position calculated in previous examples is

$$\text{Solar altitude } \beta = 57.2^\circ$$

$$\text{Solar azimuth } \phi = 75.1^\circ$$

$$\text{Surface-solar azimuth } \gamma = 15.1^\circ$$

From Chapter 15, Equation (106), profile angle Ω is calculated by

$$\tan \Omega = \tan \beta / \cos \gamma = \tan(57.2) / \cos(15.1) = 1.6087$$

$$\Omega = 58.1^\circ$$

From Chapter 15, Equation (40), shadow height S_H is

$$S_H = P_H \tan \Omega = 10(1.6087) = 16.1 \text{ ft}$$

Because the window is 6.4 ft tall, at 3:00 PM the window is completely shaded by the 10 ft deep overhang. Thus, the shaded window heat gain includes only diffuse solar and conduction gains. This is converted to cooling load by separating the radiant portion, applying RTS, and adding the resulting radiant cooling load to the convective portion to determine total cooling load. Those results are in Table 32. The total window cooling load = 2631 Btu/h.

Part 5. Room cooling load total. Calculate the sensible cooling loads for the previously described conference room at 3:00 PM in July.

Solution: The steps in the previous example parts are repeated for each of the internal and external loads components, including the southeast facing window, spandrel and brick walls, the southwest facing brick wall, the roof, people, and equipment loads. The results are tabulated in Table 33. The total room sensible cooling load for the conference room is 10,022 Btu/h at 3:00 PM in July. When this calculation process is repeated for a 24 h design day for each month, it is found that the peak room sensible cooling load actually occurs in August at hour 15 (3:00 PM solar time) at 10,126 Btu/h as indicated in Table 34.

Although simple in concept, these steps involved in calculating cooling loads are tedious and repetitive, even using the “simplified” RTS method; practically, they should be performed using a computer spreadsheet or other program. The calculations should be repeated for multiple design conditions (i.e., times of day, other months) to determine the maximum cooling load for mechanical equipment sizing. Example spreadsheets for computing each cooling load component using conduction and radiant time series have been compiled and are available from ASHRAE. To illustrate the full building example discussed previously, those individual component spreadsheets have been compiled to allow calculation of

cooling and heating loads on a room by room basis as well as for a “block” calculation for analysis of overall areas or buildings where detailed room-by-room data is not available.

SINGLE-ROOM EXAMPLE PEAK HEATING LOAD

Although the physics of heat transfer that creates a heating load is identical to that for cooling loads, a number of traditionally used simplifying assumptions facilitate a much simpler calculation procedure. As described in the Heating Load Calculations section, design heating load calculations typically assume a single outside temperature, with no heat gain from solar or internal sources, under steady-state conditions. Thus, space heating load is determined by computing the heat transfer rate through building envelope elements ($UA\Delta T$) plus heat required because of outside air infiltration.

Part 6. Room heating load. Calculate the room heating load for the previous described conference room, including infiltration airflow at one air change per hour.

Solution: Because solar heat gain is not considered in calculating design heating loads, orientation of similar envelope elements may be ignored and total areas of each wall or window type combined. Thus, the total spandrel wall area = $60 + 120 = 180 \text{ ft}^2$, total brick wall area = $60 + 75 = 135 \text{ ft}^2$, and total window area = $40 + 80 = 120 \text{ ft}^2$. For this example, use the U-factors that were used for cooling load conditions. In some climates, higher prevalent winds in winter should be considered in calculating U-factors (see Chapter 25 for information on calculating U-factors and surface heat transfer coefficients appropriate for local wind conditions). The 99.6% heating design dry-bulb temperature for Atlanta is 20.7°F and the inside design temperature is 72°F. The room volume with a 9 ft ceiling = $9 \times 274 = 2466 \text{ ft}^3$. At one air change per hour, the infiltration airflow = $1 \times 2466/60 = 41 \text{ cfm}$. Thus, the heating load is

Windows:	$0.56 \times 120 \times (72 - 20.7) =$	3447 Btu/h
Spandrel Wall:	$0.09 \times 180 \times (72 - 20.7) =$	831
Brick Wall:	$0.08 \times 135 \times (72 - 20.7) =$	554
Roof:	$0.07 \times 274 \times (72 - 20.7) =$	984
Infiltration:	$41 \times 1.1 \times (72 - 20.7) =$	2314
Total Room Heating Load:		8130 Btu/h

WHOLE-BUILDING EXAMPLE

Because a single-room example does not illustrate the full application of load calculations, a multistory, multiple-room example building has been developed to show a more realistic case. A hypothetical project development process is described to illustrate its effect on the application of load calculations.

Design Process and Shell Building Definition

A development company has acquired a piece of property in Atlanta, GA, to construct an office building. Although no tenant or end user has yet been identified, the owner/developer has decided to proceed with the project on a speculative basis. They select an architectural design firm, who retains an engineering firm for the mechanical and electrical design.

At the first meeting, the developer indicates the project is to proceed on a fast-track basis to take advantage of market conditions; he is negotiating with several potential tenants who will need to occupy the new building within a year. This requires preparing

shell-and-core construction documents to obtain a building permit, order equipment, and begin construction to meet the schedule.

The shell-and-core design documents will include finished design of the building exterior (the **shell**), as well as permanent interior elements such as stairs, restrooms, elevator, electrical rooms and mechanical spaces (the **core**). The primary mechanical equipment must be sized and installed as part of the shell-and-core package in order for the project to meet the schedule, even though the building occupant is not yet known.

The architect selects a two-story design with an exterior skin of tinted, double-glazed vision glass; opaque, insulated spandrel glass, and brick pilasters. The roof area extends beyond the building edge to form a substantial overhang, shading the second floor windows. Architectural drawings for the shell-and-core package (see Figures 17 to 22) include plans, elevations, and skin construction details, and are furnished to the engineer for use in “block” heating and cooling load calculations. Mechanical systems and equipment must be specified and installed based on those calculations. (*Note:* Full-size, scalable electronic versions of the drawings in Figures 17 to

Table 35 Block Load Example: Envelope Area Summary, ft²

	Floor Area	Brick Areas				Spandrel/Soffit Areas				Window Areas			
		North	South	East	West	North	South	East	West	North	South	East	West

Second Floor	15,050	510	510	300	300	1040	1000	540	540	560	600	360	360
Building Total	30,100	1190	1190	700	700	1740	1700	900	900	1160	1160	720	720

22, as well as detailed lighting plans, are available from ASHRAE at www.ashrae.org.)

The HVAC design engineer meets with the developer's operations staff to agree on the basic HVAC systems for the project. Based on their experience operating other buildings and the lack of specific information on the tenant(s), the team decides on two variable-volume air-handling units (AHUs), one per floor, to provide operating flexibility if one floor is leased to one tenant and the other floor to someone else. Cooling will be provided by an air-cooled chiller located on grade across the parking lot. Heating will be provided by electric resistance heaters in parallel-type fan-powered variable-air-volume (VAV) terminal units. The AHUs must be sized quickly to confirm the size of the mechanical rooms on the architectural plans. The AHUs and chiller must be ordered by the mechanical subcontractor within 10 days to meet the construction schedule. Likewise, the electric heating loads must be provided to the electrical engineers to size the electrical service and for the utility company to extend services to the site.

The mechanical engineer must determine the (1) peak airflow and cooling coil capacity for each AHU, (2) peak cooling capacity required for the chiller, and (3) total heating capacity for sizing the electrical service.

Solution: First, calculate "block" heating and cooling loads for each floor to size the AHUs, then calculate a block load for the whole building determine chiller and electric heating capacity.

Based on the architectural drawings, the HVAC engineer assembles basic data on the building as follows:

Location: Atlanta, GA. Per Chapter 14, latitude = 33.64, longitude = 84.43, elevation = 1027 ft above sea level, 99.6% heating design dry-bulb temperature = 20.7°F. For cooling load calculations, use 5% dry-bulb/coincident wet-bulb monthly design day profile from Chapter 14 (on CD-ROM). See Table 26 for temperature profiles used in these examples.

Inside design conditions: 72°F for heating; 75°F with 50% rh for cooling.

Building orientation: Plan north is 30° west of true north.

Gross area per floor: 15,050 ft²

Total building gross area: 30,100 ft²

Windows: Bronze-tinted, double-glazed. Solar heat gain coefficients, U-factors are as in the single-room example.

Walls: Part insulated spandrel glass and part brick-and-block clad columns. The insulation barrier in the soffit at the second floor is similar to that of the spandrel glass and is of lightweight construction; for simplicity, that surface is assumed to have similar thermal heat gain/loss to the spandrel glass. Construction and insulation values are as in single-room example.

Roof: Metal deck, topped with board insulation and membrane roofing. Construction and insulation values are as in the single-room example.

Floor: 5 in. lightweight concrete slab on grade for first floor and 5 in. lightweight concrete on metal deck for second floor

Total areas of building exterior skin, as measured from the architectural plans, are listed in Table 35.

The engineer needs additional data to estimate the building loads. Thus far, no tenant has yet been signed, so no interior layouts for population counts, lighting layouts or equipment loads are available.

To meet the schedule, assumptions must be made on these load components. The owner requires that the system design must be flexible enough to provide for a variety of tenants over the life of the building. Based on similar office buildings, the team agrees to base the block load calculations on the following assumptions:

Occupancy: 7 people per 1000 ft² = 143 ft²/person

Lighting: 1.5 W/ft²

Tenant's office equipment: 1 W/ft²

Normal use schedule is assumed at 100% from 7:00 AM to 7:00 PM and unoccupied/off during other hours.

With interior finishes not finalized, the owner commits to using light-colored interior blinds on all windows. The tenant interior design could include carpeted flooring or acoustical tile ceilings in all areas, but the more conservative assumption, from a peak load standpoint, is chosen: carpeted flooring and no acoustical tile ceilings (no ceiling return plenum).

For block loads, the engineer assumes that the building is maintained under positive pressure during peak cooling conditions and that infiltration during peak heating conditions is equivalent to one air change per hour in a 12 ft deep perimeter zone around the building.

To maintain indoor air quality, outside air must be introduced into the building. Air will be ducted from roof intake hoods to the AHUs where it will be mixed with return air before being cooled and dehumidified by the AHU's cooling coil. ASHRAE *Standard* 62.1 is the design basis for ventilation rates; however, no interior tenant layout is available for application of *Standard* 62.1 procedures. Based on past experience, the engineer decides to use 20 cfm of outside air per person for sizing the cooling coils and chiller.

Block load calculations were performed using the RTS method, and results for the first and second floors and the entire building are summarized in Tables 36, 37, and 38. Based on these results, the engineer performs psychrometric coil analysis, checks capacities versus vendor catalog data, and prepares specifications and schedules for the equipment. This information is released to the contractor with the shell-and-core design documents. The air-handling units and chiller are purchased, and construction proceeds.

Tenant Fit Design Process and Definition

About halfway through construction, a tenant agrees to lease the entire building. The tenant will require a combination of open and enclosed office space with a few common areas, such as conference/training rooms, and a small computer room that will operate on a 24 h basis. Based on the tenant's space program, the architect prepares interior floor plans and furniture layout plans (Figures 23 and 24), and the electrical engineer prepares lighting design plans. Those drawings are furnished to the HVAC engineer to prepare detailed design documents. The first step in this process is to prepare room-by-room peak heating and cooling load calculations, which will then be used for design of the air distribution systems from each of the VAV air handlers already installed.

The HVAC engineer must perform a room-by-room "takeoff" of the architect's drawings. For each room, this effort identifies the floor area, room function, exterior envelope elements and areas, number of occupants, and lighting and equipment loads.

The tenant layout calls for a dropped acoustical tile ceiling throughout, which will be used as a return air plenum. Typical 2 by 4 ft fluorescent, recessed, return-air-type lighting fixtures are

selected. Based on this, the engineer assumes that 20% of the heat gain from lighting will be to the return air plenum and not enter rooms directly. Likewise, some portion of the heat gain from the roof will be extracted via the ceiling return air plenum. From experience, the engineer understands that return air plenum paths are not always predictable, and decides to credit only 30% of the roof heat gain to the return air, with the balance included in the room cooling load.

For the open office areas, some areas along the building perimeter will have different load characteristics from purely interior spaces because of heat gains and losses through the building skin.

Although those perimeter areas are not separated from other open office spaces by walls, the engineer knows from experience that they must be served by separate control zones to maintain comfort conditions. The data compiled from the room-by-room takeoff are included in Tables 39 and 40.

Room by Room Cooling and Heating Loads

The room by room results of RTS method calculations, including the month and time of day of each room’s peak cooling load, are tabulated in supplemental Tables 41 and 42 (available at

www.ashrae.org), as well as peak heating loads for each room. These results are used by the HVAC engineer to select and design room air distribution devices and to schedule airflow rates for each space. That information is incorporated into the tenant fit drawings and specifications issued to the contractor.

Conclusions

The example results illustrate issues which should be understood and accounted for in calculating heating and cooling loads:

- First, peak room cooling loads occur at different months and times depending on the exterior exposure of the room. Calculation of cooling loads for a single point in time may miss the peak and result in inadequate cooling for that room.
- Often, in real design processes, all data is not known. Reasonable assumptions based on past experience must be made.
- Heating and air-conditioning systems often serve spaces whose use changes over the life of a building. Assumptions used in heating and cooling load calculations should consider reasonable possible uses over the life of the building, not just the first use of the space.

^aPeak room sensible load occurs in month 7 at hour 15.

^bPeak block load occurs in month 7 at hour 15.

- The relative importance of each cooling and heating load component varies depending on the portion of the building being considered. Characteristics of a particular window may have little effect on the entire building load, but could have a significant effect on the supply airflow to the room where the window is located and thus on the comfort of the occupants of that space.

PREVIOUS COOLING LOAD CALCULATION METHODS

Procedures described in this chapter are the most current and scientifically derived means for estimating cooling load for a defined building space, but methods in earlier editions of the ASHRAE Handbook are valid for many applications. These earlier procedures are simplifications of the heat balance principles, and their use requires experience to deal with atypical or unusual circumstances. In fact, any cooling or heating load estimate is no better than the assumptions used to define conditions and parameters such as physical makeup of the various envelope surfaces, conditions of occupancy and use, and ambient weather conditions. Experience of the practitioner can never be ignored.

The primary difference between the HB and RTS methods and the older methods is the newer methods' direct approach, compared to the simplifications necessitated by the limited computer capability available previously.

The **transfer function method (TFM)**, for example, required many calculation steps. It was originally designed for energy analysis with emphasis on daily, monthly, and annual energy use, and thus was more oriented to average hourly cooling loads than peak design loads.

The **total equivalent temperature differential method with time averaging (TETD/TA)** has been a highly reliable (if subjective) method of load estimating since its initial presentation in the 1967 *Handbook of Fundamentals*. Originally intended as a manual method of calculation, it proved suitable only as a computer application because of the need to calculate an extended profile of hourly heat gain values, from which radiant components had to be averaged over a time representative of the general mass of the building involved. Because perception of thermal storage characteristics of a given building is almost entirely subjective, with little specific information for the user to judge variations, the TETD/TA method's primary usefulness has always been to the experienced engineer.

The **cooling load temperature differential method with solar cooling load factors (CLTD/CLF)** attempted to simplify the two-step TFM and TETD/TA methods into a single-step technique that proceeded directly from raw data to cooling load without intermediate conversion of radiant heat gain to cooling load. A series of factors were taken from cooling load calculation results (produced

by more sophisticated methods) as “cooling load temperature differences” and “cooling load factors” for use in traditional conduction ($q = UA\Delta t$) equations. The results are approximate cooling load values rather than simple heat gain values. The simplifications and assumptions used in the original work to derive those factors limit this method's applicability to those building types and conditions for which the CLTD/CLF factors were derived; the method should not be used beyond the range of applicability.

Although the TFM, TETD/TA, and CLTD/CLF procedures are not republished in this chapter, those methods are not invalidated or discredited. Experienced engineers have successfully used them in millions of buildings around the world. The accuracy of cooling load calculations in practice depends primarily on the availability of accurate information and the design engineer's judgment in the assumptions made in interpreting the available data. Those factors have much greater influence on a project's success than does the choice of a particular cooling load calculation method.

The primary benefit of HB and RTS calculations is their somewhat reduced dependency on purely subjective input (e.g., determining a proper time-averaging period for TETD/TA; ascertaining appropriate safety factors to add to the rounded-off TFM results; determining whether CLTD/CLF factors are applicable to a specific unique application). However, using the most up-to-date techniques in real-world design still requires judgment on the part of the design engineer and care in choosing appropriate assumptions, just as in applying older calculation methods.

ENERGY requirements and fuel consumption of HVAC systems directly affect a building's operating cost and indirectly affect the environment. This chapter discusses methods for estimating energy use for two purposes: modeling for building and HVAC system design and associated design optimization (**forward modeling**), and modeling energy use of existing buildings for establishing baselines and calculating retrofit savings (**data-driven modeling**).

GENERAL CONSIDERATIONS

MODELS AND APPROACHES

A mathematical **model** is a description of the behavior of a system. It is made up of three components (Beck and Arnold 1977):

1. **Input variables** (statisticians call these *regressor variables*, whereas physicists call them *forcing variables*), which act on the system. There are two types: controllable by the experimenter, and uncontrollable (e.g., climate).
2. **System structure and parameters/properties**, which provide the necessary physical description of the system (e.g., thermal mass or mechanical properties of the elements).
3. **Output** (*response*, or *dependent*) variables, which describe the reaction of the system to the input variables. Energy use is often a response variable.

The science of mathematical modeling as applied to physical systems involves determining the third component of a system when the other two components are given or specified. There are two broad but distinct approaches to modeling; which to use is dictated by the objective or purpose of the investigation (Rabl 1988).

Forward (Classical) Approach. The objective is to predict the output variables of a specified model with known structure and known parameters when subject to specified input variables. To ensure accuracy, models have tended to become increasingly complex, especially with the advent of cheap and powerful computing power. This approach presumes detailed knowledge not only of the various natural phenomena affecting system behavior but also of the magnitude of various interactions (e.g., effective thermal mass, heat and mass transfer coefficients, etc.). The main advantage of this approach is that the system need not be physically built to predict its behavior. Thus, this approach is ideal in the preliminary design and analysis stage and is most often used then.

Forward modeling of building energy use begins with a physical description of the building system or component of interest. For example, building geometry, geographical location, physical characteristics (e.g., wall material and thickness), type of equipment and operating schedules, type of HVAC system, building operating schedules, plant equipment, etc., are specified. The peak and average energy use of such a building can then be predicted or simulated by the forward simulation model. The primary benefits of this method are that it is based on sound engineering principles usually taught in colleges and universities, and consequently has gained widespread acceptance by the design and professional community. Major government-developed simulation codes, such as BLAST, DOE-2, and EnergyPlus, are based on forward simulation models. Figure 1 illustrates the ordering of the analysis typically performed by a building energy simulation program.

Data-Driven (Inverse) Approach. In this case, input and output variables are known and measured, and the objective is to determine a mathematical description of the system and to estimate system parameters. In contrast to the forward approach, the data-driven approach is relevant when the system has already been built and actual performance data are available for model development and/or identification. Two types of performance data can be used: nonintrusive and intrusive. **Intrusive data** are gathered under conditions of predetermined or planned experiments on the system to elicit system response under a wider range of system performance than would have occurred under normal system operation. These performance data allow more accurate model specification and identification. When constraints on system operation do not permit such tests to be performed, the model must be identified from **nonintrusive data** obtained under normal operation.

Data-driven modeling often allows identification of system models that are not only simpler to use but also are more accurate predictors of future system performance than forward models. The data-driven approach arises in many fields, such as physics, biology, engineering, and economics. Although several monographs, textbooks, and even specialized technical journals are available in this area, the approach has not yet been widely adopted in energy-related curricula and by the building professional community.

CHARACTERISTICS OF MODELS

Forward Models

Although procedures for estimating energy requirements vary considerably in their degree of complexity, they all have three common elements: calculation of (1) space load, (2) secondary

The preparation of this chapter is assigned to TC 4.7, Energy Calculations.

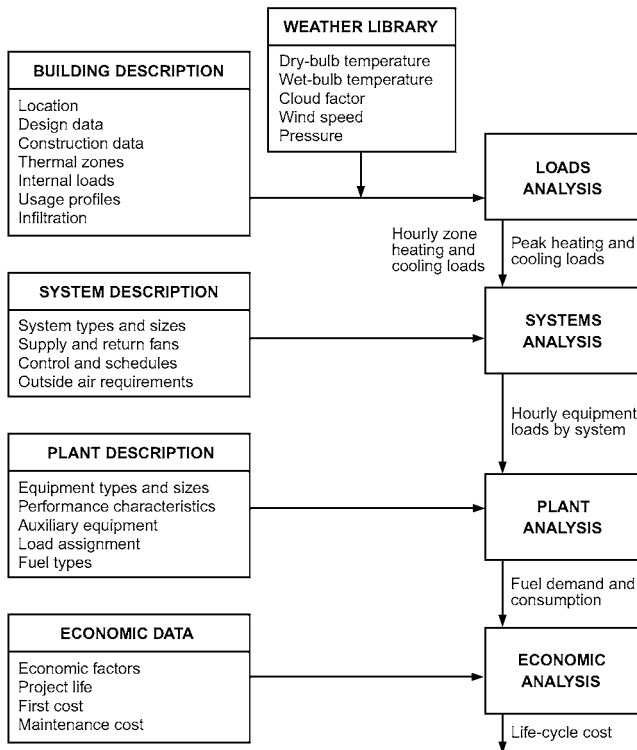

Fig. 1 Flow Chart for Building Energy Simulation Program
(Ayres and Stamper 1995)

equipment load, and (3) primary equipment energy requirements. Here, *secondary* refers to equipment that distributes the heating, cooling, or ventilating medium to conditioned spaces, whereas *primary* refers to central plant equipment that converts fuel or electric energy to heating or cooling effect.

The first step in calculating energy requirements is to determine the **space load**, which is the amount of energy that must be added to or extracted from a space to maintain thermal comfort. The simplest procedures assume that the energy required to maintain comfort is only a function of the outdoor dry-bulb temperature. More detailed methods consider solar effects, internal gains, heat storage in the walls and interiors, and the effects of wind on both building envelope heat transfer and infiltration. Chapters 17 and 18 discuss load calculation in detail.

Although energy calculations are similar to the heating and cooling load calculations used to size equipment, they are not the same. Energy calculations are based on average use and typical weather conditions rather than on maximum use and worst-case weather. Currently, the most sophisticated procedures are based on hourly profiles for climatic conditions and operational characteristics for a number of typical days of the year or on 8760 h of operation per year.

The second step translates the space load to a **load on the secondary equipment**. This can be a simple estimate of duct or piping losses or gains or a complex hour-by-hour simulation of an air system, such as variable-air-volume with outdoor-air cooling. This step must include calculation of all forms of energy required by the secondary system (e.g., electrical energy to operate fans and/or pumps, as well as energy in the form of heated or chilled water).

The third step calculates the fuel and **energy required by the primary equipment** to meet these loads and the peak demand on the utility system. It considers equipment efficiencies and part-load characteristics. It is often necessary to keep track of the different forms of energy, such as electrical, natural gas, or oil. In some cases, where calculations are required to ensure compliance with codes or standards, these energies must be converted to source energy or

resource consumed, as opposed to energy delivered to the building boundary.

Often, energy calculations lead to an economic analysis to establish the cost-effectiveness of conservation measures (ASHRAE *Standard* 90.1). Thus, thorough energy analysis provides intermediate data, such as time of energy usage and maximum demand, so that utility charges can be accurately estimated. Although not part of the energy calculations, estimated capital equipment costs should be included.

Complex and often unexpected interactions can occur between systems or between various modes of heat transfer. For example, radiant heating panels affect space loads by raising the mean radiant temperature in the space (Howell and Suryanarayana 1990). As a result, air temperature can be lowered while maintaining comfort. Compared to a conventional heated-air system, radiant panels create a greater temperature difference from the inside surface to the outside air. Thus, conduction losses through the walls and roof increase because the inside surface temperatures are greater. At the same time, the heating load caused by infiltration or ventilation decreases because of the reduced indoor-to-outdoor-air temperature difference. The infiltration rate may also decrease because the reduced air temperature difference reduces the stack effect.

Data-Driven Models

The data-driven model has to meet requirements very different from the forward model. The data-driven model can only contain a relatively small number of parameters because of the limited and often repetitive information contained in the performance data. (For example, building operation from one day to the next is fairly repetitive.) It is thus a much simpler model that contains fewer terms representative of aggregated or macroscopic parameters (e.g., overall building heat loss coefficient and time constants). Because model parameters are deduced from actual building performance, it is much more likely to accurately capture as-built system performance, thus allowing more accurate prediction of future system behavior under certain specific circumstances. Performance data collection and model formulation need to be appropriately tailored for the specific circumstance, which often requires a higher level of user skill and expertise. In general, data-driven models are less flexible than forward models in evaluating energy implications of different design and operational alternatives, and so are not a substitute in this regard.

To better understand the uses of data-driven models, consider some of the questions that a building professional may ask about an existing building with known energy consumption (Rabl 1988):

- How does consumption compare with design predictions (and, in case of discrepancies, are they caused by anomalous weather, unintended building operation, improper operation, or other causes)?
- How would consumption change if thermostat settings, ventilation rates, or indoor lighting levels were changed?
- How much energy could be saved by retrofits to the building shell, changes to air handler operation from CV to VAV, or changes in the various control settings?
- If retrofits are implemented, can one verify that the savings are due to the retrofit and not to other causes (e.g., the weather)?
- How can one detect faults in HVAC equipment and optimize control and operation?

All these questions are better addressed by the data-driven approach. The forward approach could also be used, for example, by going back to the blueprints of the building and of the HVAC system, and repeating the analysis performed at the design stage using actual building schedules and operating modes, but this is tedious and labor-intensive, and materials and equipment often perform differently in reality than as specified. Tuning the forward-simulation model is often awkward and labor intensive, although it is still an option (as adopted in the calibrated data-driven approach).

CHOOSING AN ANALYSIS METHOD

The most important step in selecting an energy analysis method is matching method capabilities with project requirements. The method must be capable of evaluating all design options with sufficient accuracy to make correct choices. The following factors apply generally (Sonderegger 1985):

- **Accuracy.** The method should be sufficiently accurate to allow correct choices. Because of the many parameters involved in energy estimation, absolutely accurate energy prediction is not possible (Waltz 1992). ANSI/ASHRAE *Standard 140*, Method of Test for the Evaluation of Building Energy Analysis Computer Programs, was developed to identify and diagnose differences in predictions that may be caused by algorithmic differences, modeling limitations, coding errors, or input errors. More information on model validation and testing can be found in the Model Validation and Testing section of this chapter and in ANSI/ASHRAE *Standard 140*.
- **Sensitivity.** The method should be sensitive to the design options being considered. The difference in energy use between two choices should be adequately reflected.
- **Versatility.** The method should allow analysis of all options under consideration. When different methods must be used to consider different options, an accurate estimate of the differential energy use cannot be made.
- **Speed and cost.** The total time (gathering data, preparing input, calculations, and analysis of output) to make an analysis should be appropriate to the potential benefits gained. With greater speed, more options can be considered in a given time. The cost of analysis is largely determined by the total time of analysis.
- **Reproducibility.** The method should not allow so many vaguely defined choices that different analysts would get completely different results (Corson 1992).
- **Ease of use.** This affects both the economics of analysis (speed) and the reproducibility of results.

Selecting Energy Analysis Computer Programs

Selecting a building energy analysis program depends on its application, number of times it will be used, experience of the user, and hardware available to run it. The first criterion is the capability of the program to deal with the application. For example, if the effect of a shading device is to be analyzed on a building that is also shaded by other buildings part of the time, the ability to analyze detached shading is an absolute requirement, regardless of any other factors.

Because almost all manual methods are now implemented on a computer, selection of an energy analysis method is the selection of a computer program. The cost of the computer facilities and the software itself are typically a small part of running a building energy analysis; the major costs are of learning to use the program and of using it. Major issues that influence the cost of learning a program include (1) complexity of input procedures, (2) quality of the user's manual, and (3) availability of a good support system to answer questions. As the user becomes more experienced, the cost of learning becomes less important, but the need to obtain and enter a complex set of input data continues to consume the time of even an experienced user until data are readily available in electronic form compatible with simulation programs.

Complexity of input is largely influenced by the availability of default values for the input variables. Default values can be used as a simple set of input data when detail is not needed or when building design is very conventional, but additional complexity can be supplied when needed. Secondary defaults, which can be supplied by the user, are also useful in the same way. Some programs allow the user to specify a level of detail. Then the program requests only the information appropriate to that level of detail, using default values for all others.

Quality of output is another factor to consider. Reports should be easy to read and uncluttered. Titles and headings should be unambiguous. Units should be stated explicitly. The user's manual should explain the meanings of data presented. Graphic output can be very helpful. In most cases, simple summaries of overall results are the most useful, but very detailed output is needed for certain studies and also for debugging program input during the early stages of analysis.

Before a final decision is made, manuals for the most suitable programs should be obtained and reviewed, and, if possible, demonstration versions of the programs should be obtained and run, and support from the software supplier should be tested. The availability of training should be considered when choosing a more complex program.

Availability of weather data and a weather data processing subroutine or program are major features of a program. Some programs include subroutine or supplementary programs that allow the user to create a weather file for any site for which weather data are available. Programs that do not have this capability must have weather files for various sites created by the program supplier. In that case, the available weather data and the terms on which the supplier will create new weather data files must be checked. More information on weather data can be found in Chapter 14.

Auxiliary capabilities, such as economic analysis and design calculations, are a final concern in selecting a program. An economic analysis may include only the ability to calculate annual energy bills from utility rates, or it might extend to calculations or even to life-cycle cost optimization. An integrated program may save time because some input data have been entered already for other purposes.

The results of computer calculations should be accepted with caution, because the software vendor does not accept responsibility for the correctness of calculations or use of the program. Manual calculation should be done to develop a good understanding of underlying physical processes and building behavior. In addition, the user should (1) review the computer program documentation to determine what calculation procedures are used, (2) compare results with manual calculations and measured data, and (3) conduct sample tests to confirm that the program delivers acceptable results.

Tools for Energy Analysis

The most accurate methods for calculating building energy consumption are the most costly because of their intense computational requirements and the expertise needed by the designer or analyst. Simulation programs that assemble component models into system models and then exercise those models with weather and occupancy data are preferred by experts for determining energy use in buildings.

Often, energy consumption at a system or whole-building level must be estimated quickly to study trends, compare systems, or study building effects such as envelope characteristics. For these purposes, simpler methods, such as degree-day and bin, may be used.

Table 1 classifies methods for analyzing building energy use as either forward or data-driven, and either steady-state or dynamic. The U.S. Department of Energy maintains an up-to-date listing of building energy software with links to other sites that describe energy modeling tools at <http://www.energytoolsdirectory.gov>.

COMPONENT MODELING AND LOADS

CALCULATING SPACE SENSIBLE LOADS

Calculating instantaneous space sensible load is a key step in any building energy simulation. The **heat balance** and **weighting-factor methods** are used for these calculations. A third method, the **thermal-network method**, is not widely used but shows promise.

The **instantaneous space sensible load** is the rate of heat flow into the space air mass. This quantity, sometimes called the *cooling load*, differs from heat gain, which usually contains a radiative

Table 1 Classification of Analysis Methods For Building Energy Use

Method	Data-Driven				Comments
	Forward	Empirical or Black-Box	Calibrated Simulation	Physical or Gray-Box	
<i>Steady-State Methods</i>					
Simple linear regression (Kissock et al. 1998; Ruch and Claridge 1991)	—	X	—	—	One dependent parameter, one independent parameter. May have slope and y -intercept.
Multiple linear regression (Dhar 1995; Dhar et al. 1998, 1999a, 1999b; Katipamula et al. 1998; Sonderegger 1998)	—	X	—	—	One dependent parameter, multiple independent parameters.
Modified degree-day method	X	—	—	—	Based on fixed reference temperature of 65°F.
Variable-base degree-day method, or 3-P change point models (Fels 1986; Reddy et al. 1997; Sonderegger 1998)	X	X	—	X	Variable base reference temperatures.
Change-point models: 4-P, 5-P (Fels 1986; Kissock et al. 1998)	—	X	—	X	Uses daily or monthly utility billing data and average period temperatures.
ASHRAE bin method and data-driven bin method (Thamilseran and Haberl 1995)	X	X	—	—	Hours in temperature bin times load for that bin.
ASHRAE TC 4.7 modified bin method (Knebel 1983)	X	—	—	—	Modified bin method with cooling load factors.
Multistep parameter identification (Reddy et al. 1999)	—	—	—	X	Uses daily data to determine overall heat loss and ventilation of large buildings.
<i>Dynamic Methods</i>					
Thermal network (Rabl 1988; Reddy 1989; Sonderegger 1977)	X	—	—	X	Uses equivalent thermal parameters (data-driven mode).
Response factors (Kusuda 1969; Mitalas 1968; Mitalas and Stephenson 1967; Stephenson and Mitalas 1967)	X	—	—	—	Tabulated or as used in simulation programs.
Fourier analysis (Shurcliff 1984; Subbarao 1988)	X	—	X	X	Frequency domain analysis convertible to time domain.
ARMA model (Rabl 1988; Reddy 1989; Subbarao 1986)	—	—	—	X	Autoregressive moving average (ARMA) model.
PSTAR (Subbarao 1988)	X	—	X	X	Combination of ARMA and Fourier series; includes loads in time domain.
Modal analysis (Bacot et al. 1984; Rabl 1988)	X	—	—	X	Building described by diagonalized differential equation using nodes.
Differential equation (Rabl 1988)	—	—	—	X	Analytical linear differential equation.
Computer simulation: DOE-2, BLAST, EnergyPlus (Crawley et al. 2001; Haberl and Bou-Saada 1998; Manke et al. 1996; Norford et al. 1994)	X	—	X	—	Hourly and subhourly simulation programs with system models.
Computer emulation (HVACSIM+, TRNSYS) (Clark 1985; Klein et al. 1994)	X	—	—	—	Subhourly simulation programs.
Artificial neural networks (Kreider and Haberl 1994; Kreider and Wang 1991)	—	X	—	—	Connectionist models.

component that passes through the air and is absorbed by other bounding surfaces. Instantaneous space sensible load is entirely convective; even loads from internal equipment, lights, and occupants enter the air by convection from the surface of such objects or by convection from room surfaces that have absorbed the radiant component of energy emitted from these sources. However, some adjustment must be made when radiant cooling and heating systems are evaluated because some of the space load is offset directly by radiant transfer without convective transfer to the air mass.

For equilibrium, the instantaneous space sensible load must match the heat removal rate of the conditioning equipment. Any imbalance in these rates changes the energy stored in the air mass. Customarily, however, the thermal mass (heat capacity) of the air itself is ignored in analysis, so the air is always assumed to be in thermal equilibrium. Under these assumptions, the instantaneous space sensible load and rate of heat removal are equal in magnitude and opposite in sign.

The weighting-factor and heat balance methods use conduction transfer functions (or their equivalents) to calculate transmission heat gain or loss. The main difference is in the methods used to

calculate the subsequent internal heat transfers to the room. Experience with both methods has indicated largely the same results, provided the weighting factors are determined for the specific building under analysis.

Heat Balance Method

The heat balance method for calculating net space sensible loads, as described in the *ASHRAE Toolkit for Building Load Calculations* (Pedersen et al. 2001, 2003), is more fundamental than the weighting-factor method. Its development relies on the first law of thermodynamics (conservation of energy) and the principles of matrix algebra. Because it requires fewer assumptions than the weighting-factor method, it is also more flexible. However, the heat balance method requires more calculations at each point in the simulation process, using more computer time. The weighting factors used are determined with a heat balance procedure. Although not necessary, linearization is commonly used to simplify the radiative transfer formulation.

The heat balance method allows the net instantaneous sensible heating and/or cooling load to be calculated on the space air mass.

Generally, a heat balance equation is written for each enclosing surface, plus one equation for room air. This set of equations can then be solved for the unknown surface and air temperatures. Once these temperatures are known, they can be used to calculate the convective heat flow to or from the space air mass. The heat balance method is developed in Chapter 18 for use in design cooling load calculations, so a fuller description is omitted here.

However, the heat balance procedure described in Chapter 18 is aimed at obtaining the design cooling load for a fixed zone air temperature. For building energy analysis purposes, it is preferable to know the actual heat extraction rate. This may be determined by recasting Equation (27) of Chapter 18 so that the system heat transfer is determined simultaneously with the zone air temperature. The system heat transfer is the rate at which heat is transferred to the space by the system. Although this can be done by simultaneously modeling the zone and the system (Taylor et al. 1990, 1991), it is convenient to make a simple, piecewise-linear representation of the system known as a *control profile*. This usually takes the form

$$q_{sysj} = a + bt_{a_j} \quad (1)$$

where

- q_{sysj} = system heat transfer at time step j , Btu/h
- a, b = coefficients that apply over a certain range of zone air temperatures
- t_{a_j} = zone air temperature at time step j , °F

System heat transfer q_{sysj} may be considered positive when heating is provided to the space and negative when cooling is provided. It is equal in magnitude but opposite in sign to the zone cooling load, as defined in Chapter 18, when zone air temperature is fixed.

Substituting Equation (1) into Equation (27) of Chapter 18 and solving for zone air temperature,

$$t_{a_j} = \frac{a + \sum_{i=1}^N A_i h_{ci} t_{si,j} + \rho c V_{infil_j} t_{o_j} + \rho c V_{vent_j} t_{v_j} + q_{c,int_j}}{-b + \sum_{i=1}^N A_i h_{ci} + \rho c V_{infil_j} + \rho c V_{vent_j}} \quad (2)$$

where

- N = number of zone surfaces
- A_i = area of i th surface, ft²
- h_{ci} = convection coefficient for i th surface, Btu/h·ft²·°F
- $t_{si,j}$ = surface temperature for i th surface at time step j , °F
- ρ = density, lb_m/ft³
- c = specific heat of air, Btu/lb_m·°F
- V = volumetric flow rate of air, ft³/h
- t_{o_j} = outdoor air temperature at time step j , °F
- t_{v_j} = ventilation air temperature at time step j , °F
- q_{c,int_j} = sum of convective portions of all internal heat gains at time step j , Btu/h

The zone air heat balance equation [Equation (2)] must be solved simultaneously with the interior and exterior surface heat balance equations [Equations (26) and (25) in Chapter 18]. Also, the correct temperature range must be found to use the proper set of a and b coefficients; this may be done iteratively. Once the zone air temperature is found, the actual system heat transfer rate may be found directly from Equation (1).

Beyond treatment of system heat transfer, other considerations that may be important in building energy analysis programs include simulations over periods as long as a year, treatment of radiant cooling and heating systems, treatment of interzone heat transfer, modeling convection heat transfer, and modeling radiation heat transfer.

The heat balance method in Chapter 18 assumes the use of a single design day. In a building energy analysis program, it is most

commonly used with a year's worth of design weather data. In this case, the first day of the year is usually simulated several times until a steady-periodic response is obtained. Then, each day is simulated sequentially, and, where needed, historical data for surface temperatures and heat fluxes from the previous day are used.

When radiant cooling and heating systems are evaluated, the radiant source should be identified as a room surface. The calculation procedure considers the radiant source in the heat balance analysis. Therefore, the heat balance method is preferred over the weighting-factor method for evaluating radiant systems. Strand and Pedersen (1997) describe implementation of heat source conduction transfer functions, which may be used for modeling radiant panels, into a heat balance-based building simulation program.

In principle, this method extends directly to multiple spaces, with heat transfer between zones. In this case, some surface temperatures appear in the surface heat balance equations for two different zones. In practice, however, the size of the coefficient array required for solving the simultaneous equations becomes prohibitively large, and the solution time excessive. For this reason, many programs solve only one space at a time and assume that adjacent space temperatures are either the same as the space in question or some assigned, constant value. Other approaches may remove this limitation (Walton 1980).

Relatively simple exterior and interior convection models may be used for design cooling load calculation procedures. However, more sophisticated exterior convection models (Cooper and Tree 1973; Fracastoro et al. 1982; Melo and Hammond 1991; Walton 1983; Yazdani and Klems 1994) that incorporate the effects of wind speed, wind direction, surface orientation, etc., may be preferable. More detailed interior convection correlations for use in buildings are also available (Alamdari and Hammond 1982, 1983; Altmayer et al. 1983; Bauman et al. 1983; Bohn et al. 1984; Chandra and Kerestecioglu 1984; Khalifa and Marshall 1990; Spitler et al. 1991; Walton 1983).

Also, more detailed models of exterior [e.g., Cole (1976); Walton (1983)] and interior [e.g., Carroll (1980); Davies (1988); Kamal and Novak (1991); Steinman et al. (1989); Walton (1980)] long-wave radiation transfer have been implemented in detailed building simulation programs.

Weighting-Factor Method

The weighting-factor method of calculating instantaneous space sensible load is a compromise between simpler methods (e.g., steady-state calculation) that ignore the ability of building mass to store energy, and more complex methods (e.g., complete energy balance calculations). With this method, space heat gains at constant space temperature are determined from a physical description of the building, ambient weather conditions, and internal load profiles. Along with the characteristics and availability of heating and cooling systems for the building, space heat gains are used to calculate air temperatures and heat extraction rates. This discussion is in terms of heat gains, cooling loads, and heat extraction rates. Heat losses, heating loads, and heat addition rates are merely different terms for the same quantities, depending on the direction of the heat flow.

The weighting factors represent Z-transfer functions (Kerrisk et al. 1981; York and Cappiello 1982). The Z-transform is a method for solving differential equations with discrete data. Two groups of weighting factors are used: heat gain and air temperature.

Heat gain weighting factors represent transfer functions that relate space cooling load to instantaneous heat gains. A set of weighting factors is calculated for each group of heat sources that differ significantly in the (1) relative amounts of energy appearing as convection to the air versus radiation, and (2) distribution of radiant energy intensities on different surfaces.

Air temperature weighting factors represent a transfer function that relates room air temperature to the net energy load of the room. Weighting factors for a particular heat source are determined by

introducing a unit pulse of energy from that source into the room's network. The network is a set of equations that represents a heat balance for the room. At each time step (1 h intervals), including the initial introduction, the energy flow to the room air represents the amount of the pulse that becomes a cooling load. Thus, a long sequence of cooling loads can be generated, from which weighting factors are calculated. Similarly, a unit pulse change in room air temperature can be used to produce a sequence of cooling loads.

A two-step process is used to determine the air temperature and heat extraction rate of a room or building zone for a given set of conditions. First, the room air temperature is assumed to be fixed at some reference value, usually the average air temperature expected for the room over the simulation period. Instantaneous heat gains are calculated based on this constant air temperature. Various types of heat gains are considered. Some, such as solar energy entering through windows or energy from lighting, people, or equipment, are independent of the reference temperature. Others, such as conduction through walls, depend directly on the reference temperature.

A space sensible cooling load for the room, defined as the rate at which energy must be removed from the room to maintain the reference value of the air temperature, is calculated for each type of instantaneous heat gain. The cooling load generally differs from the instantaneous heat gain because some energy from heat gain is absorbed by walls or furniture and stored for later release to the air. At time θ , the calculation uses present and past values of the instantaneous heat gain ($q_\theta, q_{\theta-1}$), past values of the cooling load ($Q_{\theta-1}, Q_{\theta-2}, \dots$), and the **heat gain weighting factors** ($v_0, v_1, v_2, \dots, w_1, w_2, \dots$) for the type of heat gain under consideration. Thus, for each type of heat gain q_θ , cooling load Q_θ is calculated as

$$Q_\theta = v_0 q_\theta + v_1 q_{\theta-1} + \dots - w_1 Q_{\theta-1} - w_2 Q_{\theta-2} - \dots \quad (3)$$

The heat gain weighting factors are a set of parameters that determine how much of the energy entering a room is stored and how rapidly stored energy is released later. Mathematically, the weighting factors are parameters in a Z -transfer function relating the heat gain to the cooling load.

These weighting factors differ for different heat gain sources because the relative amounts of convective and radiative energy leaving various sources differ and because the distribution of radiative energy can differ. Heat gain weighting factors also differ for different rooms because room construction affects the amount of incoming energy stored by walls or furniture and the rate at which it is released. Sowell (1988) showed the effects of 14 zone design parameters on zone dynamic response. After the first step, cooling loads from various heat gains are added to give a total cooling load for the room.

In the second step, the total cooling load is used (with information on the room's HVAC system and a set of **air temperature weighting factors**) to calculate the actual heat extraction rate and air temperature. The actual heat extraction rate differs from the cooling load (1) because, in practice, air temperature can vary from the reference value used to calculate the cooling load, or (2) because of HVAC system characteristics. Deviation of air temperature t_θ from the reference value at hour θ is calculated as

$$t_\theta = 1/g_0 + [(Q_\theta - ER_\theta) + P_1(Q_{\theta-1} - ER_{\theta-1}) + P_2(Q_{\theta-2} - ER_{\theta-2}) + \dots - g_1 t_{\theta-1} - g_2 t_{\theta-2} - \dots] \quad (4)$$

where ER_θ is the energy removal rate of the HVAC system at hour θ , and $g_0, g_1, g_2, \dots, P_1, P_2, \dots$ are air temperature weighting factors, which incorporate information about the room, particularly thermal coupling between the air and the storage capacity of the building mass.

Values of weighting factors for typical building rooms are presented in the following table. One of the three groups of weighting

factors, for light, medium, and heavy construction rooms, can be used to approximate the behavior of any room. Some automated simulation techniques allow weighting factors to be calculated specifically for the building under consideration. This option improves the accuracy of the calculated results, particularly for a building with an unconventional design. McQuiston and Spitler (1992) provided electronic tables of weighting factors for a large number of parametrically defined zones.

Normalized Coefficients of Space Air Transfer Functions

Room Envelope Construction	g_0^*	g_1^*	g_2^*	P_0	P_1
	Btu/h·ft·°F			Dimensionless	
Light	1.68	-1.73	0.05	1.0	-0.82
Medium	1.81	-1.89	0.08	1.0	-0.87
Heavy	1.85	-1.95	0.10	1.0	-0.93

Two assumptions are made in the weighting-factor method. First, the processes modeled are linear. This assumption is necessary because heat gains from various sources are calculated independently and summed to obtain the overall result (i.e., the superposition principle is used). Therefore, nonlinear processes such as radiation or natural convection must be approximated linearly. This assumption is not a significant limitation because these processes can be linearly approximated with sufficient accuracy for most calculations. The second assumption is that system properties influencing the weighting factors are constant (i.e., they are not functions of time). This assumption is necessary because only one set of weighting factors is used during the entire simulation period. This assumption can limit the use of weighting factors in situations where important room properties vary during the calculation (e.g., the distribution of solar radiation incident on the interior walls of a room, which can vary hourly, and inside surface heat transfer coefficients).

When the weighting-factor method is used, a combined radiative/convective heat transfer coefficient is used as the inside surface heat transfer coefficient. This value is assumed constant even though, in a real room, (1) radiant heat transferred from a surface depends on the temperature of other room surfaces (not on room air temperature) and (2) the combined heat transfer coefficient is not constant. Under these circumstances, an average value of the property must be used to determine the weighting factors. Cumali et al. (1979) investigated extensions to the weighting-factor method to eliminate this limitation.

Thermal-Network Methods

Although implementations of the thermal-network method vary, they all have in common the discretization of the building into a network of nodes, with interconnecting paths through which energy flows. In many respects, thermal-network models may be considered a refinement of the heat balance method. Where the heat balance model generally uses one node for zone air, the thermal-network method might use multiple nodes. For each heat transfer element (wall, roof, floor, etc.), the heat balance model generally has one interior and one exterior surface node; the thermal-network model may include additional nodes. Heat balance models generally use simple methods for distributing radiation from lights; thermal-network models may model the lamp, ballast, and luminaire housing separately. Furthermore, thermal-network models depend on a heat balance at each node to determine node temperature and energy flow between all connected nodes. Energy flows may include conduction, convection, and short- or long-wave radiation.

For any mode of energy flow, a range of techniques may be used to model the energy flow between two nodes. Taking conduction heat transfer as an example, the simplest thermal-network model would be a resistance/capacitance network (Sowell 1990). By refining network discretization, the models become what are commonly

thought of as finite-difference or finite-volume models (Clarke 2001; Lewis and Alexander 1990; Walton 1993).

Thermal-network models generally use a set of algebraic and differential equations. In most implementations, the solution procedure is separated from the models so that, in theory, different solvers might be used to perform the simulation. In contrast, most heat balance and weighting factor programs interweave the solution technique with the models. Various solution techniques have been used in conjunction with thermal-network models. Examples include graph theory combined with Newton-Raphson and predictor/corrector ordinary differential equation integration (Buhl et al. 1990) and the use of Euler explicit integration combined with sparse matrix techniques (Walton 1993).

Of the three zone models discussed, thermal-network models are the most flexible and have the greatest potential for high accuracy. However, they also require the most computation time, and, in current implementations, require more user effort to take advantage of the flexibility.

GROUND HEAT TRANSFER

The thermal performance of building foundations, including guidelines for placement of insulation, is described in Chapter 25 of this volume and Chapter 43 of the 2007 *ASHRAE Handbook—HVAC Applications*. Chapter 18 provides information for calculating transmission heat losses through slab foundations and through basement walls and floors. These calculations are appropriate for design loads but are not intended for estimating annual energy usage. This section provides simplified calculation methods suitable for energy estimates over time periods of arbitrary length.

Thermal performance of building foundations has been largely ignored. It is estimated that, in the early 1970s, only 10% of the total energy use of a typical U.S. home was attributed to heat transfer from its foundation (Labs et al. 1988). Since then, thermal performance of above-grade building elements has improved significantly, and the contribution of ground-coupled heat transfer to total energy use in a typical U.S. home has increased. Shipp and Broderick (1983) estimated that heat transfer from an uninsulated basement in Columbus, Ohio, can represent up to 67% of the total building envelope heating load.

Earth-contact heat transfer, rated at 1 to 3 quadrillion Btu of energy annually in U.S. buildings, has an effect similar to infiltration on annual heating and cooling loads in residential buildings (Claridge 1988a). Adding insulation to building foundations is estimated to save up to 0.5 quadrillion Btu of annual energy use in the U.S. (Labs et al. 1988).

Simplified Calculation Method for Slab Foundations and Basements

The design tool for slab-on-grade floors developed by Krarti and Chuangchid (1999) can be modified to a simplified design tool for calculating heat loss for slabs and basements. The design tool is easy to use and requires straightforward input parameters with continuously variable values, including foundation size, insulation R-values, soil thermal properties, and indoor and outdoor temperatures. The simplified method provides a set of equations suitable for estimating the design, seasonal, and annual total heat loss of a slab or a basement as a function of a wide range of variables.

When the indoor temperature of the building is maintained constant, the ground-coupled heat transfer $q(\theta)$ varies with time according to the following equation:

$$q(\theta) = q_{mean} + q_{amp} \sin(\omega\theta + \phi) \quad (5)$$

where

- q_{mean} = annual-mean heat loss/gain, Btu/h
- q_{amp} = heat loss/gain amplitude, Btu/h
- θ = time, s

- ω = annual angular frequency ($\omega = 1.992 \times 10^{-7}$ rad/s)
- ϕ = phase lag between total slab heat loss/gain and soil surface temperature, radians

Equation (5) is convenient and flexible because it can be used to calculate the foundation heat loss/gain not only at any time but also at design conditions and for any time period (such as a heating season or 1 year). In particular, the design heat loss/gain load q_{des} for a slab foundation is obtained as follows:

$$q_{des} = q_{mean} + q_{amp} \quad (6)$$

Parameters q_{mean} and q_{amp} are functions of variables such as building dimensions, soil properties, and insulation R-values. Expressions developed by nondimensional analysis allow calculation of q_{mean} and q_{amp} .

The soil conductivity is normalized to form four parameters (U_o , G , H , and D):

$$U_o = \frac{k_s}{(A/P)_{eff,b}} \quad (7)$$

where

- k_s = soil thermal conductivity, Btu·ft/h·ft²·°F
- P = slab perimeter, ft
- A = slab area, ft²

For mean calculations,

$$(A/P)_{eff,b,mean} = [1 + b_{eff}(-0.4 + e^{-H_b})](A/P)_b \quad (8)$$

For annual calculations,

$$(A/P)_{eff,b,amp} = (1 + b_{eff}e^{-H_b})(A/P)_b \quad (9)$$

where

$$H_b = \frac{(A/P)_b}{k_s R_{eq}} \quad (10)$$

$$b_{eff} = \frac{B}{(A/P)_b} \quad (11)$$

where B = basement depth, ft (0 ft for slab).

$$G = k_s R_{eq} \sqrt{\frac{\omega}{\alpha_s}} \quad (12)$$

where

- R_{eq} = equivalent thermal resistance for entire slab, ft²·h·°F/Btu
- α_s = soil thermal diffusivity, ft²/s

For uniform insulation configurations (placed horizontally beneath the slab floor),

$$R_{eq} = R_f + R_i \quad (13)$$

where

- R_f = thermal resistance of floor, ft²·h·°F/Btu
- R_i = thermal resistance of insulation, ft²·h·°F/Btu

For partial insulation configurations (both horizontal and vertical),

$$R_{eq} = \frac{R_f}{\left[1 - \left(\frac{c}{A/P} \frac{R_i}{R_i + R_f}\right)\right]} \quad (14)$$

Table 2 Coefficients m and a for Slab-Foundation Heat Transfer Calculations

Insulation Placement	m	a
Uniform horizontal	0.40	0.25
Partial horizontal	0.34	0.20
Vertical	0.28	0.13

where c = insulation length of slab, ft.

$$H = \frac{(A/P)_{eff,b}}{k_s R_{eq}} \quad (15)$$

$$D = \ln \left[\left(1 + H\right) \left(1 + \frac{1}{H}\right)^H \right] \quad (16)$$

The effective heat-transfer coefficients for mean heat flow $U_{eff,mean}$ and heat-flow amplitude $U_{eff,amp}$, Btu/h·ft²·°F, are

$$U_{eff,mean} = m U_o D \quad (17)$$

$$U_{eff,amp} = a U_o D^{0.16} G^{-0.6} \quad (18)$$

where the dimensionless coefficients m and a depend on the insulation placement configurations and are provided in Table 2.

The annual-mean slab foundation and basement heat loss/gain can now be defined as

$$q_{mean} = U_{eff,mean} A (t_a - t_r) \quad (19)$$

where

$$t_a = \text{annual average ambient dry-bulb temperature, } ^\circ\text{F}$$

$$t_r = \text{annual average indoor dry-bulb temperature, } ^\circ\text{F}$$

The heat loss/gain amplitude for slab foundations and basements is

$$q_{amp} = U_{eff,amp} A t_{amp} \quad (20)$$

where t_{amp} = annual amplitude ambient temperature, °F.

This simplified model for slab-foundation and basement heat flows provides accurate predictions when A/P is larger than 1.5 ft. To illustrate the use of the simplified models, two examples are presented: one for a slab-on-grade floor for a building insulated with uniform horizontal insulation, and one for a basement structure insulated with uniform insulation.

Example 1. Calculation for Slab Foundations. Determine the annual mean and annual amplitude of total slab heat loss for the slab foundation illustrated in Figure 2. The building is located in Denver, Colorado.

Solution:

Step 1. Provide the required input data.

Dimensions

Slab width = 32.81 ft
Slab length = 49.22 ft
Ratio of slab area to slab perimeter, $A/P = 9.84$ ft

4 in. thick reinforced concrete slab, thermal resistance
 $R_f = 2.84 \text{ h}\cdot\text{ft}^2\cdot^\circ\text{F}/\text{Btu}$

Soil Thermal Properties

Soil thermal conductivity $k_s = 0.70 \text{ Btu}/\text{h}\cdot\text{ft}\cdot^\circ\text{F}$
Soil density $\rho = 168.56 \text{ lb}_m/\text{ft}^3$
Soil thermal diffusivity $\alpha_s = 6.43 \times 10^{-6} \text{ ft}^2/\text{s}$

Insulation

Uniform insulation R-value $R_i = 20.0 \text{ h}\cdot\text{ft}^2\cdot^\circ\text{F}/\text{Btu}$

Temperatures

Indoor temperature $t_r = 68^\circ\text{F}$
Annual average ambient temperature $t_a = 43^\circ\text{F}$
Annual amplitude ambient temperature $t_{amp} = 36^\circ\text{F}$
Annual angular frequency $\omega = 1.992 \times 10^{-7} \text{ rad/s}$

Step 2. Calculate q_{mean} and q_{amp} values.

The various normalized parameters are first calculated using Equations (7) to (18). Then, the annual mean and amplitude of the foundation slab heat loss/gain are determined using Equations (19) and (20).

$$U_o = \frac{k_s}{(A/P)} = \frac{0.70}{9.84} = 0.0711$$

$$H = \frac{(A/P)}{k_s R_{eq}} = \frac{9.84}{0.70(2.84 + 20)} = 0.6155$$

$$D = \ln \left[\left(1 + H\right) \left(1 + \frac{1}{H}\right)^H \right] = 1.074$$

$$G = k_s R_{eq} \sqrt{\frac{\omega}{\alpha_s}} = 0.70(2.84 + 20) \sqrt{\frac{1.992 \times 10^{-7}}{6.43 \times 10^{-6}}} = 2.8141$$

Therefore,

$$q_{mean} = U_{eff,mean} A (t_r - t_a)$$

$$= 0.40 \times 0.0711 \times 1.074 \times 1615 \times (68 - 43)$$

$$= 1233 \text{ Btu/h}$$

and

$$q_{amp} = U_{eff,amp} A t_{amp}$$

$$= 0.25 \times 0.0711 \times 1.074^{0.16} \times 2.8141^{-0.6} \times 1615 \times 36$$

$$= 562 \text{ Btu/h}$$

Example 2. Calculation for Basements. Determine the annual mean and amplitude of total basement heat loss for a building located in Denver, Colorado.

Solution:

Step 1. Provide the required input data.

Dimensions

Basement width = 32.81 ft
Basement length = 49.22 ft
Basement wall height $B = 4.92$ ft
Basement slab and wall total area = 2422 ft²
Ratio of slab and wall area to slab and wall perimeter,
 $(A/P)_b = 11.91$ ft
4 in. thick reinforced concrete slab, thermal resistance
 $R_f = 2.84 \text{ h}\cdot\text{ft}^2\cdot^\circ\text{F}/\text{Btu}$

Soil Thermal Properties

Soil thermal conductivity $k_s = 0.70 \text{ Btu}/\text{h}\cdot\text{ft}\cdot^\circ\text{F}$
Soil thermal diffusivity $\alpha_s = 4.812 \times 10^{-6} \text{ ft}^2/\text{s}$

Fig. 2 Slab Foundation for Example 1

Insulation

Uniform insulation R-value $R_i = 6.54 \text{ h} \cdot \text{ft}^2 \cdot \text{°F}/\text{Btu}$

Temperatures

Indoor temperature, $t_r = 71.6^\circ\text{F}$

Annual average ambient temperature, $t_a = 50^\circ\text{F}$

Annual amplitude ambient temperature, $t_{amp} = 23^\circ\text{F}$

Annual angular frequency, $\omega = 1.992 \times 10^{-7} \text{ rad/s}$

Step 2. Calculate q_{mean} and q_{amp} values.

The normalized parameters are first calculated using Equations (7) to (18). Then, the annual mean and amplitude of the basement heat loss are determined using Equations (19) and (20).

$$H_b = \frac{(A/P)_b}{k_s R_{eq}} = \frac{11.91}{0.70(2.84 + 6.54)} = 1.8139$$

$$b_{eff} = \frac{B}{(A/P)_b} = \frac{4.92}{11.91} = 0.4131$$

$$(A/P)_{eff,b,mean} = [1 + 0.4131(-0.4 + e^{-1.8139})] \times 11.91 = 10.7440$$

$$(A/P)_{eff,b,amp} = (1 + 0.4131e^{-1.8139}) \times 11.91 = 12.7120$$

$$U_{o,mean} = \frac{k_s}{(A/P)_{eff,b,mean}} = \frac{0.70}{10.7440} = 0.0652$$

$$U_{o,amp} = \frac{k_s}{(A/P)_{eff,b,amp}} = \frac{0.70}{12.7120} = 0.0551$$

$$H_{mean} = \frac{(A/P)_{eff,b,mean}}{k_s R_{eq}} = \frac{10.7440}{0.70(2.84 + 6.54)} = 1.6363$$

$$H_{amp} = \frac{(A/P)_{eff,b,amp}}{k_s R_{eq}} = \frac{12.7120}{0.70(2.84 + 6.54)} = 1.9360$$

$$D_{mean} = \ln \left[(1 + H_{mean}) \left(1 + \frac{1}{H_{mean}} \right)^{H_{mean}} \right] = 1.7498$$

$$D_{amp} = \ln \left[(1 + H_{amp}) \left(1 + \frac{1}{H_{amp}} \right)^{H_{amp}} \right] = 1.8832$$

$$G = k_s R_{eq} \sqrt{\frac{\omega}{\alpha_s}} = 0.70(2.84 + 6.54) \sqrt{\frac{1.992 \times 10^{-7}}{48.12 \times 10^{-7}}} = 1.3359$$

Therefore,

$$q_{mean} = U_{eff,mean} A (t_a - t_r) = 0.4 \times 0.0652 \times 1.7498 \times 2422 \times (71.6 - 50) = 2387 \text{ Btu/h}$$

and

$$q_{amp} = U_{eff,amp} A t_{amp} = 0.25 \times 0.0551 \times 1.8832^{0.16} \times 1.3359^{-0.6} \times 2422 \times 23 = 714 \text{ Btu/h}$$

Table 3 compares results of the simplified method presented here and the more exact interzone temperature profile estimation (ITPE) (Krarti 1994a, 1994b; Krarti et al. 1988a, 1988b).

Table 3 Example 2 Heat Loss per Unit Area for Simplified and ITPE Methods

Method	Mean (q_{mean}), Btu/h	Amplitude (q_{amp}), Btu/h
Simplified	2387	714
ITPE solution	2245	724

SECONDARY SYSTEM COMPONENTS

Secondary HVAC systems generally include all elements of the overall building energy system between a central heating and cooling plant and the building zones. The precise definition depends heavily on the building design. A secondary system typically includes air-handling equipment; air distribution systems with associated ductwork; dampers; fans; and heating, cooling, and humidity-conditioning equipment. They also include liquid distribution systems between the central plant and the zone and air-handling equipment, including piping, valves, and pumps.

Although the exact design of secondary systems varies dramatically among buildings, they are composed of a relatively small set of generic HVAC components. These components include distribution components (e.g., pumps/fans, pipes/ducts, valves/dampers, headers/plenums, fittings) and heat and mass transfer components (e.g., heating coils, cooling and dehumidifying coils, liquid heat exchangers, air heat exchangers, evaporative coolers, steam injectors). Most secondary systems can be described by simply connecting these components to form the complete system.

Energy estimation through computer simulation often mimics the modular construction of secondary systems by using modular simulation elements [e.g., the ASHRAE *HVAC2 Toolkit* (Brandemuehl 1993; Brandemuehl and Gabel 1994), the simulation program TRNSYS (Klein et al. 1994), and Annex 10 activities of the International Energy Agency]. To the extent that the secondary system consumes energy and transfers energy between the building and central plant, an energy analysis can be performed by characterizing the energy consumption of the individual components and the energy transferred among system components. In fact, few secondary components consume energy directly, except fans, pumps, furnaces, direct-expansion air-conditioning package units with gas-fired heaters, and inline heaters. In this chapter, secondary components are divided into two categories: distribution components and heat and mass transfer components.

Fans, Pumps, and Distribution Systems

The distribution system of an HVAC system affects energy consumption in two ways. First, fans and pumps consume electrical energy directly, based on the flow and pressures under which the device operates. Ducts and dampers, or pipes and valves, and the system control strategies affect the flow and pressures at the fan or pump. Second, thermal energy is often transferred to (or from) the fluid by (1) heat transfer through pipes and ducts and (2) electrical input to fans and pumps. Analysis of system components should, therefore, account for both direct electrical energy consumption and thermal energy transfer.

Fan and pump performance are discussed in Chapters 20 and 43 of the 2008 *ASHRAE Handbook—HVAC Systems and Equipment*. In addition, Chapter 21 of this volume covers pressure loss calculations for airflow in ducts and duct fittings. Chapter 22 presents a similar discussion for fluid flow in pipes. Although these chapters do not specifically focus on energy estimation, energy use is governed by the same performance characteristics and engineering relationships. Strictly speaking, performance calculations of a building's fan and air distribution systems require a detailed pressure balance on the entire network. For example, in an air distribution system, airflow through the fan depends on its physical characteristics, operating speed, and pressure differential across the fan. Pressure drop through the duct system depends on duct design, position of all dampers, and airflow through the fan. Interaction between the fan and duct system results in a set of coupled, nonlinear algebraic equations. Models and subroutines for performing these calculations are available in the ASHRAE *HVAC2 Toolkit* (Brandemuehl 1993).

Detailed analysis of a distribution system requires flow and pressure balancing among the components, but nearly all commercially

available energy analysis methods approximate the effect of the interactions with part-load performance curves. This eliminates the need to calculate pressure drop through the distribution system at off-design conditions. Part-load curves are often expressed in terms of a **power input ratio** as a function of the part-load ratio, defined as the ratio of part-load flow to design flow:

$$\text{PIR} = \frac{W}{W_{full}} = f_{plr}\left(\frac{Q}{Q_{full}}\right) \quad (21)$$

where

- PIR = power input ratio
- W = fan motor power at part load, W
- W_{full} = fan motor power at full load or design, W
- Q = fan airflow rate at part load, cfm
- Q_{full} = fan airflow rate at full load or design, cfm
- f_{plr} = regression function, typically polynomial

The exact shape of the part-load curve depends on the effect of flow control on the pressure and fan efficiency and may be calculated using a detailed analysis or measured field data. Figure 3 shows the relationship for three typical fan control strategies, as represented in a simulation program (York and Cappiello 1982). In the simulation program, the curves are represented by polynomial regression equations. Models and subroutines for performing these calculations are also available in the ASHRAE *HVAC2 Toolkit* (Brandemuehl 1993).

Figure 4 shows an example of a similar curve for the part-load operation of a fan system in a monitored building (Brandemuehl and Bradford 1999). In this particular case, the fan system represents ten separate air handlers, each with supply and return fans, operating with variable-speed fan control to maintain a set duct static pressure. Notice that, although the shape of the curve is similar to the variable-speed curve of Figure 3, the measured data for this particular system exhibit a more linear relationship between power and flow.

Heat transferred to the airstream because of fan operation increases air temperature. Although fan shaft power directly affects heat transfer, motor inefficiencies also heat the air if the motor is mounted inside the airstream. For pumps, this contribution is typically assumed to be zero.

The following equation provides a convenient and general model to calculate the heat transferred to the fluid:

$$q_{fluid} = [\eta_m + (1 - \eta_m)f_{m,loss}]W \quad (22)$$

where

- q_{fluid} = heat transferred to fluid, Btu/h

Fig. 3 Part-Load Curves for Typical Fan Operating Strategies
(York and Cappiello 1982)

- $f_{m,loss}$ = fraction of motor heat loss transferred to fluid stream, dimensionless (= 1 if fan mounted in airstream, = 0 if fan mounted outside airstream)
- W = fan motor power, Btu/h
- η_m = motor efficiency

Heat and Mass Transfer Components

Secondary HVAC systems comprise heat and mass transfer components (e.g., steam-based air-heating coils, chilled-water cooling and dehumidifying coils, shell-and-tube liquid heat exchangers, air-to-air heat exchangers, evaporative coolers, steam injectors). Although these components do not consume energy directly, their thermal performance dictates interactions between building loads and energy-consuming primary components (e.g., chillers, boilers). In particular, secondary component performance determines the entering fluid conditions for primary components, which in turn determine energy efficiencies of primary equipment. Accurate energy calculations cannot be performed without appropriate models of the system heat and mass transfer components.

For example, load on a chiller is typically described as the sum of zone sensible and latent loads, plus any heat gain from ducts, plenums, fans, pumps, and piping. However, the chiller's energy consumption is determined not only by the load but also by the return chilled-water temperature and flow rate. The return water condition is determined by cooling coil performance and part-load operating strategy of the air and water distribution system. The cooling coil might typically be controlled to maintain a constant leaving air temperature by modulating water flow through the coil. In such a scenario, the cooling coil model must be able to calculate the leaving air humidity, water temperature, and water flow rate given the cooling coil design characteristics and entering air temperature and humidity, airflow, and water temperature.

Virtually all building energy simulation programs include, and require, models of heat and mass transfer components. These models are generally relatively simple. Whereas a coil designer might use a detailed tube-by-tube analysis of conduction and convection heat transfer and condensation on fin surfaces to develop an optimal combination of fin and tube geometry, an energy analyst is more interested in determining changes in leaving fluid states as operating conditions vary during the year. In addition, the energy analyst is likely to have limited design data on the equipment and, therefore, requires a model with very few parameters that depend on equipment geometry and detailed design characteristics.

A typical approach to modeling heat and mass transfer components for energy calculations is based on an **effectiveness-NTU heat exchanger model** (Kays and London 1984). The effectiveness-NTU (number of transfer units) model is described in most heat transfer textbooks and briefly discussed in Chapter 4.

Fig. 4 Fan Part-Load Curve Obtained from Measured Field Data under ASHRAE RP-823
(Brandemuehl and Bradford 1999)

It is particularly appropriate for describing leaving fluid conditions when entering fluid conditions and equipment design characteristics are known. Also, this model requires only a single parameter to describe the characteristics of the exchanger: the overall transfer coefficient UA , which can be determined from limited design performance data.

Because the classical effectiveness methods were developed for sensible heat exchangers, they are used to perform energy calculations for a variety of sensible heat exchangers in HVAC systems. For typical finned-tube air-heating coils, the crossflow configuration with both fluid streams unmixed is most appropriate. The same configuration typically applies to air-to-air heat exchangers. For liquid-to-liquid exchangers, tube-in-tube equipment can be modeled as parallel or counterflow, depending on flow directions; shell-and-tube equipment can be modeled as either counter- or crossflow, depending on the extent of baffling and the number of tube passes.

The energy analyst must determine the UA to describe the operations of a specific heat exchanger. There are typically two approaches to determine this important parameter: direct calculation and manufacturers' data. Given detailed information about the materials, geometry, and construction of the heat exchanger, fundamental heat transfer principles can be applied to calculate the overall heat transfer coefficient. However, the method most appropriate for energy estimation is using manufacturers' performance data or direct measurements of installed performance. In reporting the design performance of a heat exchanger, a manufacturer typically gives the heat transfer rate under various operating conditions, with operating conditions described in terms of entering fluid flow rates and temperatures. The effectiveness and UA can be calculated from the given heat transfer rate and entering fluid conditions.

Example 3. An energy analyst seeks evaluate a hot-water heating system that includes a hot-water heating coil. The energy analysis program uses an effectiveness-NTU model of the coil and requires the UA of the coil as an input parameter. Although detailed information on the coil geometry and heat transfer surfaces is not available, the manufacturer states that the one-row hot-water heating coil delivers 818,000 Btu/h of heat under the following design conditions:

Design Performance

- Entering water temperature $t_{hi} = 175^\circ\text{F}$
- Water mass flow rate $\dot{m}_h = 661 \text{ lb/min}$
- Entering air temperature $t_{ci} = 68^\circ\text{F}$
- Air mass flow rate $\dot{m}_c = 1058 \text{ lb/min}$
- Design heat transfer $q = 818,000 \text{ Btu/h}$

Solution: First determine the heat exchanger UA from design data, then use UA to predict performance at off-design conditions. Effectiveness-NTU relationships are used for both steps. The key assumption is that the UA is constant for both operating conditions.

- a) An examination of flow rates and fluid specific heats allows calculation of the hot-fluid capacity rate C_h and the cold-fluid capacity rate C_c at design conditions, and the capacity rate ratio Z .

$$C_h = (\dot{m}c_p)_h = (661)(1.00)(60) = 39,660 \text{ Btu/h} \cdot ^\circ\text{F}$$

$$C_c = (\dot{m}c_p)_c = (1058)(0.24)(60) = 15,235 \text{ Btu/h} \cdot ^\circ\text{F}$$

$$C_{max} = C_h \quad C_{min} = C_c$$

$$Z = \frac{C_{min}}{C_{max}} = 0.384$$

where c_p is specific heat and c_{max} and c_{min} are the larger and smaller of the capacity rates, respectively,

- b) Effectiveness can be directly calculated from the heat transfer definition.

$$\epsilon = \frac{(t_{co} - t_{ci})}{(t_{hi} - t_{ci})} = \frac{q/C_c}{(t_{hi} - t_{ci})} = \frac{(818,000/15,235)}{(175 - 68)} = 0.502$$

where t_{co} is the leaving air temperature.

- c) The effectiveness-NTU relationships for a crossflow heat exchanger with both fluids unmixed allow calculation of the effectiveness in terms of the capacity rate ratio Z and the NTU [the relationships are available from most heat transfer textbooks and, specifically, in Kays and London (1984)]. Given the effectiveness and capacity rate ratio, $\text{NTU} = 0.804$.
- d) The heat transfer UA is then determined from the definition of the NTU.

$$UA = C_{min}\text{NTU} = (15,235)(0.804) = 12,250 \text{ Btu/h} \cdot ^\circ\text{F}$$

Application to Cooling and Dehumidifying Coils

Analysis of air-cooling and dehumidifying coils requires coupled, nonlinear heat and mass transfer relationships. These relationships form the basis for all HVAC components with moisture transfer, including cooling coils, cooling towers, air washers, and evaporative coolers. Although the complex heat and mass transfer theory presented in many textbooks is often required for cooling coil design, simpler models based on effectiveness concepts are usually more appropriate for energy estimation. For example, the bypass factor is a form of effectiveness in the approach of the leaving air temperature to the apparatus dew-point, or coil surface, temperature.

The effectiveness-NTU method is typically developed and applied in analysis of sensible heat exchangers, but it can also be used to analyze other types of exchangers, such as cooling and dehumidifying coils, that couple heat and mass transfer. By redefining the state variables, capacity rates, and overall exchange coefficient of these enthalpy exchangers, the effectiveness concept may be used to calculate heat transfer rates and leaving fluid states. For sensible heat exchangers, the state variable is temperature, the capacity is the product of mass flow and fluid specific heat, and the overall transfer coefficient is the conventional overall heat transfer coefficient. For cooling and dehumidifying coils, the state variable becomes moist air enthalpy, the capacity has units of mass flow, and the overall heat transfer coefficient is modified to reflect enthalpy exchange. This approach is the basis for models by Brandemuehl (1993), Braun (1988), Elmahdy and Mitalas (1977), and Threlkeld (1970). The same principles also underlie the coil model described in Chapter 22 of the 2008 *ASHRAE Handbook—HVAC Systems and Equipment*.

The effectiveness model is based on the observation that, for a given set of entering air and liquid conditions, the heat and mass transfer are bounded by thermodynamic maximum values. Figure 5 shows the limits for leaving air states on a psychrometric chart. Specifically, the leaving chilled-water temperature cannot be warmer than the entering air temperature, and the leaving air temperature and humidity cannot be lower than the conditions of saturated moist air at the temperature of the entering chilled water.

Figure 5 also shows that performance of a cooling coil requires evaluating two different effectivenesses to identify the leaving air temperature and humidity. An overall effectiveness can be used to describe the approach of the leaving air enthalpy to the minimum possible value. An air-side effectiveness, related to the coil bypass factor, describes the approach of the leaving air temperature to the effective wet-coil surface temperature.

Effectiveness analysis is accomplished for wet coils by establishing a common state variable for both the moist air and liquid streams. As implied by the lower limit of the entering chilled-water temperature, this common state variable is the moist air enthalpy. In other words, all liquid and coil temperatures are transformed to the enthalpy of saturated moist air at the liquid or coil temperature. Changes in liquid temperature can similarly be expressed in terms of changes in saturated moist air enthalpy through a saturation specific heat $c_{p,sat}$ defined by the following:

$$c_{p,sat} = \frac{\Delta h_{l,sat}}{\Delta t_l} \quad (23)$$

Fig. 5 Psychrometric Schematic of Cooling Coil Processes

Using the definition of Equation (23), the basic effectiveness relationships discussed in Chapter 4 can be written as

$$q = C_a(h_{a,ent} - h_{a,lvg}) = C_l(h_{l,sat,lvg} - h_{l,sat,ent}) \quad (24)$$

$$q = \varepsilon C_{min}(h_{a,ent} - h_{l,sat,ent}) \quad (25)$$

$$C_a = \dot{m}_a \quad (26)$$

$$C_l = \frac{(\dot{m}c_p)_l}{c_{p,sat}} \quad (27)$$

$$C_{min} = \min(C_a, C_l) \quad (28)$$

where

- q = heat transfer from air to water, Btu/h
- C = fluid capacity, lb/h
- \dot{m}_a = dry air mass flow rate, lb/h
- \dot{m}_l = liquid mass flow rate, lb/h
- $c_{p,l}$ = liquid specific heat, Btu/lb · °F
- $c_{p,sat}$ = saturation specific heat, defined by Equation (23), Btu/lb · °F
- h_a = enthalpy of moist air, Btu/lb
- $h_{l,sat}$ = enthalpy of saturated moist air at the temperature of the liquid, Btu/lb

The cooling coil effectiveness of Equation (25) is defined, then, as the ratio of moist air enthalpies in Figure 5. As with sensible heat exchangers, effectiveness is also a function of the physical coil characteristics and can be obtained by modeling the coil as a counterflow heat exchanger. However, because heat transfer calculations are performed based on enthalpies, the overall transfer coefficient must be based on enthalpy potential rather than temperature potential. The enthalpy-based heat transfer coefficient UA_h is related to the conventional temperature-based coefficient by the specific heat:

$$q = UA\Delta t = UA_h\Delta h \quad (29)$$

$$UA_h = \frac{UA\Delta t}{\Delta h} = \frac{UA}{c_p}$$

A similar analysis can be performed to evaluate the air-side effectiveness, which identifies the leaving air temperature. Whereas the overall enthalpy-based effectiveness is based on an overall heat transfer coefficient between the chilled water and air, air-side effectiveness is based on a heat transfer coefficient between the coil surface and air.

As with sensible heat exchangers, the overall heat transfer coefficients UA can be determined either from direct calculation from

coil properties or from manufacturers' performance data. A sensible heat exchanger is modeled with a single effectiveness and can be described by a single parameter UA , but a wet cooling and dehumidifying coil requires two parameters to describe the two effectivenesses shown in Figure 5. These parameters are the internal and external UAs : one describes heat transfer between the chilled water and the air-side surface through the pipe wall, and the other between the surface and the moist air. UA values can be determined from the sensible and latent capacity of a cooling coil at a single rating condition. A significant advantage of the effectiveness-NTU method is that the component can be described with as little as one measured data point or one manufacturer's design calculation.

PRIMARY SYSTEM COMPONENTS

Primary HVAC systems consume energy and deliver heating and cooling to a building, usually through secondary systems. Primary equipment generally includes chillers, boilers, cooling towers, cogeneration equipment, and plant-level thermal-storage equipment. In particular, primary equipment generally represents the major energy-consuming equipment of a building, so accurate characterization of building energy use relies on accurate modeling of primary equipment energy consumption.

Modeling Strategies

Energy consumption characteristics of primary equipment generally depend on equipment design, load conditions, environmental conditions, and equipment control strategies. For example, chiller performance depends on the basic equipment design features (e.g., heat exchange surfaces, compressor design), temperatures and flow through the condenser and evaporator, and methods for controlling the chiller at different loads and operating conditions (e.g., inlet guide vane control on centrifugal chillers to maintain leaving chilled-water temperature set point). In general, these variables vary constantly and require calculations on an hourly basis.

Regression Models. Although many secondary components (e.g., heat exchangers, valves) are readily described by fundamental engineering principles, the complex nature of most primary equipment has discouraged the use of first-principle models for energy calculations. Instead, energy consumption characteristics of primary equipment have traditionally been modeled using simple equations developed by regression analysis of manufacturers' published design data. Because published data are often available only for full-load design conditions, additional correction functions are used to correct the full-load data to part-load conditions. The functional form of the regression equations and correction functions takes many forms, including exponentials, Fourier series, and, most of the time, second- or third-order polynomials. Selection of an appropriate functional form depends on the behavior of the equipment. In some cases, energy consumption is calculated using direct interpolation from tables of data, but this often requires excessive data input and computer memory.

The typical approach to modeling primary equipment in energy simulation programs is to assume the following functional form for equipment power consumption:

$$P = \text{PIR} \times \text{Load} \quad (30)$$

$$\text{PIR} = \text{PIR}_{nom} f_1(t_a, t_b, \dots) f_2(\text{PLR})$$

$$C_{avail} = C_{nom} f_3(t_a, t_b, \dots) \quad (31)$$

$$\text{PLR} = \frac{\text{Load}}{C_{avail}}$$

where

- P = equipment power, kW
- PIR = energy input ratio
- PIR_{nom} = energy input ratio under nominal full-load conditions

Load = power delivered to load, kW
 C_{avail} = available equipment capacity, kW
 C_{nom} = nominal equipment capacity, kW
 f_1 = function relating full-load power at off-design conditions (t_a, t_b, \dots) to full-load power at design conditions
 f_2 = fraction full-load power function, relating part-load power to full-load power
 f_3 = function relating available capacity at off-design conditions (t_a, t_b, \dots) to nominal capacity
 t_a, t_b = various operating temperatures that affect power
 PLR = part-load ratio

The part-load ratio is the ratio of the load to the available equipment capacity at given off-design operating conditions. Like the power, the available, or full-load, capacity is a function of operating conditions.

The particular forms of off-design functions f_1 and f_3 depend on the specific type of primary equipment. For example, for fossil-fuel boilers, full-load capacity and power (or fuel use) can be affected by thermal losses to ambient temperature. However, these off-design functions are typically considered to be unity in most building simulation programs. For chillers, both capacity and power are affected by condenser and evaporator temperatures, which are often characterized in terms of their secondary fluids. For direct-expansion air-cooled chillers, operating temperatures are typically the wet-bulb temperature of air entering the evaporator and the dry-bulb temperature of air entering the condenser. For liquid chillers, the temperatures are usually the leaving chilled-water temperature and the entering condenser water temperature.

As an example, consider the performance of a direct-expansion (DX) packaged single-zone rooftop unit. The nominal rated performance of these units is typically given for an outdoor air temperature of 95°F and evaporator entering coil conditions of 80°F db and 67°F wb. However, performance changes as outdoor temperature and entering coil conditions vary. To account for these effects, the DOE-2.1E simulation program expresses the off-design functions f_1 and f_3 with biquadratic functions of the outdoor dry-bulb temperature and the coil entering wet-bulb temperature.

$$f_1(t_{wb,ent}, t_{oa}) = a_0 + a_1 t_{wb,ent} + a_2 t_{wb,ent}^2 + a_3 t_{oa} + a_4 t_{oa}^2 + a_5 t_{wb,ent} t_{oa} \quad (32)$$

$$f_3(t_{wb,ent}, t_{oa}) = c_0 + c_1 t_{wb,ent} + c_2 t_{wb,ent}^2 + c_3 t_{oa} + c_4 t_{oa}^2 + c_5 t_{wb,ent} t_{oa} \quad (33)$$

The constants in Equations (32) and (33) are given in Table 4.

The fraction full-load power function f_2 represents the change in equipment efficiency at part-load conditions and depends heavily on the control strategies used to match load and capacity. Figure 6 shows several possible shapes of these functional relationships. (Notice that these curves are similar to the fan part-load curves of Figure 3.) Curve 1 represents equipment with constant efficiency, independent of load. Curve 2 represents equipment that is most efficient in the middle of its operating range. Curve 3 represents equipment that is most efficient at full load. Note that these types of curves apply to both boilers and chillers.

First-Principle Models. As with the secondary components, engineering first principles can also be used to develop models of primary equipment. Gordon and Ng (1994, 1995), Gordon et al. (1995), Lebrun et al. (1999), and others have sought to develop such models in which unknown model parameters are extracted from measured or published manufacturers' data.

The energy analyst often must choose the appropriate model for the job. For example, a complex boiler model is not appropriate if the boiler operates at virtually constant efficiency. Similarly, a regression-based model might be appropriate when the user has a

Table 4 Correlation Coefficients for Off-Design Relationships

Corr.	0	1	2	3	4	5
f_1	-1.063931	0.0306584	0.0001269	0.0154213	0.0000497	0.0002096

Fig. 6 Possible Part-Load Power Curves

full dataset of reliable in-situ measurements of the plant. However, first-principle physical models generally have several advantages over pure regression models:

- Physical models allow confident extrapolation outside the range of available data.
- Regression is still required to obtain values for unknown physical parameters. However, the values of these parameters usually have physical significance, which can be used to estimate default parameter values, diagnose errors in data analysis through checks for realistic parameter values, and even evaluate potential performance improvements.
- The number of unknown parameters is generally much smaller than the number of unknown coefficients in the typical regression model. For example, the standard ARI compressor model requires as many as 30 coefficients, 10 each for regressions of capacity, power, and refrigerant flow. By comparison, a physical compressor model may have as few as four or five unknown parameters. Thus, physical models require fewer measured data.
- Data on part-load operation of chillers and boilers are notoriously difficult to obtain. Part-load corrections often represent the greatest uncertainty in the regression models, while causing the greatest effect on annual energy predictions. By comparison, physical models of full-load operation often allow direct extension to part-load operation with little additional required data.

Physical models of primary HVAC equipment are generally based on fundamental engineering analysis and found in many HVAC textbooks, but the models described here are specifically based on the work of Bourdouxhe et al. (1994a, 1994b, 1994c) in developing the ASHRAE *HVAC 1 Toolkit* (Lebrun et al. 1999). Each elementary component's behavior is characterized by a limited number of physical parameters, such as heat exchanger heat transfer area or centrifugal compressor impeller blade angle. Values of these parameters are identified, or tuned, based on regression fits of overall performance compared to measured or published data.

Although physical models are based on physical characteristics, values obtained through a regression analysis of manufacturers'

Fig. 7 Boiler Steady-State Modeling

data are not necessarily representative of the actual measured values. Strictly speaking, the parameter values are regression coefficients with estimated values, identified to minimize the error in overall system performance. In other words, errors in the fundamental models of equipment are offset by over- or under-estimation of the parameter values.

Boiler Model

The literature on boiler models is extensive, ranging from steady-state performance models (DeCicco 1990; Lebrun 1993) to detailed dynamic simulation models (Bonne and Jansen 1985; Lebrun et al. 1985), to a combination of these two schemes (Laret 1991; Malmström et al. 1985).

Dynamic models are meant to describe transient behavior of the equipment. Consequently, these models need to accurately capture the combustion process and the complex energy exchange that occurs inside the combustion chamber. Usually, this kind of model is very detailed and demanding to formulate and use. Hence, a dynamic boiler model should be considered only in more complex situations (e.g., large boilers in large buildings, district heating systems, cogeneration systems), where a complete, detailed representation of heat distribution, emission, and operation and control under varying external conditions is warranted.

Although all major variables of a boiler may vary with load and environmental conditions, assuming steady-state conditions during burner-on and burner-off times results in a relationship between input and output variables that is much simpler than those in dynamic models. Model evaluation against actual measurements shows that the steady-state model can be sufficiently accurate for energy calculations over relatively long time periods (e.g., weeks or months) with regard to the measuring accuracy.

In steady-state modeling, it is assumed that, during continuous operation, the boiler can be disaggregated into one adiabatic combustion chamber and two heat exchangers (Figure 7). The following fluid streams flow across the

- Combustion chamber (CC): air (subscript *a*) and fuel (subscript *f*) streams at the inlet, and combustion gas (subscript *fg*) at the outlet
- First heat exchanger (HEX1): combustion gas outlet and supply water streams (subscript *in*)
- Second heat exchanger (HEX2): heated water stream (subscript *out*) and a fluid representing the environment

The boiler model is characterized by three parameters, which represent the following heat transfer coefficients:

- UA_{ge} : between the flue gas and the environment in CC
- UA_{gw} : between the flue gas and the water in HEX1
- UA_{we} : between the water and the environment in HEX2

Primary model inputs to the model are the leaving water set-point temperature ($T_{w,out}$) and control model and the load characteristics (i.e., entering water temperature $T_{w,in}$ and water flow rate \dot{m}_w). Secondary model inputs include the air, fuel, and ambient temperatures (T_a , T_f , and T_e) as well as the fuel/air ratio *f*.

Modern boilers are airtight, so there is almost no air circulation across the combustion chamber when the burner is off. In this case, the boiler behaves as a simple water/environment heat exchanger (i.e., HEX1 and HEX2 are combined) and the thermal model is reduced to that of a simple heat exchanger.

Combustion Chamber Model. Mathematical description of this model allows the flue gas mass flow rate and enthalpy $h_{fg,in1}$ (in Btu/lb_{fg}) at the flue gas/water heat exchanger (HEX1) inlet to be calculated. The calculated flue gas mass flow rate is not necessarily the one associated with the specified value of the flue gas/water heat transfer coefficient/area product. Therefore, the following empirical relationship is used to adjust the value of this coefficient to the calculated value of the flue gas mass flow rate.

$$\dot{m}_{fg} = 1 + \frac{1}{f} \dot{m}_f \quad (34)$$

$$h_{fg,in} = \frac{h_{fg,in1}}{1 + \frac{1}{f}} \quad (35)$$

$$(UA_{gw})_{calc} = UA_{gw} \left[\frac{\dot{m}_{fg}}{(\dot{m}_{fg})_{rated}} \right]^{0.65} \quad (36)$$

where

- $h_{fg,in1}$ = known function of composition of combustion products and flue gas temperature at inlet of gas/water heat exchanger, Btu/lb_{fg}
- $h_{fg,in}$ = gas enthalpy at outlet of gas/water heat exchanger, Btu/lb_f
- $(\dot{m}_{fg})_{rated}$ = flue gas mass flow rate associated with specified value of gas/water heat transfer coefficient/area product, lb/min

Flue Gas-Water Heat Exchanger Model. The first step is to calculate the heat transfer rate q_{gw} across HEX1:

$$q_{gw} = \epsilon_{gw} C_{fg} (T_{fg,in} - T_{w,in}) \quad (37)$$

where

- $C_{fg} = c_{p,fg} \dot{m}_{fg}$ = heat capacity flow rate of flue gas
- $\epsilon_{gw} = \frac{1 - \exp[-NTU(1-C)]}{1 - C \exp[-NTU(1-C)]}$ = effectiveness for HEX1

For a counterflow heat exchanger,

$$NTU = \frac{UA_{gw}}{C_{fg}} \quad \text{and} \quad C = \frac{C_{fg}}{C_w} \quad (38)$$

where $C_{fg} \leq C_w$ and $C_w = c_{p,w} \dot{m}_w$.

The temperature of flue gas leaving HEX1 ($T_{fg,out}$) can be calculated from

$$\epsilon_{gw} (T_{fg,in} - T_{w,in}) = (T_{fg,in} - T_{fg,out}) \quad (39)$$

Other unknowns need also to be calculated. In HEX1, heat is transferred from hot flue gas to the water

$$q_{gw} = C_w (T_{w,out}^* - T_{w,in}) \quad (40)$$

from which the temperature of water leaving HEX1 and entering HEX2 is

$$T_{w,out}^* = \frac{q_{gw}}{C_w} + T_{w,in} \quad (41)$$

Water-Environment Heat Exchanger Model. In HEX2,

$$\varepsilon_{we}(T_{w,out}^* - T_e) = (T_{w,out}^* - T_{w,out}) \quad (42)$$

where $\varepsilon_{we} = 1 - \exp(-UA_{we}/C_w)$. Then water temperature at the outlet of HEX2 is

$$T_{w,out} = T_e + \frac{T_{w,out}^* - T_e}{\exp\left(\frac{UA_{we}}{C_w}\right)} \quad (43)$$

Consequently, heat loss from hot water in HEX2 is

$$q_{we} = C_w(T_{w,out}^* - T_{w,out}) \quad (44)$$

Useful heat given to the water stream is

$$q_b = q_{gw} - q_{we} \quad (45)$$

Finally, boiler efficiency is given by

$$\eta = \frac{q_b}{\dot{m}_f \times \text{FLHV}} \quad (46)$$

where FLHV is fuel lower heating value.

The main outputs of this model are

- The “useful” boiler output: its leaving water temperature (to be compared with its set point), or its corresponding “useful” power (i.e., net rate of heat transfer q_b by the heated water)
- Its energy consumption: burner fuel flow rate \dot{m}_f or corresponding efficiency η

Secondary model outputs include

- Flue gas temperature, specific heat, and corresponding enthalpy flow in the chimney
- Environmental loss q_{we} in boiler room

The three-parameter model allows simulation of boilers using most conventional fuels under a wide range of operating conditions with less than 1% error. A two-exchanger model appears to be flexible enough to describe boiler behavior at different load conditions and water temperatures. This simple model is stated to accurately predict the sensitivity of a boiler to variations of burner fuel rate and airflow rates as well as water/environment losses.

Vapor Compression Chiller Models

Figure 8 shows a schematic of a vapor compression chiller. In this case, the components include two heat exchangers, an expansion valve, and a compressor with a motor and transmission. Chiller components are linked through the refrigerant. For energy estimating, a simplified approach is sufficient to represent the refrigerant as a “perfect” fluid with fictitious property values. That is, refrigerant liquid is modeled as incompressible, and vapor properties are described by ideal gas laws with effective average values of property parameters, such as specific heat.

Condenser and Evaporator Modeling. Both condensers and evaporators are modeled as classical heat exchangers. The two heat exchangers are each assumed to have a constant overall heat transfer coefficient. In addition, the models used in chiller systems suffer from one additional assumption: the refrigerant fluid is assumed to be isothermal for both heat exchangers, which effectively ignores the superheated and subcooled regions of the heat exchanger. The assumption of an isothermal refrigerant is particularly crude for the condenser, which sees very high refrigerant

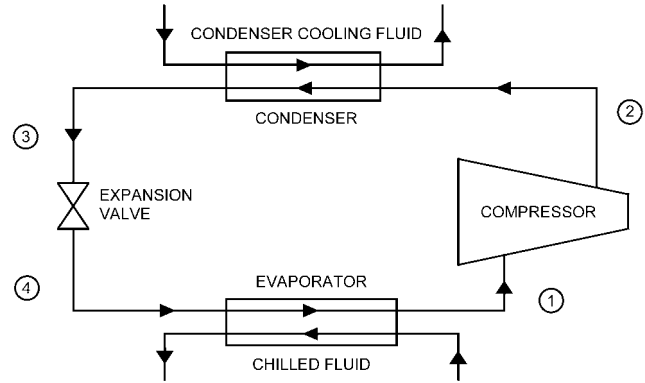

Fig. 8 Chiller Model Using Elementary Components
(See Figure 10 for description of points 1 to 4)

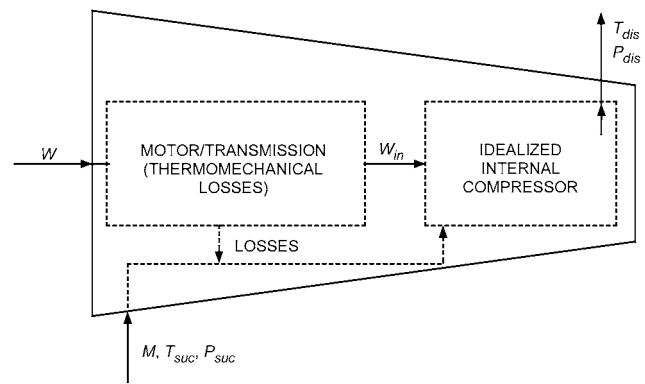

Fig. 9 General Schematic of Compressor

temperatures from the compressor discharge; thus, the mean temperature difference between refrigerant and water in the heat exchanger is significantly underestimated. Fortunately, this systematic error is offset by a significant overestimate of the corresponding heat transfer coefficient.

General Compressor Modeling. Modeling real compressors requires description of many thermomechanical losses (e.g., heat loss, fluid friction, throttling losses in valves, motor and transmission inefficiencies) within the compressor. Some of these losses can be modeled within the compressor, but others are too complex or unknown to describe in a model for energy calculations.

The general approach used here for compressor modeling is described in Figure 9. The compressor is described by two distinct internal elements: an idealized internal compressor and a motor-transmission element to account for unknown losses. Schematically, the motor-transmission subsystem represents an inefficiency of energy conversion. Losses from these inefficiencies are assumed to heat the fluid before compression. Mathematically, it can be modeled by the following linear relationship:

$$W = W_{lo} + (1 + \alpha)W_{int} \quad (47)$$

where

W = electrical power for a hermetic or semihermetic compressor, or shaft power for an open compressor

W_{lo} = constant electromechanical loss

W_{int} = idealized internal compressor power (depends on type of compressor)

α = proportional power loss factor

W_{lo} and α are empirical parameters determined by performing a regression analysis on manufacturers' data. Other parameters are also required to model W_{int} , depending on the type of compressor.

Fig. 10 Schematic of Reciprocating Compressor Model

The following sections describe different modeling techniques for reciprocating, screw, and centrifugal compressors. Detailed modeling techniques are available in the ASHRAE *HVAC 1 Toolkit* (Lebrun et al. 1999) and associated references.

Modeling the Reciprocating Compressor. The schematic for a reciprocating compressor, for use with the general model, is shown in Figure 10. Refrigerant enters the compressor at state 1 and is heated to state 1a by thermomechanical losses of the motor-transmission model in Figure 9. The refrigerant undergoes isentropic compression to state 2s, followed by throttling to the compressor discharge at state 2. The throttling valve is a simplified approach to model known losses within the compressor caused by pressure drops across the suction and discharge valves. A more accurate model might include pressure losses at both the compressor inlet and outlet, but analysis of compressor data reveals that the simpler model is adequate for modeling of typical reciprocating compressors. In fact, many compressors can be adequately modeled with no throttling valve at all.

The refrigerant flow rate through the system must be determined to predict chiller and compressor performance. In general, volumetric flow depends on the pressure difference across the compressor. The compressor refrigerant flow rate is a decreasing function of the pressure ratio because of vapor re-expansion in the clearance volume. With refrigerant vapor modeled as an ideal gas, the volumetric flow rate is given by

$$V = V_s \left[1 + C_f - C_f \left(\frac{p_{ex}}{p_{suc}} \right)^{1/\gamma} \right] \quad (48)$$

where

V = volumetric flow rate

V_s = swept volumetric flow rate (geometric displacement of the compressor)

C_f = clearance factor = $V_{clearance}/V_s$

p_{ex}/p_{suc} = cylinder pressure ratio

γ = specific heat ratio

V_s and C_f must be identified using data for the actual reciprocating compressor.

Although the models discussed apply to full-load operation, Equation (48) is also valid at part-load conditions. However, the internal power use can be different at part load depending on the particular strategy for capacity modulation, such as on-off cycling, cylinder unloading, hot-gas bypass, or variable-speed motor. In most cases, simple physical models can be developed to describe these methods, which generally vary the swept volumetric rate. Additional thermomechanical losses can also be modeled but often

involve additional parameters. For example, the effect of cylinder unloading can be modeled by the following relationship:

$$W_{int} = W_s + \left(1 - \frac{N_c}{N_{c,FL}} \right) W_{pump} \quad (49)$$

where

W_{int} = idealized internal compressor power

N_c = number of cylinders in use

$N_{c,FL}$ = number of cylinders in use in full-load regime

W_{pump} = internal power of the compressor when all the cylinders are unloaded (pumping power)

W_s = isentropic power

The variable W_{pump} characterizes the part-load regime of the reciprocating compressor, and is assumed to be constant throughout the entire part-load range.

In summary, a realistic physical model of a reciprocating compressor, covering both full- and part-load operations, can be developed based on six parameters: the constant and proportional loss terms of the motor-transmission model W_{lo} and α , the swept volumetric flow rate V_s of the compressor cylinders, the cylinder clearance volume factor C_f , the fictitious exhaust valve flow area A_{ex} and the zero-load pumping power of the unloaded compressor W_{pump} . The entire chiller can then be modeled with two additional parameters for the overall heat transfer coefficients of the condenser and evaporator.

Modeling Other Compressors and Chillers. From a modeling perspective, the thermodynamic processes of a screw compressor are similar to those of a reciprocating compressor. Physically, the screw compressor transports an initial volumetric flow rate of refrigerant vapor to a higher pressure and density by squeezing it into a smaller space. A realistic physical model of a variable-volume-ratio, twin-screw compressor, covering both full- and part-load operations, can be developed based on five parameters: the (1) constant and (2) proportional loss terms of the motor-transmission model of Equation (47), (3) swept volumetric flow rate of the compressor screw, (4) internal leakage area, and (5) pumped pressure differential for diverted flow at part load (Lebrun et al. 1999). The entire chiller can then be modeled with two additional parameters for the overall heat transfer coefficients of the condenser and evaporator.

An idealized internal model of a centrifugal compressor, to be used in conjunction with Equation (47) and Figure 9, can be based on an ideal analysis of a single-stage compressor composed of an isentropic impeller and isentropic diffuser. In addition to the thermomechanical loss parameters of Equation (47), only three additional parameters are required: the (1) peripheral speed of the impeller, (2) vane inclination at the impeller exhaust, and (3) impeller exhaust area.

The refrigerant cycle of an absorption chiller is the same as for a vapor compression cycle, except for the absorption-generation subsystem in place of the compressor (see Chapter 2 for more information). The absorption-generation subsystem includes an absorber, steam-fired generator, recovery heat exchanger, pump, and control valve. All components except the pump and control valve can be modeled as heat exchangers.

Cooling Tower Model

A cooling tower is used in primary systems to reject heat from the chiller condenser. Controls typically manage tower fans and pumps to maintain a desired water temperature entering the condenser. Like cooling and dehumidifying coils in secondary systems, cooling tower performance has a strong influence on the chiller's energy consumption. In addition, tower fans consume electrical energy directly.

Fundamentally, a cooling tower is a direct contact heat and mass exchanger. Equations describing the basic processes are given in

Chapter 6 and in many HVAC textbooks. Chapter 39 of the 2008 *ASHRAE Handbook—HVAC Systems and Equipment* describes the specific performance of cooling towers. Performance subroutines are also available in Klein et al. (1994) and Lebrun et al. (1999).

For energy calculations, cooling tower performance is typically described in terms of the outdoor wet-bulb temperature, temperature drop of water flowing through the tower (range), and difference between leaving water and air wet-bulb temperatures (approach). Simple models assume constant range and approach, but more sophisticated models use rating performance data to relate leaving water temperature to the outdoor wet-bulb temperature, water flow, and airflow. Simple cooling tower models, such as those based on a single overall transfer coefficient that can be directly inferred from a single tower rating point, are often appropriate for energy calculations.

SYSTEM MODELING

OVERALL MODELING STRATEGIES

In developing a simulation model for building energy prediction, two basic issues must be considered: (1) modeling components or subsystems and (2) overall modeling strategy. Modeling components, discussed in the section on Component Modeling and Loads, results in sets of equations describing the individual components. The overall modeling strategy refers to the **sequence** and **procedures** used to solve these equations. The accuracy of results and the computer resources required to achieve these results depend on the modeling strategy.

In most building energy programs, load models are executed for every space for every hour of the simulation period. (Practically all models use 1 h as the time step, which excludes any information on phenomena occurring in a shorter time span.) The load model is followed by running models for every secondary system, one at a time, for every hour of the simulation. Finally, the plant simulation model is executed again for the entire period. Each sequential execution processes the fixed output of the preceding step.

This procedure is illustrated in Figure 11. Solid lines represent data passed from one model to the next; dashed lines represent information, usually provided by the user, about one model passed to the preceding model. For example, the system information consists of a piecewise-linear function of zone temperature that gives the system capacity.

Because of this loads-systems-plants sequence, certain phenomena cannot be modeled precisely. For example, if the heat balance method for computing loads is used, and some component in the system simulation model cannot meet the load, the program can only report the current load. In actuality, the space temperature should readjust until the load matches equipment capacity, but this cannot be modeled because loads have been precalculated and fixed. If the weighting-factor method is used for loads, this problem is partially overcome, because loads are continually readjusted during the system simulation. However, the weighting factor technique is based on linear mathematics, and wide departures of room temperatures from those used during execution of the load program can introduce errors.

Fig. 11 Overall Modeling Strategy

A similar problem arises in plant simulation. For example, in an actual building, as the load on the central plant varies, the supply chilled-water temperature also varies. This variation in turn affects the capacity of secondary system equipment. In an actual building, when the central plant becomes overloaded, space temperatures should rise to reduce load. However, in most energy estimating programs, this condition cannot occur; thus, only the overload condition can be reported. These are some of the penalties associated with decoupling of the load, system, and plant models.

An alternative strategy, in which all calculations are performed at each time step, is possible. Here, the load, system, and plant equations are solved simultaneously at each time interval. With this strategy, unmet loads and imbalances cannot occur; conditions at the plant are immediately reflected to the secondary system and then to the load model, forcing them to readjust to the instantaneous conditions throughout the building. The results of this modeling strategy are superior, although the magnitude and importance of the improvement are uncertain.

The principal disadvantage of this approach, and the reason that it was not widely used in the past, is that it demands more computing resources. However, most current desktop computers can now run programs using the alternative approach in a reasonable amount of time. Programs that, to one degree or another, implement simultaneous solution of the loads, system, and plant models have been developed by Clarke (2001), Crawley et al. (2001), Klein et al. (1994), Park et al. (1985), and Taylor et al. (1990, 1991). Some of these programs simulate the loads, systems, and plants using sub-hourly time steps.

An economic model, as shown in Figure 11, calculates energy costs (and sometimes capital costs) based on the estimated required input energy. Thus, the simulation model calculates energy use and cost for any given input weather and internal loads. By applying this model (i.e., determining output for given inputs) at each hour (or other suitable interval), the hour-by-hour energy consumption and cost can be determined. Maintaining running sums of these quantities yields monthly or annual energy usage and costs.

These models only compare design alternatives; a large number of uncontrolled and unknown factors usually rule out such models for accurate prediction of utility bills. For example, Miller (1980) found that the dynamics of control of components may have at least minor effects on predicted energy use. The Bibliography lists several models, which are also described in Walton (1983) and York and Capiello (1982). Generally, load models tend to be the most complex and time-consuming, whereas the central plant model is the least complex.

Because detailed models are computationally intensive, several simplified methods have been developed, including the degree-day, bin, and correlation methods.

DEGREE-DAY AND BIN METHODS

Degree-day methods are the simplest methods for energy analysis and are appropriate if building use and HVAC equipment efficiency are constant. Where efficiency or conditions of use vary with outdoor temperature, consumption can be calculated for different values of the outdoor temperature and multiplied by the corresponding number of hours; this approach is used in various **bin methods**. When the indoor temperature is allowed to fluctuate or when interior gains vary, simple steady-state models must not be used.

Although computers can easily calculate the energy consumption of a building, the concepts of degree-days and balance point temperature remain valuable tools. A climate's severity can be characterized concisely in terms of degree-days. Also, the degree-day method and its generalizations can provide a simple estimate of annual loads, which can be accurate if the indoor temperature and internal gains are relatively constant and if the heating or cooling systems operate for a complete season.

Balance Point Temperature

The balance point temperature t_{bal} of a building is defined as that value of the outdoor temperature t_o at which, for the specified value of the interior temperature t_i , the total heat loss q_{gain} is equal to the heat gain from sun, occupants, lights, and so forth.

$$q_{gain} = K_{tot}(t_i - t_{bal}) \quad (50)$$

where K_{tot} is the total heat loss coefficient of the building in Btu/h·°F. For any steady-state method described in this section, heat gains must be the average for the period in question, not for the peak values. In particular, solar radiation must be based on averages, not peak values. The balance point temperature is therefore

$$t_{bal} = t_i - \frac{q_{gain}}{K_{tot}} \quad (51)$$

Heating is needed only when t_o drops below t_{bal} . The rate of energy consumption of the heating system is

$$q_h = \frac{K_{tot}}{\eta_h} [t_{bal} - t_o(\theta)]^+ \quad (52)$$

where η_h is the efficiency of the heating system, also designated on an annual basis as the annual fuel use efficiency (AFUE), θ is time, and the plus sign above the bracket indicates that only positive values are counted. If t_{bal} , K_{tot} , and η_h are constant, the annual heating consumption can be written as an integral:

$$Q_{h, yr} = \frac{K_{tot}}{\eta_h} \int [t_{bal} - t_o(\theta)]^+ d\theta \quad (53)$$

This integral of the temperature difference conveniently summarizes the effect of outdoor temperatures on a building. In practice, it is approximated by summing averages over short time intervals (daily or hourly); the results are called **degree-days** or **degree-hours**.

Annual Degree-Day Method

Annual Degree-Days. If daily average values of outdoor temperature are used for evaluating the integral, the degree-days for heating $DD_h(t_{bal})$ are obtained as

$$DD_h(t_{bal}) = (1 \text{ day}) \sum_{\text{days}} (t_{bal} - t_o)^+ \quad (54)$$

with dimensions of °F·days. Here the summation is to extend over the entire year or over the heating season. It is a function of t_{bal} , reflecting the roles of t_i , heat gain, and loss coefficient. The balance point temperature t_{bal} is also known as the base of the degree-days. In terms of degree-days, the annual heating consumption is

$$Q_{h, yr} = \frac{K_{tot}}{\eta_h} DD_h(t_{bal}) \quad (55)$$

Heating degree-days or degree-hours for a balance point temperature of 65°F have been widely tabulated (this temperature represents average conditions in typical buildings in the past). The 65°F base is assumed whenever t_{bal} is not indicated explicitly. The extension of degree-day data to different bases is discussed later.

Cooling degree-days can be calculated using an equation analogous to Equation (54) for heating degree-days as

$$DD_c(t_{bal}) = (1 \text{ day}) \sum_{\text{days}} (t_o - t_{bal})^+ \quad (56)$$

Although the definition of the balance point temperature is the same as that for heating, in a given building its numerical value for cooling is generally different from that for heating because q_i , K_{tot} , and t_i can be different. According to Claridge et al. (1987), t_{bal} can include both solar and internal gains as well as losses to the ground.

Calculating cooling energy consumption using degree-days is more difficult than heating. For cooling, the equation analogous to Equation (55) is

$$Q_{c, yr} = \frac{K_{tot}}{\eta_h} DD_c(t_{bal}) \quad (57)$$

for a building with static K_{tot} . That assumption is generally acceptable during the heating season, when windows are closed and the air exchange rate is fairly constant. However, during the intermediate or cooling season, heat gains can be eliminated, and the onset of mechanical cooling can be postponed by opening windows or increasing the ventilation. (In buildings with mechanical ventilation, this is called the **economizer mode**.) Mechanical air conditioning is needed only when the outdoor temperature exceeds the threshold t_{max} . This threshold is given by an equation analogous to Equation (51), replacing the closed-window heat transmission coefficient K_{tot} with K_{max} for open windows:

$$t_{max} = t_i - \frac{q_{gain}}{K_{max}} \quad (58)$$

K_{max} varies considerably with wind speed, but a constant value can be assumed for simple cases. The resulting sensible cooling load is shown schematically in Figure 12 as a function of t_o . The solid line is the load with open windows or increased ventilation; the dashed line shows the load if K_{max} were kept constant. The annual cooling load for this mode can be calculated by breaking the area under the solid line into a rectangle and a triangle, or

$$Q_c = K_{tot} [DD_c(t_{max}) + (t_{max} - t_{bal})N_{max}] \quad (59)$$

where $DD_c(t_{max})$ are the cooling degree-days for base t_{max} , and N_{max} is the number of days during the season when t_o rises above t_{max} . This is merely a schematic model of air conditioning. In practice, heat gains and ventilation rates vary, as does occupant behavior in using the windows and air conditioner. Also, in commercial buildings with economizers, the extra fan energy for increased ventila-

Fig. 12 Cooling Load as Function of Outdoor Temperature t_o

tion must be added to the calculations. Finally, air-conditioning systems are often turned off during unoccupied periods. Therefore, cooling degree-hours better represent the period when equipment is operating than cooling degree-days because degree-days assume uninterrupted equipment operation as long as there is a cooling load.

Latent loads can form an appreciable part of a building's cooling load. The degree-day method can be used to estimate the latent load during the cooling season on a monthly basis by adding the following term to Equation (59):

$$q_{latent} = \dot{m}h_{fg}(W_o - W_i) \quad (60)$$

where

- q_{latent} = monthly latent cooling load, Btu/h
- \dot{m} = monthly infiltration (total airflow), lb/h
- h_{fg} = heat of vaporization of water, Btu/lb
- W_o = outdoor humidity ratio (monthly averaged)
- W_i = indoor humidity ratio (monthly averaged)

The degree-day method assumes that t_{bal} is constant, which is not well satisfied in practice. Solar gains are zero at night, and internal gains tend to be highest during the evening. The pattern for a typical house is shown in Figure 13. As long as t_o always stays below t_{bal} , variations average out without changing consumption. But for the situation in Figure 13, t_o rises above t_{bal} from shortly after 1000 h to 2200 h; the consequences for energy consumption depend on thermal inertia and HVAC system control. If this building had low inertia and temperature control were critical, heating would be needed at night and cooling during the day. In practice, this effect is reduced by thermal inertia and by the dead band of the thermostat, which allows t_i to float.

The closer t_o is to t_{bal} , the greater the uncertainty. If occupants keep windows closed during mild weather, t_i will rise above the set point. If they open windows, the potential benefit of heat gains is reduced. In either case, the true values of t_{bal} become uncertain. Therefore, the degree-day method, like any steady-state method, is unreliable for estimating consumption during mild weather. In fact, consumption becomes most sensitive to occupant behavior and cannot be predicted with certainty.

Despite these problems, the degree-day method (using an appropriate base temperature) can give remarkably accurate results for the annual heating energy of single-zone buildings dominated by losses through the walls and roof and/or ventilation. Typical buildings have time constants that are about 1 day, and a building's thermal inertia essentially averages over the diurnal variations, especially if

Fig. 13 Variation of Balance Point Temperature and Internal Gains for a Typical House (Nisson and Dutt 1985)

t_i is allowed to float. Furthermore, energy consumption in mild weather is small; hence, a relatively large error here has only a small effect on the total for the season.

Variable-Base Annual Degree-Days. Calculating Q_h from degree-days $DD_h(t_{bal})$ depends on the value of t_{bal} . This value varies widely from one building to another because of widely differing personal preferences for thermostat settings and setbacks and because of different building characteristics. In response to the fuel crises of the 1970s, heat transmission coefficients have been reduced, and thermostat setback has become common. At the same time, energy use by appliances has increased. These trends all reduce t_{bal} (Fels and Goldberg 1986). Hence, in general, degree-days with the traditional base 65°F are not to be used.

Figure 14A shows how heating degree-days vary with t_{bal} for a particular site (New York). The plot is obtained by evaluating Equation (54) with data for the number of hours per year during which t_o is within 5°F temperature intervals centered at 77°F, 72°F, 67°F, 62°F, ..., 7°F. Data for the number of hours in each interval, or **bin**, are included as labels in this plot. Analogous curves, without these labels, are shown in Figure 14B for Houston, Washington, D.C., and Denver. If the annual average of t_o is known, the cooling degree-days to any base below $72 \pm 2.5^\circ\text{F}$ can also be found.

Seasonal Efficiency. The seasonal efficiency η_h of heating equipment depends on factors such as steady-state efficiency, sizing, cycling effects, and energy conservation devices. It can be much lower than or comparable to steady-state efficiency. Alereza and Kusuda (1982) developed expressions to estimate seasonal efficiency for a variety of furnaces, if information on rated input and output is available. These expressions correlate seasonal efficiency with variables determined by using the equipment simulation capabilities of a large hourly simulation program and typical equipment performance curves supplied by the National Institute of Standards and Technology (NIST):

$$\eta = \frac{\eta_{ss}CF_{pl}}{1 + \alpha_D} \quad (61)$$

where

- η_{ss} = steady-state efficiency (rated output/input)
- CF_{pl} = part-load correction factor
- α_D = fraction of heat loss from ducts

The dimensionless term CF_{pl} is a characteristic of the part-load efficiency of the heating equipment, which may be calculated as follows:

Gas Forced-Air Furnaces

With pilot

$$CF_{pl} = 0.6328 + 0.5738(RLC) - 0.3323(RLC)^2$$

With intermittent ignition

$$CF_{pl} = 0.7791 + 0.1983(RLC) - 0.0711(RLC)^2$$

With intermittent ignition and loose stack damper

$$CF_{pl} = 0.9276 + 0.0732(RLC) - 0.0284(RLC)^2$$

Oil Furnaces Without Stack Damper

$$CF_{pl} = 0.7092 + 0.6515(RLC) - 0.4711(RLC)^2$$

Resistance Electric Furnaces

$$CF_{pl} = 1.0$$

These equations are based on many annual simulations for the equipment. The dimensionless ratio RLC of building design load to the capacity (rated output) of the equipment is defined as follows:

$$RLC = \frac{BLC}{CHT}(t_{bal} - t_{od})(1 + \alpha_D)$$

where

- BLC = building loss coefficient, Btu/h·°F
- t_{od} = outside design temperature, °F
- CHT = capacity (rated output) of heating equipment, Btu/h

BLC can be defined as design-day heat loss/($t_{bal} - t_{od}$). The design-day heat loss includes both infiltration and ground losses. Duct losses as a percentage of the design-day heat loss are added using the factor $(1 + \alpha_D)$. RLC assumes values in the range 0 to 1.0, appropriate for typical cases when heating equipment is oversized. Seasonal efficiency is also discussed by Chi and Kelly (1978), Mitchell (1983), and Parker et al. (1980).

Monthly Degree-Days

Many formulas have been proposed for estimating degree-days relative to an arbitrary base when detailed data are not available. The basic idea is to assume a typical probability distribution of temperature data, characterized by its average \bar{t}_o and by its standard deviation σ . Erbs et al. (1983) developed a model that needs as input only the average \bar{t}_o for each month of the year. The standard deviations σ_m for each month are then estimated from the correlation

$$\sigma_m = 3.54 - 0.0290\bar{t}_o + 0.0664\sigma_{yr} \tag{62}$$

Fig. 14 Annual Heating Days $DD_h(t_{bal})$ as Function of Balance Temperature t_{bal}

This is a dimensional equation with t and σ in °F; σ_{yr} is the standard deviation of the monthly average temperatures about the annual average $\bar{t}_{o, yr}$:

$$\sigma_{yr} = \sqrt{\frac{1}{12} \sum_{i=1}^{12} (\bar{t}_{o,i} - \bar{t}_{o, yr})^2} \tag{63}$$

To obtain a simple expression for degree-days, a normalized temperature variable ϕ is defined as

$$\phi = \frac{\bar{t}_{bal} - \bar{t}_o}{\sigma_m \sqrt{N}} \tag{64}$$

where N = number of days in the month (N has units of day/month and ϕ has units of $\sqrt{\text{month/day}}$). Although temperature distributions can be different from month to month and location to location, most of this variability can be accounted for by the average and standard deviation of \bar{t}_o . Being centered around \bar{t}_o and scaled by σ_m , ϕ eliminates these effects. In terms of ϕ , the monthly heating degree-days for any location are well approximated by

$$DD_h(t_{bal}) = \sigma_m N^{1.5} \left[\frac{\phi}{2} + \frac{\ln(e^{-a\phi} + e^{a\phi})}{2a} \right] \tag{65}$$

where $a = 1.698 \sqrt{\text{day/month}}$.

For nine locations spanning most climatic zones of the United States, Erbs et al. (1983) verified that the annual heating degree-days can be estimated with a maximum error of 315°F·days if Equation (65) is used for each month. For cooling degree-days, the largest error is 270°F·days. Such errors are quite acceptable, representing less than 5% of the total.

Table 5 lists monthly heating degree-days for New York City, using the model of Erbs et al. (1983), given monthly averages of t_o as reproduced in column 2 of Table 5. The degree-days are based on a balance temperature of 60°F.

Table 6 contains degree-day data for several sites and monthly averaged outdoor temperatures needed for the algorithm. More complete tabulations of the latter are contained in Cinquemani et al. (1978) and in local climatological data summaries available from the National Climatic Data Center, Asheville, NC (NOAA 1973; www.ncdc.noaa.gov). Monthly degree-day data at various bases, as well as other climatic information for 209 U.S. and 14 Canadian cities, may be found in Appendix 3 to Balcomb et al. (1982).

Table 5 Degree-Day Calculation for New York City from Monthly Averaged Data

Month	\bar{t}_o , °F	N , day/mo.	σ_m , °F	ϕ , $\sqrt{\text{mo./day}}$	$DD_h(t_{bal})$, °F·day
January	32.2	31	3.65	1.37	864

Bin Method

For many applications, the degree-day method should not be used, even with the variable-base method, because the heat loss coefficient K_{tot} , the efficiency η_h of the HVAC system, or the balance point temperature t_{bal} may not be sufficiently constant. Heat pump efficiency, for example, varies strongly with outdoor temperature; efficiency of HVAC equipment may be affected indirectly by t_o when efficiency varies with load (common for boilers and chillers). Furthermore, in most commercial buildings, occupancy has a pronounced pattern, which affects heat gain, indoor temperature, and ventilation rate.

In such cases, steady-state calculation can yield good results for annual energy consumption if different temperature intervals and time periods are evaluated separately. This approach is known as the *bin method* because consumption is calculated for several values of the outdoor temperature t_o and multiplied by the number of hours N_{bin} in the temperature interval (bin) centered around that temperature:

$$Q_{bin} = N_{bin} \frac{K_{tot}}{\eta_h} [t_{bal} - t_o]^+ \tag{66}$$

The superscript plus sign indicates that only positive values are counted; no heating is needed when t_o is above t_{bal} . Equation (66) is evaluated for each bin, and the total consumption is the sum of the Q_{bin} over all bins.

In the United States, the necessary weather data are available in ASHRAE (1995) and USAF (1978). Bins are usually in 5°F increments and are often collected in three daily 8 h shifts. Mean coincident wet-bulb temperature data (for each dry-bulb bin) are used to calculate latent cooling loads from infiltration and ventilation. The bin method considers both occupied and unoccupied building conditions and gives credit for internal loads by adjusting the balance point. For example, a calculation could be performed for 42°F outdoors (representing all occurrences from 39.5 to 44.5°F) and with building operation during the midnight to 0800 shift. Because

there are 23 5°F bins between -10 and 105°F and 3 8 h shifts, 69 separate operating points are calculated. For many applications, the number of calculations can be reduced. A residential heat pump (heating mode), for example, could be calculated for just the bins below 65°F without the three-shift breakdown. The data in Table 7 are samples of annual totals for a few sites, but ASHRAE (1995) and USAF (1978) include monthly data and data further separated into time intervals during the day.

Equipment performance may vary with load. For heat pumps, the U.S. Department of Energy adopted test procedures to determine the effect of dynamic operations. The bin method uses these results for a specific heat pump to adjust the integrated capacity for the effect of part-load operation. Figure 15 compares adjusted heat pump capacity to building heat loss in Example 4. This type of curve must be developed for each model heat pump as applied to an individual profile. The heat pump cycles on and off above the balance point temperature to meet the house load; supplemental heat is required at lower temperatures. This cycling can reduce performance, depending on the part-load factor at a given temperature. The cycling capacity adjustment factors used in this example to account for cycling degradation can be calculated from the equation in footnote a of Table 8.

Frosting and the necessary defrost cycle can reduce performance over steady-state conditions that do not include frosting. The effects of frosting and defrosting are already integrated into many (but not all) manufacturer’s published performance data. Example 4 assumes that the manufacturer’s data already account for frosting/defrosting losses (as indicated by the characteristic notch of the capacity curve in Figure 15) and shows how to adjust an integrated performance curve for cycling losses.

Example 4. Estimate the energy requirements for a residence with a design heat loss of 40,000 Btu at 53°F design temperature difference. The inside design temperature is 70°F. Average internal heat gains are estimated to be 4280 Btu/h. Assume a 3 ton heat pump with the characteristics given in Columns E and H of Table 8 and in Figure 15.

^dColumn J = (Column I × Column G × Column C)/1000
^eColumn K = Column I × Column H × Column C
^fColumn L = Column C × Column D/1000
^gColumn M = (Column L - Column J) × 10⁶/3413
^hColumn N = Column K + Column M

Fig. 15 Heat Pump Capacity and Building Load

Solution: The design heat loss is based on no internal heat generation. The heat pump system energy input is the net heat requirement of the space (i.e., envelope loss minus internal heat generation). The net heat loss per degree and the heating/cooling balance temperature may be computed:

$$K_{tot} = HL / \Delta t = 40,000 / 53 = 755 \text{ Btu/h} \cdot \text{°F}$$

From Equation (51),

$$t_{bal} = 70 - (4280 / 755) = 64.3 \text{°F}$$

Table 8 is then computed, resulting in 9578 kWh.

The **modified bin method** (Knebel 1983) extends the basic bin method to account for weekday/weekend and partial-day occupancy effects, to calculate net building loads (conduction, infiltration, internal loads, and solar loads) at four temperatures, rather than interpolate from design values, and to better describe secondary and primary equipment performance.

CORRELATION METHODS

One way to simplify energy analyses is to correlate energy requirements to various inputs. Typically, the result of a correlation is a simple equation that may be used in a calculator or small computer

program, or to develop a graph that provides quick insight into the energy requirements. Examples are in ASHRAE *Standard* 90.1, which includes several empirical equations that may be used to predict energy consumption by many types of buildings.

The accuracy of correlation methods depends on the size and accuracy of the database and the statistical means used to develop the correlation. A database generated from measured data can lead to accurate correlations (Lachal et al. 1992). The key to proper use of a correlation is ensuring that the case being studied matches the cases used in developing the database. Inputs to the correlation (independent variables) indicate factors that are considered to significantly affect energy consumption. A correlation is invalid either when an input parameter is used beyond its valid range (corresponding to extrapolation rather than interpolation) or when some important feature of the building/system is not included in the available inputs to the correlation.

SIMULATING SECONDARY AND PRIMARY SYSTEMS

Traditionally, most energy analysis programs include a set of preprogrammed models that represent various systems (e.g., variable-air-volume, terminal reheat, multizone). In this scheme, the equations for each system are arranged so they can be solved sequentially. If this is not possible, then the smallest number of equations that must be solved simultaneously is solved using an appropriate technique. Furthermore, individual equations may vary from hour to hour in the simulation, depending on controls and operating conditions. For example, a dry coil uses different equations than a wet coil.

The primary disadvantage of this scheme is that it is relatively inflexible: to modify a system, the program source code may have to be modified and recompiled. Alternative strategies (Klein et al. 1994; Park et al. 1985) view the system as a series of components (e.g., fan, coil, pump, duct, pipe, damper, thermostat) that may be organized in a component library. Users of the program specify the connections between the components. The program then resolves the specification of components and connections into a set of simultaneous equations.

A refinement of component-based modeling is known as **equation-based modeling** (Buhl et al. 1993; Sowell and Moshier

1995). These models do not follow predetermined rules for a solution, and the user can specify which variables are inputs and which are outputs.

MODELING OF SYSTEM CONTROLS

Building control systems are typically hierarchical: higher-level, supervisory controls generate set points for lower-level, local loop controls. Supervisory-level controls, which include reset and optimal control, directly influence energy consumption. Local loop controllers may also affect energy performance; for example, proportional-only room temperature control results in a tradeoff between energy use and comfort. Faults in control systems and devices can also affect energy consumption (e.g., leaking valves and dampers can significantly increase energy use). It is particularly important to account for these departures from ideal behavior when simulating performance of real buildings using calibrated models. Modeling and simulation of supervisory control are increasingly handled by whole-building simulation programs. Simulation of local loop controls requires more specialized, component- or equation-based modeling environments.

Modern control systems, particularly direct digital controls (DDC), typically use integral action to drive the controlled variable to its set point. For energy modeling purposes, the controlled variable (e.g., supply air temperature) can be treated as being at the set point unless system capacity is insufficient. The simulation must determine whether the capacity required to meet set point exceeds available capacity. If it does, the available capacity is used to determine the actual value of the controlled variable. Where there is only proportional action, the resulting relationship between the controlled variable and the output of the system can be used to determine both values. For example, the action of a conventional pneumatic room temperature controller can be represented by a function relating heating and cooling delivery to space temperature. Similarly, supply air temperature reset control can be modeled as a relationship between outside or zone temperature and coil or fan discharge temperature. An accurate secondary system model must ensure that all controls are properly represented and that the governing equations are satisfied at each simulation time step. This often creates a need for iteration or for use of values from an earlier solution point.

Controls on space temperature affect the interaction between loads calculations and the secondary system simulation. A realistic model might require a dead band in space temperature in which no heating or cooling is called for; within this range, the true space sensible load is zero, and the true space temperature must be adjusted

accordingly. If the thermostat has proportional control between zero and full capacity, the space temperature rises in proportion to the load during cooling and falls similarly during heating. Capacity to heat or cool also varies with space temperature after the control device has reached its maximum because capacity is proportional to the difference between supply and space temperatures. Failure to properly model these phenomena results in overestimating required energy.

INTEGRATION OF SYSTEM MODELS

Energy calculations for secondary systems involve construction of the complete system from the set of HVAC components. For example, a variable-air-volume (VAV) system is a single-path system that controls zone temperature by modulating airflow while maintaining constant supply air temperature. VAV terminal units, located at each zone, adjust the quantity of air reaching each zone depending on its load requirements. Reheat coils may be included to provide required heating for perimeter zones.

This VAV system simulation consists of a central air-handling unit and a VAV terminal unit with reheat coil located at each zone, as shown in Figure 16. The central air-handling unit includes a fan, cooling coil, preheat coil, and outside air economizer. Supply air leaving the air-handling unit is controlled to a fixed set point. The VAV terminal unit at each zone varies airflow to meet the cooling load. As zone cooling load decreases, the VAV terminal unit decreases zone airflow until the unit reaches its minimum position. If the cooling load continues to decrease, the reheat coil is activated to meet the zone load. As supply air volume leaving the unit decreases, fan power consumption also reduces. A variable-speed drive is used to control the supply fan.

The simulation is based on system characteristics and zone design requirements. For each zone, the inputs include sensible and latent loads, zone set-point temperature, and minimum zone supply-air mass flow. System characteristics include supply air temperature set point; entering water temperature of reheat, preheat, and cooling coils; minimum mass flow of outside air; and economizer temperature/enthalpy set point for minimum airflow.

The algorithm for performing calculations for this VAV system is shown in Figure 17. The algorithm directs sequential calculations of system performance. Calculations proceed from the zones along the return air path to the cooling coil inlet and back through the supply air path to the cooling coil discharge.

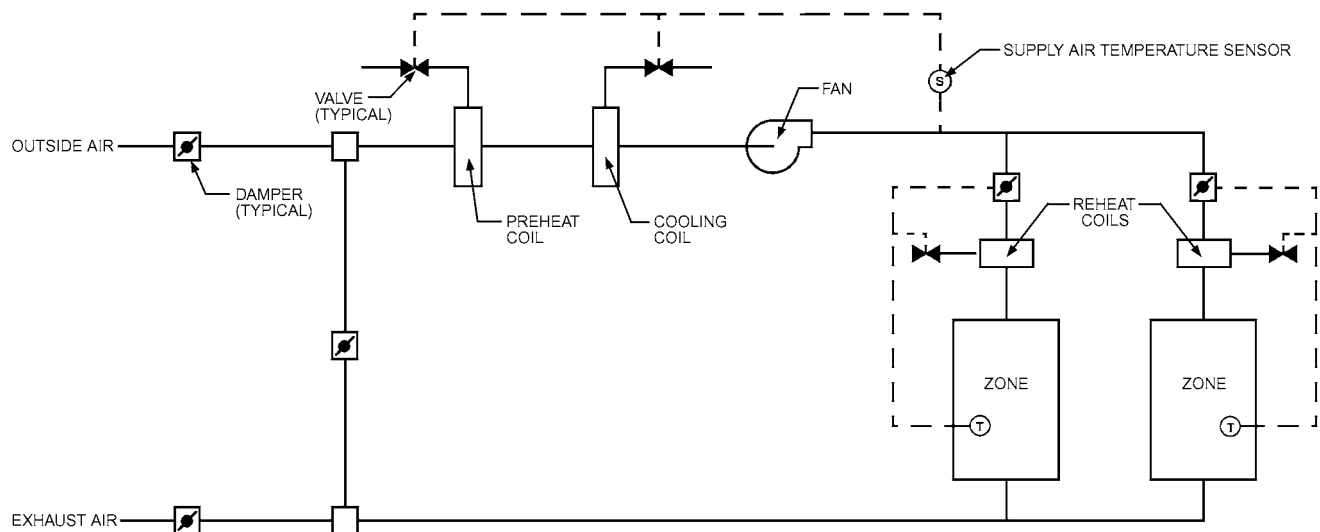

Fig. 16 Schematic of Variable-Air-Volume System with Reheat

```

BEGIN LOOP Calculate zone related design requirements
  • Calculate required supply airflow to meet zone load
  • Sum actual zone mass airflow rate
  • Sum zone latent loads
IF zone equals last zone THEN Exit Loop
END LOOP
  • Calculate system return air temperature from zone temps
  • Assume an initial cooling coil leaving air humidity ratio
BEGIN LOOP Iterate on cooling coil leaving air humidity ratio
  • Calculate return air humidity ratio from latent loads
  • Calculate supply fan power consumption and entering fan air temperature
  • Calculate mixed air temperature and humidity ratio using an economizer cycle
IF mixed air temperature is less than design supply air temperature THEN
  • Calculate preheat coil load
ELSE
  • Calculate cooling coil load and leaving air humidity ratio
ENDIF
IF cooling coil leaving air humidity ratio converged THEN Exit Loop
END LOOP
BEGIN LOOP Calculate the zone reheat coil loads
IF zone supply air temperature is greater than system design supply air temperature THEN

ENDIF
  • Sum reheat coil loads for all zones
IF zone equals last zone THEN Exit Loop
END LOOP

```

Fig. 17 Algorithm for Calculating Performance of VAV with System Reheat

Moving back along the supply air path, the fan entering air temperature is calculated by setting fan outlet air temperature to the system design supply air temperature. The known fan inlet air temperature is then used as both the cooling coil and preheat coil discharge air temperature set point. Moving along the return air path, the cooling coil entering air temperature can be determined by sequentially moving through the economizer cycle and preheat coil.

Unlike temperature, the humidity ratio at any point in a system cannot be explicitly determined because of the dependence of cooling coil performance on the mixed air humidity ratio. The latent load defines the difference between zone humidity and supply air humidity. However, the humidity ratio of supply air depends on the humidity ratio entering the coil, which in turn depends on that of the return air. This calculation must be performed either by solving simultaneous equations or, as in this case, iteration.

Assuming a trial value for the humidity ratio at the cooling coil discharge (e.g., 55°F, 90% rh), the humidity ratio at all other points throughout the system can be calculated. With known cooling coil inlet air conditions and a design discharge air temperature, the inverted cooling coil subroutine iterates on the coil fluid mass flow to converge on the discharge air temperature with the discharge air humidity ratio as an output. The cooling coil discharge air humidity ratio is then compared to the previous discharge humidity ratio. Iteration continues through the loop several times until the values of the cooling coil discharge air humidity ratio stabilize within a specified tolerance.

This basic algorithm for simulation of a VAV system might be used in conjunction with a heat balance type of load calculation. For

a weighting factor approach, it would have to be modified to allow zone temperatures to vary and consequently zone loads to be readjusted. It should also be enhanced to allow possible limits on reheat temperature and/or cooling coil limits, zone humidity limits, outside air control (economizers), and/or heat-recovery devices, zone exhaust, return air fan, heat gain in the return air path because of lights, the presence of baseboard heaters, and more realistic control profiles. Most current building energy programs incorporate these and other features as user options, as well as algorithms for other types of systems.

DATA-DRIVEN MODELING

CATEGORIES OF DATA-DRIVEN METHODS

Data-driven methods for energy-use estimation in buildings and related HVAC&R equipment can be classified into three broad categories. These approaches differ widely in data requirements, time and effort needed to develop the associated models, user skill demands, and sophistication and reliability provided.

Empirical or “Black-Box” Approach

With this approach, a simple or multivariate regression model is identified between measured energy use and the various influential parameters (e.g., climatic variables, building occupancy). The form of the regression models can be either purely statistical or loosely based on some basic engineering formulation of energy use in the building. In any case, the identified model coefficients are such that no (or very little) physical meaning can be assigned to them. This approach can be used with any time scale (monthly, daily, hourly or subhourly) if appropriate data are available. Single-variate, multivariate, change point, Fourier series, and artificial neural network (ANN) models fall under this category, as noted in Table 1.

Model identification is relatively straightforward, usually requires little effort, and can be used in several diverse circumstances. The empirical approach is thus the most widely used data-driven approach. Although more sophisticated regression techniques such as maximum likelihood and two-stage regression schemes can be used for model identification, least-squares regression is most common. The purely statistical approach is usually adequate for evaluating demand-side management (DSM) programs to identify simple and conventional energy conservation measures in an actual building (lighting retrofits, air handler retrofits such as CV to VAV retrofits) and for baseline model development in energy conservation measurement and verification (M&V) projects (Claridge 1998b; Dhar 1995; Dhar et al. 1998, 1999a, 1999b; Fels 1986; Kaptipamula et al. 1998; Kissock et al. 1998; Krarti et al. 1998; Kreider and Wang 1991; MacDonald and Wasserman 1989; Miller and Seem 1991; Reddy et al. 1997; Ruch and Claridge 1991). It is also appropriate for modeling equipment such as pumps and fans, and even more elaborate equipment such as chillers and boilers, if the necessary performance data are available (Braun 1992; Englander and Norford 1992; Lorenzetti and Norford 1993; Phelan et al. 1996). Although this approach allows detection or flagging of equipment or system faults, it is usually of limited value for diagnosis and on-line control (with ANN as a possible exception).

Calibrated Simulation Approach

This approach uses an existing building simulation computer program and “tunes” or calibrates the various physical inputs to the program so that observed energy use matches closely with that predicted by the simulation program. Once that is achieved, more reliable predictions can be made than with statistical approaches. Calibrated simulation is advocated where only whole-building metering is available and M&V calls for estimating energy savings of individual retrofits. Practitioners tend to use common forward-simulation programs such as DOE-2 to calibrate with performance

data. Hourly subaggregated monitored energy data (most compatible with the time step adopted by most building energy simulation programs) allow development of the most accurate calibrated model, but analysts usually must work with less data. Tuning can be done with monthly data or data that span only a few weeks or months over the year, but the resulting model is very likely to be increasingly less accurate with decrease in performance data.

The main challenges of calibrated simulation are that it is labor-intensive, requires a high level of user skill and knowledge in both simulation and practical building operation, is time-consuming, and often depends on the person doing the calibration. Several practical difficulties prevent achieving a calibrated simulation or a simulation that closely reflects actual building performance, including (1) measurement and adaptation of weather data for use by simulation programs (e.g., converting global horizontal solar into beam and diffuse solar radiation), (2) choice of methods used to calibrate the model, and (3) choice of methods used to measure required input parameters for the simulation (i.e., building mass, infiltration coefficients, and shading coefficients). Truly “calibrated” models have been achieved in only a few applications because they require a very large number of input parameters, a high degree of expertise, and enormous amounts of computing time, patience, and financial resources. Bou-Saada and Haberl (1995a, 1995b), Bronson et al. (1992), Corson (1992), Haberl and Bou-Saada (1998), Kaplan et al. (1990) Manke et al. (1996), and Norford et al. (1994) provide examples of different methods used to calibrate simulation models.

Katipamula and Claridge (1993) and Liu and Claridge (1998) suggested that simpler models could also work, and allow model calibration to be done much faster. Typically, the building is divided into two zones: an exterior or perimeter zone and an interior or a core zone. The core zone is assumed to be insulated from envelope heat losses/gains, and solar heat gains, infiltration heat loss/gain, and conduction gains/losses from the roof are taken as loads on the external zone only. Given the internal load schedule, building description, type of HVAC system, and climatic parameters, HVAC system loads can be estimated for each hour of the day and for as many days of the year as needed by the simplified systems model. Because there are fewer parameters to vary, calibration is much faster. Therefore, these models have a significant advantage over general-purpose models in buildings where the HVAC systems can be adequately modeled. These studies, based on the ASHRAE Simplified Energy Analysis Procedure (Knebel 1983), illustrate the applicability of this method both to baseline model development for M&V purposes and as a diagnostic tool for identifying potential operational problems and for estimating potential savings from optimized operating parameters.

Gray-Box Approach

This approach first formulates a physical model to represent the structure or physical configuration of the building or HVAC&R equipment or system, and then identifies important parameters representative of certain key and aggregated physical parameters and characteristics by statistical analysis (Rabl and Riahle 1992). This requires a high level of user expertise both in setting up the appropriate modeling equations and in estimating these parameters. Often an intrusive experimental protocol is necessary for proper parameter estimation, which also requires skill. This approach has great potential, especially for fault detection and diagnosis (FDD) and online control, but its applicability to whole-building energy use is limited. Examples of parameter estimation studies applied to building energy use are Andersen and Brandemuehl (1992), Braun (1990), Gordon and Ng (1995), Guyon and Palomo (1999a), Hammersten (1984), Rabl (1988), Reddy (1989), Reddy et al. (1999), Sonderegger (1977), and Subbarao (1988).

TYPES OF DATA-DRIVEN MODELS

Steady-state models do not consider effects such as thermal mass or capacitance that cause short-term temperature transients. Generally, these models are appropriate for monthly, weekly, or daily data and are often used for baseline model development. **Dynamic models** capture effects such as building warm-up or cooldown periods and peak loads, and are appropriate for building load control, FDD, and equipment control. A simple criterion to determine whether a model is steady-state or dynamic is to look for the presence of time-lagged variables, either in the response or regressor variables. Steady-state models do not contain time-lagged variables.

Steady-State Models

Several types of steady-state models are used for both building and equipment energy use: single-variate, multivariate, polynomial, and physical.

Single-Variate Models. Single-variate models (i.e., models with one regressor variable only) are perhaps the most widely used. They formulate energy use in a building as a function of one driving force that affects building energy use. An important aspect in identifying statistical models of baseline energy use is the choice of the functional form and the independent (or regressor) variables. Extensive studies (Fels 1986; Katipamula et al. 1994; Kissock et al. 1993; Reddy et al. 1997) have clearly indicated that the outdoor dry-bulb temperature is the most important regressor variable, especially at monthly time scales but also at daily time scales.

The simplest steady-state data-driven model is one developed by regressing monthly utility consumption data against average billing-period temperatures. The model must identify the balance-point temperatures (or change points) at which energy use switches from weather-dependent to weather-independent behavior. In its simplest form, the 65°F degree-day model is a change-point model that has a fixed change point at 65°F. Other examples include three- and five-parameter Princeton Scorekeeping Methods (PRISM) based on the variable-base degree-day concept (Fels 1986). An allied modeling approach for commercial buildings is the four-parameter (4-P) model developed by Ruch and Claridge (1991), which is based on the monthly mean temperature (and not degree-days). Table 9 shows the appropriate model functional forms. The three parameters are a weather-independent base-level use, a change point, and a temperature-dependent energy use, characterized as a slope of a line that is determined by regression. The four parameters include a change point, a slope above the change point, a slope below the change point, and the energy use associated with the change point. An data-driven bin method has also been proposed to handle more than four change points (Thamilseran and Haberl 1995).

Figure 18 shows several types of steady-state, single-variate data-driven models. Figure 18A shows a simple one-parameter, or constant, model, and Table 9 gives the equivalent notation for calculating the constant energy use using this model. Figure 18B shows a steady-state two-parameter (2-P) model where b_0 is the y -axis intercept and b_1 is the slope of the regression line for positive values of x , where x represents the ambient air temperature. The 2-P model represents cases when either heating or cooling is always required.

Figure 18C shows a three-parameter change-point model, typical of natural gas energy use in a single-family residence that uses gas for space heating and domestic water heating. In the notation of Table 9 for the three-parameter model, b_0 represents the baseline energy use and b_1 is the slope of the regression line for values of ambient temperature less than the change point b_2 . In this type of notation, the superscripted plus sign indicates that only positive values of the parenthetical expression are considered. Figure 18D shows a three-parameter model for cooling energy use, and Table 9 provides the appropriate analytic expression.

Figures 18E and 18F illustrate four-parameter models for heating and cooling, respectively. The appropriate expressions for

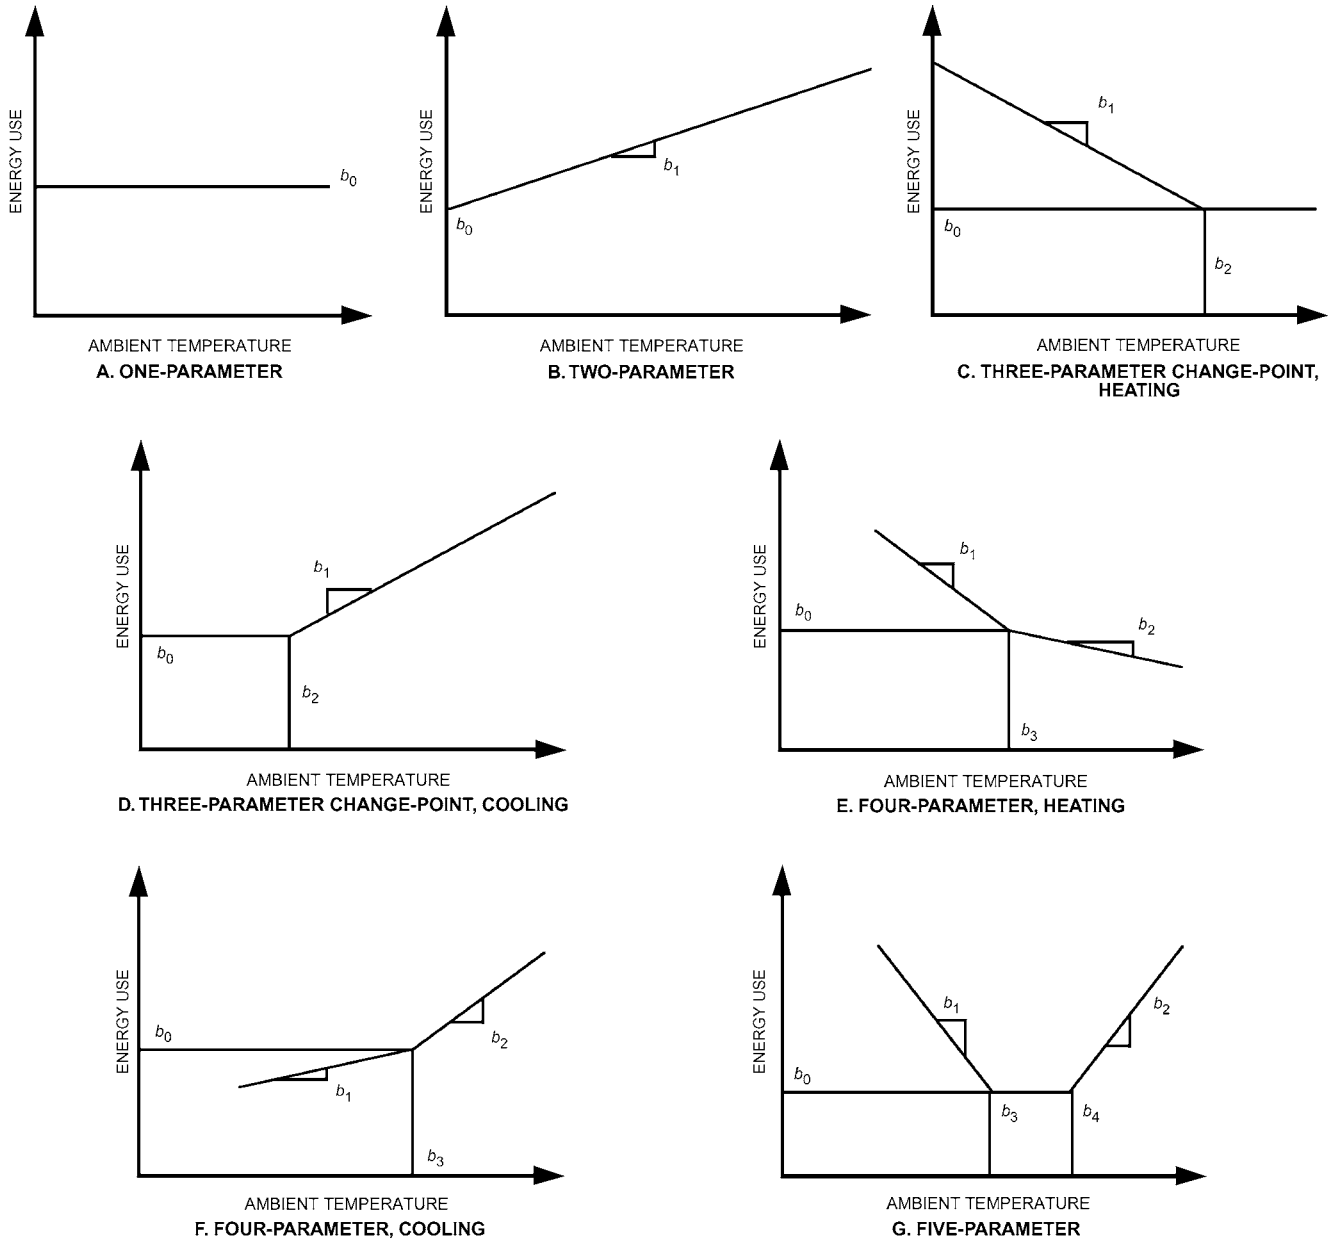

Fig. 18 Steady-State, Single-Variate Models for Modeling Energy Use in Residential and Commercial Buildings

Table 9 Single-Variate Models Applied to Utility Billing Data

Model Type	Independent Variable(s)	Form	Examples
One-parameter or constant (1-P)	None	$E = b_0$	Non-weather-sensitive demand
Two-parameter (2-P)	Temperature	$E = b_0 + b_1(T)$	
Three-parameter (3-P)	Degree-days/ Temperature	$E = b_0 + b_1(DD_{BT})$ $E = b_0 + b_1(b_2 - T)^+$ $E = b_0 + b_1(T - b_2)^+$	Seasonal weather-sensitive use (fuel in winter, electricity in summer for cooling)
Four-parameter change point (4-P)	Temperature	$E = b_0 + b_1(b_3 - T)^+ - b_2(T - b_3)^+$ $E = b_0 - b_1(b_3 - T)^+ + b_2(T - b_3)^+$	Energy use in commercial buildings
Five-parameter (5-P)	Degree-days/ Monthly mean temperature	$E = b_0 - b_1(DD_{TH}) + b_2(DD_{TC})$ $E = b_0 + b_1(b_3 - T)^+ + b_2(T - b_4)^+$	Heating and cooling supplied by same meter

Note: DD denotes degree-days and T is monthly mean daily outdoor dry-bulb temperature.

calculating the heating and cooling energy consumption are found in Table 9: b_0 represents the baseline energy exactly at the change point b_3 , and b_1 and b_2 are the lower and upper region regression slopes for ambient air temperature below and above the change point b_3 . Figure 18G illustrates a 5-P model (Fels 1986), which is useful for modeling buildings that are electrically heated and cooled. The 5-P model has two change points and a base level consumption value.

The advantage of these steady-state data-driven models is that their use can be easily automated and applied to large numbers of buildings where monthly utility billing data and average daily temperatures for the billing period are available. Steady-state single-variate data-driven models have also been applied with success to daily data (Kissock et al. 1998). In such a case, the variable-base degree-day method and monthly mean temperature models described earlier for utility billing data analysis become identical in their functional form. Single-variate models can also be applied to daily data to compensate for differences such as weekday and weekend use by separating the data accordingly and identifying models for each period separately.

Disadvantages of steady-state single-variate data-driven models include insensitivity to dynamic effects (e.g., thermal mass) and to variables other than temperature (e.g., humidity and solar gain), and inappropriateness for some buildings (e.g., buildings with strong on/off schedule-dependent loads or buildings with multiple change points). Moreover, a single-variable, 3-P model such as the PRISM model (Fels 1986) has a physical basis only when energy use above a base level is linearly proportional to degree-days. This is a good approximation in the case of heating energy use in residential buildings where heating load never exceeds the heating system's capacity. However, commercial buildings generally have higher internal heat generation with simultaneous heating and cooling energy use and are strongly influenced by HVAC system type and control strategy. This makes energy use in commercial buildings less strongly influenced by outdoor air temperature alone. Therefore, it is not surprising that blind use of single-variate models has had mixed success at modeling energy use in commercial buildings (MacDonald and Wasserman 1989).

Change-point regression models work best with heating data from buildings with systems that have few or no part-load nonlinearities (i.e., systems that become less efficient as they begin to cycle on/off with part loads). In general, change-point regression models do not predict cooling loads as well because outdoor humidity has a large influence on latent loads on the cooling coil. Other factors that decrease the accuracy of change-point models include solar effects, thermal lags, and on/off HVAC schedules. Four-parameter models are a better statistical fit than three-parameter models in buildings with continuous, year-round cooling or heating (e.g., grocery stores and office buildings with high internal loads). However, every model should be checked to ensure that the regression does not falsely indicate an unreasonable relationship.

A major advantage of using a steady-state data-driven model to evaluate the effectiveness of energy conservation retrofits is its ability to factor out year-to-year weather variations by using a normalized annual consumption (NAC) (Fels 1986). Basically, annual energy conservation savings can be calculated by comparing the difference obtained by multiplying the pre- and postretrofit parameters by the weather conditions for the average year. Typically, 10 to 20 years of average daily weather data from a nearby weather service site are used to calculate 365 days of average weather conditions, which are then used to calculate the average pre- and postretrofit conditions.

Utilities and government agencies have found it advantageous to prescreen many buildings against test regression models. These data-driven models can be used to develop comparative figures of merit for buildings in a similar standard industrial code (SIC)

classification. A minimum goodness of fit is usually established that determines whether the monthly utility billing data are well fitted by the one-, two-, three-, four-, or five-parameter model being tested. Comparative figures of merit can then be determined by dividing the parameters by the conditioned floor area to yield average daily energy use per unit area of conditioned space. For example, an area-normalized comparison of base-level parameters across residential buildings would be used to analyze weather-independent energy use. This information can be used by energy auditors to focus their efforts on those systems needing assistance (Haberl and Komor 1990a, 1990b).

Multivariate Models. Two types of steady-state, multivariate models have been reported:

- **Standard multiple-linear or change-point regression models**, where the set of data observations is treated without retaining the time-series nature of the data (Katipamula et al. 1998).
- **Fourier series models** that retain the time-series nature of building energy use data and capture the diurnal and seasonal cycles according to which buildings are operated (Dhar 1995; Dhar et al. 1998, 1999a, 1999b; Seem and Braun 1991).

These models are a logical extension of single-variate models, provided that the choice of variables to be included and their functional forms are based on the engineering principles on which HVAC systems and other systems in commercial buildings operate. The goal of modeling energy use by the multivariate approach is to characterize building energy use with a few readily available and reliable input variables. These input variables should be selected with care. The model should contain variables not affected by the retrofit and likely to change (for example, climatic variables) from preretrofit to postretrofit periods. Other less obvious variables, such as changes in operating hours, base load, and occupancy levels, should be included in the model if these are not energy conservation measures (ECMs) but variables that may change during the postretrofit period.

Environmental variables that meet these criteria for modeling heating and cooling energy use include outdoor air dry-bulb temperature, solar radiation, and outdoor specific humidity. Some of these are difficult to estimate or measure in an actual building and hence are not good candidates for regressor variables. Further, some of the variables vary little. Although their effect on energy use may be important, a data-driven model will implicitly lump their effect into the parameter that represents constant load. In commercial buildings, internally generated loads, such as the heat given off by people, lights, and electrical equipment, also affect heating and cooling energy use. These internal loads are difficult to measure in their entirety given the ambiguous nature of occupant and latent loads. However, monitored electricity used by internal lights and equipment is a good surrogate for total internal sensible loads (Reddy et al. 1999). For example, when the building is fully occupied, it is also likely to be experiencing high internal electric loads, and vice versa.

The effect of environmental variables is important for buildings such as offices but may be less so for mixed-use buildings (e.g., hotels and hospitals) and buildings such as retail buildings, schools, and assembly buildings. Differences in HVAC system behavior during occupied and unoccupied periods can be modeled by a dummy or indicator variable (Draper and Smith 1981). For some office buildings, there seems to be little need to include a dummy variable, but its inclusion in the general functional form adds flexibility.

Several standard statistical tests evaluate the goodness-of-fit of the model and the degree of influence that each independent variable exerts on the response variable (Draper and Smith 1981; Neter et al. 1989). Although energy use in fact depends on several variables, there are strong practical incentives for identifying the simplest model that results in acceptable accuracy. Multivariate models require more metering and are unusable if even one of the variables becomes unavailable. In addition, some regressor variables may be

linearly correlated. This condition, called **multicollinearity**, can result in large uncertainty in the estimates of the regression coefficients (i.e., unintended error) and can also lead to poorer model prediction accuracy compared to a model where the regressors are not linearly correlated.

Several authors recommend using **principal component analysis (PCA)** to overcome multicollinearity effects. PCA was one of the strongest analysis methods in the ASHRAE Predictor Shootout I and II contests (Haberl and Thamilsaran 1996; Kreider and Haberl 1994). Analysis of multiyear monitored daily energy use in a grocery store found a clear superiority of PCA over multivariate regression models (Ruch et al. 1993), but this conclusion is unproven for commercial building energy use in general. A more general evaluation by Reddy and Claridge (1994) of both analysis techniques using synthetic data from four different U.S. locations found that injudicious use of PCA may exacerbate rather than overcome problems associated with multicollinearity. Draper and Smith (1981) also caution against indiscriminate use of PCA.

The functional basis of air-side heating and cooling use in various HVAC system types has been addressed by Reddy et al. (1995) and subsequently applied to monitored data in commercial buildings (Katipamula et al. 1994, 1998). Because quadratic and cross-product terms of engineering equations are not usually picked up by multivariate models, strictly linear energy use models are often the only option.

In addition to T_o , internal electric equipment and lighting load E_{int} , solar loads q_{sol} , and latent effects via the outdoor dew-point temperature T_{dp} are candidate regressor variables. In commercial buildings, a major portion of the latent load derives from fresh air ventilation. However, this load appears only when the outdoor air dew-point temperature exceeds the cooling coil temperature. Hence, the term $(T_{dp} - T_s)^+$ (where the + sign indicates that the term is to be set to zero if negative, and T_s is the mean surface temperature of the cooling coil, typically about 51 to 55°F) is a more realistic descriptor of the latent loads than is T_{dp} alone. Using $(T_{dp} - T_s)^+$ as a regressor in the model is a simplification that seems to yield good accuracy.

Therefore, a multivariate linear regression model with an engineering basis has the following structure:

$$Q_{bldg} = \beta_0 + \beta_1(T_o - \beta_3)^- + \beta_2(T_o - \beta_3)^+ + \beta_4(T_{dp} - \beta_6)^- + \beta_5(T_{dp} - \beta_6)^+ + \beta_7q_{sol} + \beta_8E_{int} \quad (67)$$

Based on the preceding discussion, $\beta_4 = 0$. Introducing indicator variable terminology (Draper and Smith 1981), Equation (67) becomes

$$Q_{bldg} = a + bT_o + cI + dIT_o + eT_{dp}^+ + fq_{sol} + gE_{int} \quad (68)$$

where the indicator variable I is introduced to handle the change in slope of the energy use due to T_o . The variable I is set equal to 1 for T_o values to the right of the change point (i.e., for high T_o range) and set equal to 0 for low T_o values. As with the single-variate segmented models (i.e., 3-P and 4-P models), a search method is used to determine the change point that minimizes the total sum of squares of residuals (Fels 1986; Kisssock et al. 1993).

Katipamula et al. (1994) found that Equation (68), appropriate for VAV systems, could be simplified for constant-volume HVAC systems:

$$Q_{bldg} = a + bT_o + eT_{dp}^+ + fq_{sol} + gE_{int} \quad (69)$$

Note that instead of using $(T_{dp} - T_s)^+$, the absolute humidity potential $(W_0 - W_s)^+$ could also be used, where W_0 is the outdoor absolute humidity, and W_s is the absolute humidity level at the dew

point of the cooling coil (typically about 0.198 lb/lb). A final aspect to keep in mind is that the term T_{dp}^+ should be omitted from the regressor variable set when regressing heating energy use, because there are no latent loads on a heating coil.

These multivariate models are very accurate for daily time scales and slightly less so for hourly time scales. This is because changes in the way the building is operated during the day and the night lead to different relative effects of the various regressors on energy use, which cannot be accurately modeled by one single hourly model. Breaking up energy use data into hourly bins corresponding to each hour of the day and then identifying 24 individual hourly models leads to appreciably greater accuracy (Katipamula et al. 1994).

Polynomial Models. Historically, polynomial models have been widely used as pure statistical models to model the behavior of equipment such as pumps, fans, and chillers (Stoecker and Jones 1982). The theoretical aspects of calculating pump performance are well understood and documented. Pump capacity and efficiency are calculated from measurements of pump head, flow rate, and pump electrical power input. Phelan et al. (1996) studied the predictive ability of linear and quadratic models for electricity consumed by pumps and water mass flow rate, and concluded that quadratic models are superior to linear models. For fans, Phelan et al. (1996) studied the predictive ability of linear and quadratic polynomial single-variate models of fan electricity consumption as a function of supply air mass flow rate, and concluded that, although quadratic models are superior in terms of predicting energy use, the linear model seems to be the better overall predictor of both energy use and demand (i.e., maximum monthly power consumed by the fan). This is a noteworthy conclusion given that a third-order polynomial is warranted analytically as well as from monitored field data presented by previous authors (e.g., Englander and Norford 1992; Lorenzetti and Norford 1993).

Polynomial models have been used to correlate chiller (or evaporator) thermal cooling capacity or load Q_{evap} and the electrical power consumed by the chiller (or compressor) E_{comp} with the relevant number of influential physical parameters. For example, based on the functional form of the DOE-2 building simulation software (York and Cappiello 1982), models for part-load performance of energy equipment and plant, E_{comp} , can be modeled as the following triquadratic polynomial:

$$E_{comp} = a + bQ_{evap} + cT_{cond}^{in} + dT_{evap}^{out} + eQ_{evap}^2 + fT_{cond}^{in 2} + gT_{evap}^{out 2} + hQ_{evap}T_{cond}^{in} + iT_{evap}^{out}Q_{evap} + jT_{cond}^{in}T_{evap}^{out} + kQ_{evap}T_{cond}^{in}T_{evap}^{out} \quad (70)$$

In this model, there are 11 model parameters to identify. However, because all of them are unlikely to be statistically significant, a step-wise regression to the sample data set yields the optimal set of parameters to retain in a given model. Other authors, such as Braun (1992), have used slightly different polynomial forms.

Physical Models. In contrast to polynomial models, which have no physical basis (merely a convenient statistical one), physical models are based on fundamental thermodynamic or heat transfer considerations. These types of models are usually associated with the parameter estimation approach. Often, physical models are preferred because they generally have fewer parameters, and their mathematical formulation can be traced to actual physical principles that govern the performance of the building or equipment. Hence, model coefficients tend to be more robust, leading to sounder model predictions. Only a few studies have used steady-state physical models for parameter estimation relating to commercial building energy use [e.g., Reddy et al. (1999)]. Unlike in single-family residences, it is difficult to perform elaborately planned experiments in large buildings and obtain representative values of indoor fluctuations.

The generalized Gordon and Ng (GN) model (Gordon and Ng 2000) is a simple, analytical, universal model for chiller performance based on first principles of thermodynamics and linearized heat losses. The model predicts the dependent chiller coefficient of performance (COP) [the ratio of chiller (or evaporator) thermal cooling capacity Q_{ch} to electrical power E consumed by the chiller] with specially chosen independent, easily measurable parameters such as the fluid (water or air) temperature entering the condenser T_{cdi} , fluid temperature entering the evaporator T_{chi} , and the thermal cooling capacity of the evaporator. The GN model is a three-parameter model in the following form:

$$\left(\frac{1}{\text{COP}} + 1\right) \frac{T_{chi}}{T_{cdi}} - 1 = a_1 \frac{T_{chi}}{Q_{ch}} + a_2 \frac{(T_{cdi} - T_{chi})}{T_{cdi} Q_{ch}} + a_3 \frac{(1/\text{COP} + 1) Q_{ch}}{T_{cdi}} \quad (71a)$$

where temperatures are in absolute units.

Substituting the following,

$$x_1 = \frac{T_{chi}}{Q_{ch}}, \quad x_2 = \frac{(T_{cdi} - T_{chi})}{T_{cdi} Q_{ch}}, \quad x_3 = \frac{(1/\text{COP} + 1) Q_{ch}}{T_{cdi}} \quad (71b)$$

and
$$y = \left(\frac{1}{\text{COP}} + 1\right) \frac{T_{chi}}{T_{cdi}} - 1$$

the model given by Equation (71a) becomes

$$y = a_1 x_1 + a_2 x_2 + a_3 x_3 \quad (71c)$$

which is a three-parameter linear model with no intercept term. The parameters of the model in Equation (71c) have the following physical meaning:

$a_1 = \Delta S$ = total internal entropy production in chiller

$a_2 = Q_{leak}$ = heat losses (or gains) from (or into) chiller

$a_3 = R$ = total heat exchanger thermal resistance = $1/C_{cd} + 1/C_{ch}$, where C is effective thermal conductance

Gordon and Ng (2000) point out that Q_{leak} is typically an order of magnitude smaller than the other terms, but it is not negligible for accurate modeling, and should be retained in the model if the other two parameters identified are to be used for chiller diagnostics. The same linear model structure as Equation (71c) can be used if the fluid temperature leaving the evaporator T_{cho} is used instead of T_{chi} . However, the physical interpretation of the term a_3 is modified accordingly.

Reddy and Anderson (2002) and Sreedharan and Haves (2001) found that the GN and multivariate polynomial (MP) models were comparable in their predictive abilities. The GN model requires much less data if selected judiciously [even four well-chosen data points can yield accurate models, as demonstrated by Corcoran and Reddy (2003)]. Jiang and Reddy (2003) tested the GN model against more than 50 data sets covering various generic types and sizes of water-cooled chillers (single- and double-stage centrifugal chillers with inlet guide vanes and variable-speed drives, screw, scroll), and found excellent predictive ability (coefficient of variation of RMSE in the range of 2 to 5%).

Dynamic Models

In general, steady-state data-driven models are used with monthly and daily data containing one or more independent variables. Dynamic data-driven models are usually used with hourly or sub-hourly data in cases where the building's thermal mass is signifi-

cant enough to delay heat gains or losses. Dynamic models traditionally required solving a set of differential equations. Disadvantages of dynamic data-driven models include their complexity and the need for more detailed measurements to tune the model. More information on measurements, including whole-building metering, retrofit isolation metering, and whole-building calibrated simulation, can be found in ASHRAE *Guideline 14*, Measurement of Energy and Demand Savings, and the International Performance Measurement and Verification Protocol (IPMVP) (U.S. Department of Energy 2001a, 2001b, 2003). Unlike steady-state data-driven models, dynamic data-driven models usually require a high degree of user interaction and knowledge of the building or system being modeled.

Several residential energy studies have used dynamic data-driven models based on parameter estimation approaches, usually involving intrusive data gathering. Rabl (1988) classified the various types of dynamic data-driven models used for whole-building energy use identified the common underlying features of these models. There are essentially four different types of model formulations: thermal-network, time series, differential equation, and modal, all of which qualify as parameter-estimation approaches. Table 1 lists several pertinent studies in each category. A few studies (Hammersten 1984; Rabl 1988; Reddy 1989) evaluated these different approaches with the same data set. A number of papers reported results of applying different techniques, such as thermal-network and ARMA models, to residential and commercial building energy use (see Table 1). Examples of dynamic data-driven models for commercial building are found in Andersen and Brandemuehl (1992), Braun (1990), and Rabl (1988).

Dynamic data-driven models based on pure statistical approaches have also been reported. Two examples are machine learning (Miller and Seem 1991) and artificial neural networks (Kreider and Haberl 1994; Kreider and Wang 1991; Miller and Seem 1991).

Neural networks are considered to be intuitive because they learn by example rather than by following programmed rules. The ability to "learn" is one of their key aspects. A neural network consists of one input layer (which can contain one or more inputs), one or more hidden layers, and an output or target layer. One challenge of this technology is to construct a net with sufficient complexity to learn accurately without imposing excessive computational time.

The weights of a net are initiated with small random numbers. Then, the weights are adjusted iteratively or "trained" so that applying a set of inputs produces the desired set of outputs. Usually, a network is trained with a training data set that consists of many input/output pairs. Artificial neural networks have been trained by a wide variety of methods (McClelland and Rumelhart 1988, Wasserman 1989), including back propagation.

Neural networks have been useful in modeling energy use in commercial buildings for

- Predicting what a properly operating building should be doing compared to actual operation. If there is a difference, it can be used in an expert system to produce early diagnoses of building operation problems.
- Predicting what a building, before an energy retrofit, would have consumed under present conditions. When compared to the measured consumption of the retrofitted building, the difference represents a good estimate of the energy savings due to the retrofit. This represents one of the few ways that actual energy savings can be determined after the preretrofit building configuration has ceased to exist.

EXAMPLES USING DATA-DRIVEN METHODS

Modeling Utility Bill Data

The following example (taken from Sonderegger 1998) illustrates a utility bill analysis. Assume that values of utility bills over an entire year have been measured. To obtain the equation coefficients through regression, the utility bills must be normalized by the length of the time interval between utility bills. This is equivalent to expressing all utility bills, degree-days, and other independent variables by their daily averages.

Appropriate modeling software is used in which values are assumed for heating and cooling balance points; from these, the corresponding heating and cooling degree-days for each utility bill period are determined. Repeated regression is done till the regression equation represents the best fit to the meter data. The model coefficients are then assumed to be tuned. Some programs allow direct determination of these optimal model parameters without the user's manual tuning of the parameters.

A widely used statistic to gage the goodness-of-fit of the model is the **coefficient of determination R^2** . A value of $R^2 = 1$ indicates a perfect correlation between actual data and the regression equation; a value of $R^2 = 0$ indicates no correlation. For tuning for a performance contract, as a rule of thumb the value of R^2 should never be less than 0.75.

When more than one independent variable is included in the regression, R^2 is no longer sufficient to determine the goodness-of-fit. The standard error of the estimate of the coefficients becomes the more important determinant. The smaller the standard error compared to the coefficient's magnitude, the more reliable the coefficient estimate. To identify the significance of individual coefficients, **t -statistics** (or **t -values**) are used. These are simply the ratio of the coefficient estimate divided by the standard error of the estimate.

The coefficient of each variable included in the regression has a t -statistic. For a coefficient to be statistically meaningful, the absolute value of its t -statistic must be at least 2.0. In other words, under no circumstances should a variable be included in a regression if the standard error of its coefficient estimate is greater than half the magnitude of the coefficient (even when including a variable that increases the R^2). Generally, including more variables in a regression results in a higher R^2 , but the significance of most individual coefficients is likely to decrease.

Fig. 19 Variable-Base Degree-Day Model Identification Using Electricity Utility Bills at Hospital (Sonderegger 1998)

Figure 19 illustrates how well a regression fit captures measured baseline energy use in a hospital building. Cooling degree-days are found to be a significant variable, with the best fit for a base temperature of 54°F.

Individual utility bills may be unsuitable to develop a baseline and should be excluded from the regression. For example, a bill may be atypically high because of a one-time equipment malfunction that was subsequently repaired. However, it is often tempting to look for reasons to exclude bills that fall far from “the line” and not question those that are close to it. For example, bills for periods containing vacations or production shutdowns may look anomalously low, but excluding them from the regression would result in a chronic overestimate of the future baseline during the same period.

Neural Network Models

Figure 20 shows results for a single neural network typical of several hundred networks constructed for an academic engineering center located in central Texas. The cooling load is created by solar gains, internal gains, outdoor air sensible heat, and outdoor air humidity loads. The neural network is used to predict the preretrofit energy consumption for comparison with measured consumption of the retrofitted building. Six months of preretrofit data were available to train the network. Solid lines show the known building consumption data, and dashed lines show the neural network predictions. This figure shows that a neural network trained for one period (September 1989) can predict energy consumption well into the future (in this case, January 1990).

The network used for this prediction had two hidden layers. The input layer contained eight neurons that receive eight different types of input data as listed below. The output layer consisted of one neuron that gave the output datum (chilled-water consumption). Each training fact (i.e., training data set), therefore, contained eight input data (independent variables) and one pattern datum (dependent variable). The eight hourly input data used in each hour's data vector were selected on physical bases (Kreider and Rabl 1994) and were as follows:

- Hour number (0 to 2300)
- Ambient dry-bulb temperature
- Horizontal insolation
- Humidity ratio
- Wind speed
- Weekday/weekend binary flag (0, 1)

NOTE: Utility bills excluded from the regression due to a degree-day threshold.

- Past hour's chilled-water consumption
- Second past hour's chilled-water consumption

These measured independent variables were able to predict chilled-water use to an RMS error of less than 4% (JCEM 1992).

Choosing an optimal network's configuration for a given problem remains an art. The number of hidden neurons and layers must be sufficient to meet the requirement of the given application. However, if too many neurons and layers are used, the network tends to memorize data rather than learning (i.e., finding the underlying patterns in the data). Further, choosing an excessively large number of hidden layers significantly increases the required training time for certain learning algorithms. Anstett and Kreider (1993), Krarti et al. (1998), Kreider and Wang (1991), and Wang and Kreider (1992) report additional case studies for commercial buildings.

MODEL SELECTION

Steady-state and dynamic data-driven models can be used with energy management and control systems to predict energy use (Kreider and Haberl 1994). Hourly or daily comparisons of measured versus predicted energy use can be used to determine whether systems are being left on unnecessarily or are in need of maintenance. Combinations of predicted energy use and a knowledge-based system can indicate above-normal energy use and diagnose

Fig. 20 Neural Network Prediction of Whole-Building, Hourly Chilled-Water Consumption for Commercial Building

the possible cause of the malfunction if sufficient historical information has been previously gathered (Haberl and Claridge 1987). Hourly systems that use artificial neural networks have also been constructed (Kreider and Wang 1991).

More information on data-driven models can be found in the ASHRAE *Inverse Modeling Toolkit* (Haberl et al. 2003; Kissock et al. 2003). This toolkit contains FORTRAN 90 and executable code for performing linear and change-point linear regressions, variable-based degree-days, multilinear regression, and combined regressions. It also includes a complete test suite of data sets for testing all models.

Table 10 presents a decision diagram for selecting a forward or data-driven model where use of the model, degree of difficulty in understanding and applying the model, time scale for data used by the model, calculation time, and input variables used by the models are the criteria used to choose a particular model.

MODEL VALIDATION AND TESTING

ANSI/ASHRAE *Standard 140*, Method of Test for the Evaluation of Building Energy Analysis Computer Programs, was developed to identify and diagnose differences in predictions that may be caused by algorithmic differences, modeling limitations, or coding or input errors. *Standard 140* allows all elements of a complete validation approach to be added as they become available. This structure corresponds to the following validation methodology, with subdivisions creating a matrix of six areas for testing:

1. Comparative tests—building envelope
2. Comparative tests—mechanical equipment
3. Analytical verification—building envelope
4. Analytical verification—mechanical equipment
5. Empirical validation—building envelope
6. Empirical validation—mechanical equipment

The current set of tests focus on categories 1 and 4. These tests are based on procedures developed by the National Renewable Energy Laboratory and field-tested by the International Energy Agency (IEA) over three IEA research tasks (Judkoff and Neymark 1995a; Neymark and Judkoff 2002). Additional tests are being developed under ASHRAE research projects (Spitler et al. 2001; Yuill and Haberl 2002) and under joint IEA Solar Heating and Cooling Programme/Energy Conservation in Buildings and Community Systems Task 34/Annex 43 (Judkoff and Neymark 2004) that are intended to fill in other categories of the validation matrix.

Table 10 Capabilities of Different Forward and Data-Driven Modeling Methods

Methods	Use ^a	Difficulty	Time Scale ^b	Calc. Time	Variables ^c	Accuracy
Simple linear regression	ES	Simple	D, M	Very fast	<i>T</i>	Low
Multiple linear regression	D, ES	Simple	D, M	Fast	<i>T, H, S, W, t</i>	Medium
ASHRAE bin method and data-driven bin method	ES	Moderate	H	Fast	<i>T</i>	Medium
Change-point models	D, ES	Simple	H, D, M	Fast	<i>T</i>	Medium
ASHRAE TC 4.7 modified bin method	ES, DE	Moderate	H	Medium	<i>T, S, tm</i>	Medium
Artificial neural networks	D, ES, C	Complex	S, H	Fast	<i>T, H, S, W, t, tm</i>	High

Notes:

^aUse shown includes diagnostics (D), energy savings calculations (ES), design (DE), and control (C).

^bTime scales shown are hourly (H), daily (D), monthly (M), and subhourly (S).

^cVariables include temperature (*T*), humidity (*H*), solar (*S*), wind (*W*), time (*t*), and thermal mass (*tm*).

METHODOLOGICAL BASIS

There are three ways to evaluate a whole-building energy simulation program's accuracy (Judkoff et al. 1983; Neymark and Judkoff 2002):

- *Empirical validation*, which compares calculated results from a program, subroutine, algorithm, or software object to monitored data from a real building, test cell, or laboratory experiment
- *Analytical verification*, which compares outputs from a program, subroutine, algorithm, or software object to results from a known analytical solution or a generally accepted numerical method calculation for isolated heat transfer under very simple, highly constrained boundary conditions
- *Comparative testing*, which compares a program to itself or to other programs

Table 11 compares these techniques (Judkoff 1988). In this table, the term “model” is the representation of reality for a given physical behavior. For example, heat transfer may be simulated with one-, two-, or three-dimensional thermal conduction models. The term “solution process” encompasses the mathematics and computer coding to solve a given model. The solution process for a model can be perfect, while the model remains inappropriate for a given physical situation, such as using a one-dimensional conduction model where two-dimensional conduction dominates. The term “truth standard” represents the standard of accuracy for predicting real behavior. An analytical solution is a “mathematical truth standard,” but only tests the solution process for a model, not the appropriateness of the model. An approximate truth standard from an experiment tests both the solution process and appropriateness of the model within experimental uncertainty. The ultimate (or “absolute”) validation truth standard would be comparison of simulation results with a perfectly performed empirical experiment, with all simulation inputs perfectly defined.

Establishing an absolute truth standard for evaluating a program's ability to analyze physical behavior requires empirical validation, but this is only possible within the range of measurement uncertainty, including that related to instruments, spatial and temporal discretization, and the overall experimental design. Test cells and buildings are large, relatively complex experimental objects. The exact design details, material properties, and construction in the field may not be known, so there is some uncertainty about the simulation model inputs that accurately represent the experimental object. Meticulous care is required to describe the experimental apparatus as clearly as possible to modelers to minimize this uncertainty. This includes experimental determination of as many material properties as possible, including overall building parameters such as overall steady-state heat transmission coefficient, infiltration rate, and thermal capacitance. Also required are detailed meteorological measurements. For

example, many experiments measure global horizontal solar radiation, but very few experiments measure the splits between direct, diffuse, and ground reflected radiation, all of which are inputs to many whole-building energy simulation programs.

The National Renewable Energy Laboratory (NREL) divides empirical validation into different levels, because many validation studies produced inconclusive results. The levels of validation depend on the degree of control over possible sources of error in a simulation. These error sources consist of seven types, divided into two groups:

External Error Types

- Differences between actual building microclimate versus weather input used by the program
- Differences between actual schedules, control strategies, effects of occupant behavior, and other effects from the real building versus those assumed by the program user
- User error deriving building input files
- Differences between actual physical properties of the building (including HVAC systems) versus those input by the user

Internal Error Types

- Differences between actual thermal transfer mechanisms in the real building and its HVAC systems versus the simplified model of those processes in the simulation (all models, no matter how detailed, are simplifications of reality)
- Errors or inaccuracies in the mathematical solution of the models
- Coding errors

The simplest level of empirical validation compares a building's actual long-term energy use to that calculated by a computer program, with no attempt to eliminate sources of discrepancy. Because this is similar to how a simulation tool is used in practice, it is favored by many in the building industry. However, it is difficult to interpret the results because all possible error sources are acting simultaneously. Even if there is good agreement between measured and calculated performance, possible offsetting errors prevent a definitive conclusion about the model's accuracy. More informative levels of validation involve controlling or eliminating various combinations of error types and increasing the density of output-to-data comparisons (e.g., comparing temperature and energy results at time scales ranging from subhourly to annual). At the most detailed level, all known sources of error are controlled to identify and quantify unknown error sources and to reveal causal relationships associated with error sources.

This principle also applies to intermodel comparative testing and analytical verification. The more realistic the test case, the more difficult it is to establish causality and diagnose problems; the simpler

Table 11 Validation Techniques

Technique	Advantages	Disadvantages
<i>Empirical</i> (test of model and solution process)	<ul style="list-style-type: none"> • Approximate truth standard within experimental accuracy • Any level of complexity 	<ul style="list-style-type: none"> • Experimental uncertainties: <ul style="list-style-type: none"> • Instrument calibration, spatial/temporal discretization • Imperfect knowledge/specification of experimental object (building) being simulated • High-quality, detailed measurements are expensive and time-consuming • Only a limited number of test conditions are practical
<i>Analytical</i> (test of solution process)	<ul style="list-style-type: none"> • No input uncertainty • Exact mathematical truth standard for given model • Inexpensive 	<ul style="list-style-type: none"> • No test of model validity • Limited to highly constrained cases for which analytical solutions can be derived
<i>Comparative</i> (relative test of model and solution process)	<ul style="list-style-type: none"> • No input uncertainty • Any level of complexity • Many diagnostic comparisons possible • Inexpensive and quick 	<ul style="list-style-type: none"> • No absolute truth standard (only statistically based acceptance ranges are possible)

Table 12 Types of Extrapolation

Obtainable Data Points	Extrapolation
A few climates	Many climates
Short-term total energy use	Long-term total energy use, or vice versa
Short-term (hourly) temperatures and/or fluxes	Long-term total energy use, or vice versa
A few equipment performance points	Many equipment performance points
A few buildings representing a few sets of variable and parameter combinations	Many buildings representing many sets of variable and parameter combinations, or vice versa
Small-scale: simple test cells, buildings, and mechanical systems; laboratory experiments	Large-scale complex buildings with complex HVAC systems, or vice versa

Source: Neymark and Judkoff (2002).

and more controlled the test case, the easier it is to pinpoint sources of error or inaccuracy. Methodically building up to realistic cases is useful for testing interactions between algorithms modeling linked mechanisms.

A comparison between measured and calculated performance represents a small region in an immense N -dimensional parameter space. Investigators are constrained to exploring relatively few regions in this space, yet would like to be assured that the results are not coincidental (e.g., not a result of offsetting errors) and do represent the validity of the simulation elsewhere in the parameter space. Analytical and comparative techniques minimize the uncertainty of extrapolations around the limited number of sampled empirical domains. Table 12 classifies these extrapolations. Use of the term “vice versa” in Table 12 is intended to mean that the extrapolation can go both ways (e.g., from short-term to long-term data and from long-term to short-term data). This does not mean that such extrapolations are correct, but only that researchers and practitioners have either explicitly or implicitly made such inferences in the past.

Figure 21 shows one process to combine analytical, empirical, and comparative techniques. These three techniques may also be used together in other ways; for example, intermodel comparisons may be done before an empirical validation exercise, to better define the experiment and to help estimate experimental uncertainty by propagating all known error sources through one or more whole-building energy simulation programs (Hunn et al. 1982; Lomas et al. 1994).

For the path shown in Figure 21, the first step is running the code against analytical verification test cases to check its mathematical solution. Discrepancies must be corrected before proceeding further.

Second, the code is run against high-quality empirical validation data, and errors are corrected. Diagnosing error sources can be quite difficult and is an area of research in itself. Comparative techniques can be used to create diagnostics procedures (Judkoff 1988; Judkoff and Neymark 1995a, 1995b; Judkoff et al. 1980, 1983; Morck 1986; Neymark and Judkoff 2002; Spitler et al. 2001) and better define the experiments.

The third step is to check agreement of several different thermal solution and modeling approaches (that have passed through steps 1 and 2) in a variety of representative cases. This uses the comparative technique as an extrapolation tool. Deviations in the program predictions indicate areas for further investigation.

When programs successfully complete these three stages, they are considered validated for cases where acceptable agreement was achieved (i.e., for the range of building, climate, and mechanical system types represented by the test cases). Once several detailed simulation programs have satisfactorily completed the procedure, other programs and simplified design tools can be tested against them. A validation code does not necessarily represent truth. It does represent a set of algorithms that have been shown, through a repeatable procedure, to perform according to the current state of the art.

NREL methodology for validating building energy simulation programs has been generally accepted by the International Energy

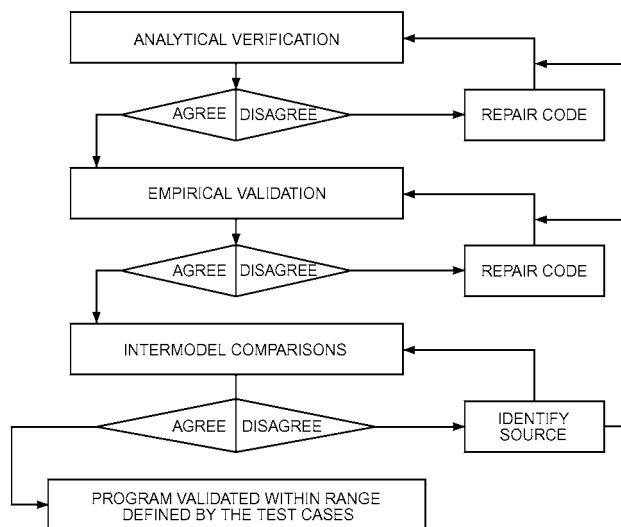

Fig. 21 Validation Method
(Neymark and Judkoff 2002)

Agency (Irving 1988), ASHRAE *Standard* 140 and Addendum p to ASHRAE *Standard* 90.1, and elsewhere, with refinements suggested by other researchers (Bland 1992; Bloomfield 1988, 1999; Guyon and Palomo 1999b; Irving 1988; Lomas 1991; Lomas and Bowman 1987; Lomas and Eppel 1992). Additionally, the Commission of European Communities has conducted considerable work under the PASSYS program (Jensen 1989; Jensen and van de Perre 1991).

SUMMARY OF PREVIOUS TESTING AND VALIDATION WORK

Neymark and Judkoff (2002) summarize approximately 100 articles and research papers on analytical, empirical, and comparative testing, from 1980 to 2004. Some of these works are listed by subject in the Bibliography.

<i>SYSTEM DESIGN</i>	20.7	<i>Symbols</i>	20.20

ROOM air distribution systems are intended to provide thermal comfort and ventilation for space occupants and processes. Although air terminals (inlets and outlets), terminal units, local ducts, and rooms themselves may affect room air diffusion, this chapter addresses only air terminals and their direct effect on occupant comfort. This chapter is intended to present HVAC designers the fundamental characteristics of air distribution devices. For information on naturally ventilated spaces, see Chapter 16. For a discussion of various air distribution strategies, tools, and guidelines for design and application, see Chapter 56 in the 2007 *ASHRAE Handbook—HVAC Applications*. Chapter 19 in the 2008 *ASHRAE Handbook—HVAC Systems and Equipment* provides descriptions of the characteristics of various air terminals (inlets and outlets) and terminal units, as well as selection tools and guidelines. Other fundamental references include Bauman and Daly (2003), Chen and Glicksman (2003), Kirkpatrick and Elleson (1996), Rock and Zhu (2002), and Skistad et al. (2002).

Room air diffusion methods can be classified as one of the following:

- **Mixed systems** produce little or no thermal stratification of air within the space. Overhead air distribution is an example of this type of system.
- **Fully (thermally) stratified systems** produce little or no mixing of air within the occupied space. Thermal displacement ventilation is an example of this type of system.
- **Partially mixed systems** provide some mixing within the occupied and/or process space while creating stratified conditions in the volume above. Most underfloor air distribution designs are examples of this type of system.
- **Task/ambient conditioning systems** focus on conditioning only a certain portion of the space for thermal comfort and/or process control. Examples of task/ambient systems are personally controlled desk outlets (sometimes referred to as personal ventilation systems) and spot-conditioning systems.

Air distribution systems, such as displacement ventilation (DV) and underfloor air distribution (UFAD), that deliver air in cooling mode at or near floor level and return air at or near ceiling level produce varying amounts of room air stratification. Figure 1 presents a series of simplified vertical profiles of temperature and pollutant concentration representing the spectrum of stratified conditions that may exist under cooling operation, from fully stratified (e.g., DV systems) to fully mixed (e.g., conventional overhead systems). For floor-level supply, thermal plumes that develop over heat sources in the room play a major role in driving overall floor-to-ceiling air motion. The amount of stratification in the room is primarily determined by the balance between total room airflow and heat load. In practice, the actual temperature (or concentration) profile depends on the combined effects of various factors, but is largely driven by

the characteristics of the room supply airflow and heat load configuration.

For room supply airflow, the major factors are

- Total room supply airflow quantity
- Room supply air temperature
- Diffuser type
- Diffuser throw height (or outlet velocity); this is associated with the amount of mixing provided by a floor diffuser (or room conditions near a low-sidewall DV diffuser)

For room heat loads, the major factors are

- Magnitude and number of loads in space
- Load type (point or distributed source)
- Elevation of load (e.g., overhead lighting, person standing on floor, floor-to-ceiling glazing)
- Radiative/convective split
- For pollutant concentration profiles, whether pollutants are associated with heat sources

INDOOR AIR QUALITY AND SUSTAINABILITY

Air diffusion methods affect not only indoor air quality (IAQ) and thermal comfort, but also energy consumption over the building's life. Choices made early in the design process are important. The U.S. Green Building Council's (USGBC 2005) Leadership in Energy and Environmental Design (LEED®) rating system, which was originally created in response to indoor air quality concerns, now includes prerequisites and credits for increasing ventilation effectiveness and improving thermal comfort. These requirements and optional points are relatively easy to achieve if good room air diffusion design principles, methods, and standards are followed.

Environmental tobacco smoke (ETS) control is a LEED prerequisite. Banning indoor smoking is a common approach, but if indoor smoking is to be allowed, ANSI/ASHRAE *Standard* 62.1 requires that more than the base non-ETS ventilation air be provided where ETS is present in all or part of a building. Rock (2006) provides additional guidance on dealing with ETS.

The **air change effectiveness** is affected directly by the room air distribution system's design, construction, and operation, but is very difficult to predict. Many attempts have been made to quantify air change effectiveness, including ASHRAE *Standard* 129. However, this standard is only for experimental tests in well-controlled laboratories, and should not be applied directly to real buildings.

ANSI/ASHRAE *Standard* 62.1-2007 provides a table of typical values to help predict ventilation effectiveness. For example, well-designed ceiling-based air distribution systems produce near-perfect air mixing in cooling mode, and yield an air change effectiveness of almost 1.0.

Displacement and underfloor air distribution (UFAD) systems have the potential for values greater than 1.0. More information on ceiling- and wall-mounted air inlets and outlets can be found in Rock and Zhu (2002). Displacement system performance is described in Chen and Glicksman (2003). Bauman and Daly (2003)

The preparation of this chapter is assigned to TC 5.3, Room Air Distribution.

Fig. 1 Classification of Air Diffusion Methods

discuss UFAD in detail. (These three ASHRAE books were produced by research projects for Technical Committee 5.3.) More information on ANSI/ASHRAE *Standard* 62.1-2007 is available in its user's manual (ASHRAE 2007).

APPLICABLE STANDARDS AND CODES

The following standards and codes should be reviewed when applying various room air diffusion methods:

- ASHRAE *Standard* 55 specifies the combination of indoor thermal environmental factors and personal factors that will produce thermal acceptability to a majority of space occupants.
- ASHRAE *Standard* 62.1 establishes the ventilation requirements for acceptable indoor environmental quality. This standard is adopted as part of many building codes.
- ASHRAE/IESNA *Standard* 90.1 provides energy efficiency requirements that affect supply air characteristics.
- ASHRAE *Standard* 113 describes a method for evaluating the effectiveness of various room air distribution systems in achieving thermal comfort.
- ASHRAE *Standard* 129 specifies a method for measuring air-change effectiveness in mechanically ventilated spaces.

Local codes should also be checked to see how they apply to each of these subjects.

TERMINOLOGY

Adjacent zone. Area adjacent to an outlet in which long term occupancy is not recommended because of potential discomfort. Also called **clear** or **near zone**.

Aspect ratio. Ratio of length to width of opening or core of a grille.

Axial flow jet. Stream of air with motion approximately symmetrical along a line, although some spreading and drop or rise can occur from diffusion and buoyancy effects.

CAV. Constant air volume.

Coanda effect. Effect of a moving jet attaching to a parallel surface because of negative pressure developed between jet and surface.

Coefficient of discharge. Ratio of area at vena contracta to area of opening.

Cold air. General term for supply air, typically between 35 to 45°F.

Core area. Area of a register, grille, or linear slot pertaining to the frame or border, whichever is less.

Damper. Device used to vary the volume flow rate of air passing through a confined cross section by varying the cross-sectional area.

Diffuser. Outlet discharging supply air in various directions and planes.

Diffusion. Dispersion of air within a space.

Distribution. Moving air to or in a space by an outlet discharging supply air.

Draft. Undesired or excessive local cooling of a person caused by low temperature and air movement.

Drop. Vertical distance that the lower edge of a horizontally projected airstream descends between the outlet and the end of its throw.

Effective area. Net area of an outlet or inlet device through which air can pass; equal to the free area times the coefficient of discharge.

Entrainment. Movement of space air into the jet caused by the airstream discharged from the outlet (also known as secondary air motion).

Entrainment (or induction) ratio. Volume flow rate of total air (primary plus entrained air) divided by the volume flow rate of primary air at a given distance from the outlet.

Envelope. Outer boundary of an airstream moving at a perceptible velocity.

Exhaust opening or inlet. Any opening through which air is removed from a space.

Free area. Total minimum area of openings in an air outlet or inlet through which air can pass.

Grille. Functional or decorative device covering any area through which air passes.

Induction. See Entrainment.

Isothermal jet. Air jet with same temperature as surrounding air.

Lower (mixed) zone. In partially mixed systems, zone directly adjacent to floor, in which air is relatively well mixed.

Neck area. Nominal area of duct connection to air outlet or inlet.

Nonisothermal jet. Air jet with a discharge temperature different from surrounding air.

Occupied zone. Room volume where occupants are located (typically 6 ft above floor level and 1 ft from walls).

Outlet velocity. Average velocity of air emerging from outlet, measured in plane of opening.

Primary air. Air delivered to an outlet by a supply duct.

Radius of diffusion. Horizontal axial distance an airstream travels after leaving an air outlet before the maximum stream velocity is reduced to a specified terminal level (e.g., 50, 100, 150, or 200 fpm).

Register. Grille equipped with a flow control damper.

Spread. Divergence of airstream in horizontal and/or vertical plane after it leaves an outlet.

Stagnant zone. Area characterized by stratification and little air motion. This term does not necessarily imply poor air quality.

Stratification height. Vertical distance from floor to horizontal plane that defines lower boundary of upper mixed zone (in a fully stratified or partially mixed system).

Stratified zone. Zone in which air movement is entirely driven by buoyancy caused by convective heat sources. Typically found in fully stratified or partially mixed systems

Supply opening or outlet. Any opening or device through which supply air is delivered into a ventilated space being heated, cooled, humidified, or dehumidified. Supply outlets are classified according to their location in a room as sidewall, ceiling, baseboard, or floor outlets. However, because numerous designs exist, they are more accurately described by their construction features. (See Chapter 19 of the 2008 *ASHRAE Handbook—HVAC Systems and Equipment*.)

Terminal velocity. Maximum airstream velocity at end of throw.

Throw. Horizontal or vertical axial distance an airstream travels after leaving an air outlet before maximum stream velocity is reduced to a specified terminal velocity (e.g., 50, 100, 150, or 200 fpm), defined by ASHRAE *Standard 70*.

Total air. Mixture of discharged and entrained air.

Upper (mixed) zone. Zone in which air is relatively well mixed, with generally low average air velocities caused by the momentum of thermal plumes penetrating its lower boundary. Typically found in fully stratified or partially mixed systems.

Vane. Component of supply air outlet that imparts direction to the discharge jet.

Vane ratio. Ratio of depth of a vane to the space between two adjacent vanes.

VAV. Variable air volume.

Vena contracta. Smallest cross-sectional area of a fluid stream leaving an orifice.

PRINCIPLES OF JET BEHAVIOR

Air Jet Fundamentals

Air supplied to rooms through various types of outlets (e.g., grilles, ceiling diffusers, perforated panels) can be distributed by turbulent air jets (mixed and partially mixed systems) or in a low-velocity, unidirectional manner (stratified systems). The air jet discharged from an outlet is the primary factor affecting room air motion. Baturin (1972), Christianson (1989), and Murakami (1992) have further information on the relationship between the air jet and occupied zone.

If an air jet is not obstructed or affected by walls, ceiling, or other surfaces, it is considered a **free jet**.

Characteristics of the air jet in a room might be influenced by reverse flows created by the same jet entraining ambient air. If the supply air temperature is equal to the ambient room air temperature, the air jet is called an **isothermal jet**. A jet with an initial temperature different from the ambient air temperature is called a **non-isothermal jet**. The air temperature differential between supplied and ambient room air generates thermal forces (buoyancy) in jets, affecting the jet's (1) trajectory, (2) location at which it attaches to and separates from the ceiling/floor, and (3) throw. The significance of these effects depends on the ratio between the thermal buoyancy of the air and inertial forces.

Angle of Divergence. The angle of divergence is well defined near the outlet face, but the boundary contours are billowy and easily affected by external influences. Near the outlet, as in the room, air movement has local eddies, vortices, and surges. Internal forces

governing this air motion are extremely delicate (Nottage et al. 1952a).

Measured angles of divergence (spread) for discharge into large open spaces usually range from 20 to 24°, with an average of 22°. Coalescing jets for closely spaced multiple outlets expand at smaller angles, averaging 18°, and jets discharging into relatively small spaces show even smaller angles of expansion (McElroy 1943). When outlet area is small compared to the dimensions of the space normal to the jet, the jet may be considered free as long as

$$X \leq 1.5 \sqrt{A_R} \quad (1)$$

where

X = distance from face of outlet, ft

A_R = cross-sectional area of confined space normal to jet, ft²

Jet Expansion Zones. The full length of an air jet, in terms of the maximum or centerline velocity and temperature differential at the cross section, can be divided into four zones:

- **Zone 1**, a short core zone extending about four diameters or widths from the outlet face, in which the maximum velocity (temperature) of the airstream remains practically unchanged.
- **Zone 2**, a transition zone, with its length determined by the type of outlet, aspect ratio of the outlet, initial airflow turbulence, etc.
- **Zone 3**, a zone of fully established turbulent flow that may be 25 to 100 equivalent air outlet diameters (widths for slot air diffusers) long.
- **Zone 4**, a zone of diffuser jet degradation, where maximum air velocity and temperature decrease rapidly. Distance to this zone and its length depend on the velocities and turbulence characteristics of ambient air. In a few diameters or widths, air velocity becomes less than 50 fpm. Characteristics of this zone are still not well understood.

Zone 3 is of major engineering importance because, in most cases, the diffuser jet enters the occupied area within this zone.

Centerline Velocities in Zones 1 and 2. In zone 1, the ratio V_x/V_o is constant and equal to the ratio of the center velocity of the jet at the start of expansion to the average velocity. The ratio V_x/V_o varies from approximately 1.0 for rounded entrance nozzles to about 1.2 for straight pipe discharges; it has much higher values for diverging discharge outlets.

Experimental evidence indicates that, in zone 2,

$$\frac{V_x}{V_o} = \sqrt{\frac{K_c H_o}{X}} \quad (2)$$

where

V_x = centerline velocity at distance X from outlet, fpm

V_o = $V_c/C_d R_{fa}$ = average initial velocity at discharge from open-ended duct or across contracted stream at vena contracta of orifice or multiple-opening outlet, fpm

V_c = nominal velocity of discharge based on core area, fpm

C_d = discharge coefficient (usually between 0.65 and 0.90)

R_{fa} = ratio of free area to gross (core) area

H_o = width of jet at outlet or at vena contracta, ft

K_c = centerline velocity constant, depending on outlet type and discharge pattern (see Table 1)

X = distance from outlet to measurement of centerline velocity V_x , ft

The aspect ratio (Tuve 1953) and turbulence (Nottage et al. 1952a) primarily affect centerline velocities in zones 1 and 2. Aspect ratio has little effect on the terminal zone of the jet when H_o is greater than 4 in. This is particularly true of nonisothermal jets. When H_o is very small, induced air can penetrate the core of the jet, thus reducing centerline velocities. The difference in performance between a radial outlet with small H_o and an axial outlet with large H_o shows the importance of jet thickness.

Note: Airflow patterns shown with darker shading indicate primary air patterns for terminal velocities above 150 fpm.

Fig. 2 Airflow Patterns of Different Diffusers

Table 1 Recommended Values for Centerline Velocity Constant K_c for Commercial Supply Outlets

Outlet Type	Discharge Pattern	A_o	K_c
High sidewall grilles (Figure 2A)	0° deflection ^a	Free	5.7
	Wide deflection	Free	4.2
High sidewall linear (Figure 2B)	Core less than 4 in. high ^b	Free	4.4
	Core more than 4 in. high	Free	5.0
Low sidewall (Figure 2C)	Up and on wall, no spread	Free	4.5
	Wide spread ^b	Free	3.0
Baseboard (Figure 2C)	Up and on wall, no spread	Core	4.0
	Wide spread	Core	2.0
Floor grille (Figure 2C)	No spread ^b	Free	4.7
	Wide spread	Free	1.6
Ceiling (Figure 2D)	360° horizontal ^c	Neck	1.1
	Four-way; little spread	Neck	3.8
Ceiling linear slot (Figure 2E)	One-way; horizontal along ceiling ^b	Free	5.5

^aFree area is about 80% of core area.
^bFree area is about 50% of core area.

^cCone free area is greater than duct area.

When air is discharged from relatively large perforated panels, the constant-velocity core formed by coalescence of individual jets extends a considerable distance from the panel face. In zone 1, when the ratio is less than 5, use the following equation for estimating centerline velocities (Koestel et al. 1949):

$$V_x = 1.2V_o \sqrt{C_d R_{fa}} \quad (3)$$

Centerline Velocity in Zone 3. In zone 3, maximum or centerline velocities of straight-flow isothermal jets can be determined accurately from the following equations:

$$\frac{V_x}{V_o} = \frac{K_c H_o}{X} = \frac{K_c \sqrt{A_o}}{X} \quad (4)$$

$$V_x = \frac{K_c V_o \sqrt{A_o}}{X} = \frac{K_c Q_o}{X \sqrt{A_o}} \quad (5)$$

Fig. 3 Chart for Determining Centerline Velocities of Axial and Radial Jets

where

- K_c = centerline velocity constant
- H_o = effective or equivalent diameter of stream at discharge from open-ended duct or at contracted section, ft
- A_o = core area or neck area as shown in Table 1, ft²
- A_c = measured gross (core) area of outlet, ft²
- Q_o = discharge from outlet, cfm

Because A_o equals the effective area of the stream, the flow area for commercial registers and diffusers, according to ASHRAE Standard 70, can be used in Equation (4) with the appropriate value of K_c .

Determining Centerline Velocities. To correlate data from all four zones, centerline velocity ratios are plotted against distance from the outlet in Figure 3.

Airflow patterns of diffusers are related to the throw K -factors and throw distance. In general, diffusers with a circular airflow pattern have a shorter throw than those with a directional or cross-flow pattern. During cooling, the circular pattern tends to curl back from the end of the throw toward the diffuser, reducing the drop and ensuring that the cool air remains near the ceiling.

Cross-flow airflow patterns have a longer throw, and the individual side jets react similarly to jets from sidewall grilles. Jets with this pattern have a longer throw, and airflow does not roll back to the diffuser at the end of the throw, but continues to move away from the diffuser at low velocities.

Throw. Equation (5) can be transposed to determine the throw X of an outlet if the discharge volume and the centerline velocity are known:

$$X = \frac{K_c Q_o}{V_x \sqrt{A_o}} \quad (6)$$

The following example illustrates the use of Table 1 and Figure 3.

Example 1. A 12 by 18 in. high sidewall grille with an 11.25 by 17.25 in. core area is selected. From Table 1, $K_c = 5$ for zone 3. If the airflow is 600 cfm, what is the throw to 50, 100, and 150 fpm?

Solution:

From Equation (6),

$$X = \frac{K_c Q_o}{V_x \sqrt{A_o}} = \frac{5 \times 600}{V_x \sqrt{11.25 \times 17.25 / 144}} = \frac{2920}{V_x}$$

Solving for 50 fpm throw,

$$X = 2920 / 50 = 58.4 \text{ ft}$$

But, according to Figure 3, 50 fpm is in zone 4, which is typically 20% less than calculated in Equation (4), or

$$X = 58.4 \times 0.80 = 47 \text{ ft}$$

Solving for 100 fpm throw,

$$X = 2920 / 100 = 29 \text{ ft}$$

Solving for 150 fpm throw,

$$X = 2920 / 150 = 19 \text{ ft}$$

Velocity Profiles of Jets. In zone 3 of both axial and radial jets, the velocity distribution may be expressed by a single curve (Figure 3) in terms of dimensionless coordinates; this same curve can be used as a good approximation for adjacent portions of zones 2 and 4. Temperature and density differences have little effect on cross-sectional velocity profiles.

Velocity distribution in zone 3 can be expressed by the Gauss error function or probability curve, which is approximated by the following equation:

$$\left(\frac{r}{r_{0.5V}} \right)^2 = 3.3 \log \frac{V_x}{V} \quad (7)$$

where

- r = radial distance of point under consideration from centerline of jet
- $r_{0.5V}$ = radial distance in same cross-sectional plane from axis to point where velocity is one-half centerline velocity (i.e., $V = 0.5V_x$)
- V_x = centerline velocity in same cross-sectional plane
- V = actual velocity at point being considered

Experiments show that the conical angle for $r_{0.5V}$ is approximately one-half the total angle of divergence of a jet. The velocity profile curve for one-half of a straight-flow turbulent jet (the other half being a symmetrical duplicate) is shown in Figure 4. For multiple-opening outlets, such as grilles or perforated panels, the velocity profiles are similar, but the angles of divergence are smaller.

Entrainment Ratios. The following equations are for entrainment of circular jets and of jets from long slots. For third-zone expansion of circular jets,

$$\frac{Q_x}{Q_o} = \frac{2X}{K_c \sqrt{A_o}} \quad (8)$$

By substituting from Equation (4),

$$\frac{Q_x}{Q_o} = 2 \frac{V_o}{V_x} \quad (9)$$

For a continuous slot with active sections up to 10 ft and separated by 2 ft,

$$\frac{Q_x}{Q_o} = \sqrt{2} \frac{\sqrt{X}}{\sqrt{H_s}} \quad (10)$$

or, substituting from Equation (2),

$$\frac{Q_x}{Q_o} = \sqrt{2} \frac{V_o}{V_x} \quad (11)$$

where

- Q_x = total volumetric flow rate at distance X from face of outlet, cfm
- Q_o = discharge from outlet, cfm
- X = distance from face of outlet, ft
- K_c = centerline velocity constant

Fig. 4 Cross-Sectional Velocity Profiles for Straight-Flow Turbulent Jets

A_o = core area or neck area free (see Table 1), ft²
 H_s = width of slot, ft

The entrainment ratio Q_x/Q_o is important in determining total air movement at a given distance from an outlet. For a given outlet, the entrainment ratio is proportional to the distance X [Equation (8)] or to the square root of the distance X [Equation (10)] from the outlet. Equations (9) and (11) show that, for a fixed centerline velocity V_c , the entrainment ratio is proportional to outlet velocity. Equations (9) and (11) also show that, at a given centerline and outlet velocity, a circular jet has greater entrainment and total air movement than a long slot. Comparing Equations (8) and (10), the long slot should have a greater rate of entrainment. The entrainment ratio at a given distance is less with a large K than with a small K .

Isothermal Radial Flow Jets

In a radial jet, as with an axial jet, the cross-sectional area at any distance from the outlet varies as the square of this distance. Centerline velocity gradients and cross-sectional velocity profiles are similar to those of zone 3 of axial jets, and the angles of divergence are about the same.

A jet from a ceiling plaque has the same form as half of a free radial jet. The jet is wider and longer than a free jet, with maximum velocity close to the surface. Koestel (1957) provides an equation for radial flow outlets.

Nonisothermal Jets

When the temperature of introduced air is different from the room air temperature, the diffuser air jet is affected by thermal buoyancy caused by air density difference. The trajectory of a nonisothermal jet introduced horizontally is determined by the Archimedes number (Baturin 1972):

$$\text{Ar} = \frac{g L_o (T_o - T_A)}{V_o^2 T_A} \quad (12)$$

where

g = gravitational acceleration rate, ft/min²
 L_o = length scale of diffuser outlet equal to hydraulic diameter of outlet, ft
 $(T_o - T_A)$ = initial temperature of jet – temperature of ambient air, °F
 V_o = initial air velocity of jet, fpm
 T_A = room air temperature, °R

The influence of buoyant forces on horizontally projected heated and chilled jets is significant in heating and cooling with wall outlets. Koestel's (1955) equation describes the behavior of these jets.

Helander and Jakowatz (1948), Helander et al. (1953, 1954, 1957), Knaak (1957), and Yen et al. (1956) developed equations

for outlet characteristics that affect the downthrow of heated air. Koestel (1954, 1955) developed equations for temperatures and velocities in heated and chilled jets. Kirkpatrick and Elleson (1996) and Li et al. (1993, 1995) provide additional information on nonisothermal jets.

Nonisothermal Horizontal Free Jet

A horizontal free jet rises or falls according to the temperature difference between it and the ambient environment. The horizontal jet throw to a given distance follows an arc, rising for heated air and falling for cooled air. The distance from the diffuser to a given terminal velocity along the discharge jet remains essentially the same.

Comparison of Free Jet to Attached Jet

Most manufacturers' throw data obtained in accordance with ASHRAE Standard 70 assume the discharge is attached to a surface. An attached jet induces air along the exposed side of the jet, whereas a free jet can induce air on all its surfaces. Because a free jet's induction rate is larger compared to that of an attached jet, a free jet's throw distance will be shorter. To calculate the throw distance X for a noncircular free jet from catalog data for an attached jet, the following estimate can be used.

$$X_{free} = X_{attached} \times 0.707 \quad (13)$$

Circular free jets generally have longer throws compared to non-circular jets.

Jets from ceiling diffusers initially tend to attach to the ceiling surface, because of the force exerted by the Coanda effect. However, cold air jets will detach from the ceiling if the airstream's buoyancy forces are greater than the inertia of the moving air stream.

With separation, a cold draft may enter the occupied space, resulting in thermal discomfort. The thermal discomfort is caused by two factors: the cold draft of the separated jet in the occupied space, and the lack of adequate mixing in areas of the room not reached by the separated jet. The separation distance parameter x_s is the distance from the diffuser at which a jet separates from the ceiling.

Separation distance correlates with outlet jet conditions. Separation distance depends on the velocity constant K , outlet temperature, flow rate, and static pressure drop. For slot and round diffusers,

$$x_s = (11.91)(1.2)K^{1/2}(\Delta T/T)^{-1/2}Q_o^{1/4}\Delta P^{3/8} \quad (14)$$

where

x_s = jet separation distance, ft
 K_c = centerline velocity constant
 ΔT = room-jet temperature difference, °F
 T = average absolute room temperature, °R
 Q_o = outlet flow rate, cfm
 ΔP = diffuser static pressure drop, in. of water

A representative value of C_s that has been found to best match the results of analyses and experiments of a wide variety of diffusers is 1.2.

Surface Jets (Wall and Ceiling)

Attached jets travel at a higher velocity and entrain less air than a free jet. Values of centerline velocity constant K are approximately those for a free jet multiplied by $\sqrt{2}$; that is, the normal maximum of 6.2 for K for free jets becomes 8.8 for a similar jet discharged parallel to an adjacent surface.

When a jet is discharged parallel to but at some distance from a solid surface (wall, ceiling, or floor), its expansion in the direction of the surface is reduced, and entrained air must be obtained by recirculation from the jet instead of from ambient air (McElroy 1943; Nottage et al. 1952b; Zhang et al. 1990). The restriction to entrainment caused by the solid surface induces the **Coanda effect**, which makes the jet attach to a surface a short distance after

it leaves the diffuser outlet. The jet then remains attached to the surface for some distance before separating again.

In nonisothermal cases, the jet's trajectory is determined by the balance between thermal buoyancy and the Coanda effect, which depends on jet momentum and distance between the jet exit and solid surface. The behavior of such nonisothermal surface jets has been studied by Kirkpatrick et al. (1991), Oakes (1987), Wilson et al. (1970), and Zhang et al. (1990), each addressing different factors. More systematic study of these jets in room ventilation flows is needed to provide reliable guidelines for designing air distribution systems.

Multiple Jets

Twin parallel air jets act independently until they interfere. The point of interference and its distance from outlets vary with the distance between outlets. From outlets to the point of interference, maximum velocity, as for a single jet, is on the centerline of each jet. After interference, velocity on a line midway between and parallel to the two jet centerlines increases until it equals jet centerline velocity. From this point, maximum velocity of the combined jet stream is on the midway line, and the profile seems to emanate from a single outlet of twice the area of one of the two outlets.

Airflow in Occupied Zone

Mixing Systems. Laboratory experiments on jets usually involve recirculated air with negligible resistance to flow on the return path. Experiments in small-cross-sectional mine tunnels, where return flow meets considerable resistance, show that jet expansion terminates abruptly at a distance that is independent of discharge velocity and is only slightly affected by outlet size. These distances are determined primarily by the return path's size and length. In a long tunnel with a cross section of 5 by 6 ft, a jet may not travel more than 25 ft; in a tunnel with a relatively large section (25 by 60 ft), the jet may travel more than 250 ft. McElroy (1943) provides data on this phase of jet expansion.

Zhang et al. (1990) found that, for a given heat load and room air supply rate, air velocity in the occupied zone increases when outlet discharge velocity increases. Therefore, the design supply air velocity should be high enough to maintain the jet traveling in the desired direction, to ensure good mixing before it reaches the occupied zone. Excessively high outlet air velocity induces high air velocity in the occupied zone and results in thermal discomfort.

Turbulence Production and Transport. Air turbulence in a room is mainly produced at the diffuser jet region by interaction of supply air with room air and with solid surfaces (walls or ceiling) in the vicinity. It is then transported to other parts of the room, including the occupied zone (Zhang et al. 1992). Turbulence is also damped by viscous effect. Air in the occupied zone usually contains very small amounts of turbulent kinetic energy compared to the jet region. Because turbulence may cause thermal discomfort (Fanger et al. 1989), air distribution systems should be designed so that stationary occupants are not subjected to the region where primary mixing between supply and room air occurs (except in specialized applications such as task ambient or spot-conditioning systems).

SYSTEM DESIGN

MIXED-AIR SYSTEMS

In mixed-air systems, high-velocity supply jets from air outlets maintain comfort by mixing room air with supply air. This air mixing, heat transfer, and resultant velocity reduction should occur outside the occupied zone. Occupant comfort is maintained not directly by motion of air from the outlets, but from secondary air motion that results from mixing in the unoccupied zone. Comfort is maximized when uniform temperature distribution and room air velocities of less than 50 fpm are maintained in the occupied zone.

Outlet Types

Straub and Chen (1957) and Straub et al. (1956) classified outlets into five groups:

Group A. Outlets mounted in or near the ceiling that discharge air horizontally.

Group B. Outlets mounted in or near the floor that discharge air vertically in a nonspreading jet.

Group C. Outlets mounted in or near the floor that discharge air vertically in a spreading jet.

Group D. Outlets mounted in or near the floor that discharge air horizontally.

Group E. Outlets mounted in or near the ceiling that project primary air vertically.

Analysis of outlet performance was based on primary air pattern, total air pattern, stagnant air layer, natural convection currents, return air pattern, and room air motion. Figures 5 to 9 show room air motion characteristics of the five outlet groups; exterior walls are depicted by heavy lines. The principles of air diffusion emphasized by these figures are as follows:

- Primary air (shown by dark envelopes in Figures 5 to 9) from the outlet down to a velocity of about 150 fpm can be treated analytically. Heating or cooling load has a strong effect on the characteristics of primary air.
- Total air, shown by light gray envelopes in Figures 5 to 9, is influenced by primary air and is of relatively high velocity (but less than 150 fpm). Total air is also influenced by the environment and drops during cooling or rises during heating; it is not subject to precise analytical treatment.
- Natural convection currents form a stagnant zone from the ceiling down during cooling, and from the floor up during heating. This zone forms below the terminal point of the total air during heating and above the terminal point during cooling. Because this zone results from natural convection currents, its air velocities are usually low (approximately 20 fpm), and the air stratifies in layers of increasing temperatures. The concept of a stagnant zone is important in properly applying and selecting outlets because it considers the natural convection currents from warm and cold surfaces and internal loads.
- A return inlet affects room air motion only in its immediate vicinity. The intake should be located in the stagnant zone to return the warmest room air during cooling or the coolest room air during heating. The importance of the location depends on the relative size of the stagnant zone, which depends on the type of outlet.
- The general room air motion (shown by arrows in white areas in Figures 5 to 9) is a gentle drift toward the total air. Room conditions are maintained by entraining room air into the total airstream. The room air motion between the stagnant zone and the total air is relatively slow and uniform. The highest air motion occurs in and near the total airstreams.

Group A Outlets. This group includes high sidewall grilles, sidewall diffusers, ceiling diffusers, linear ceiling diffusers, and similar outlets. High sidewall grilles and ceiling diffusers are illustrated in Figure 5.

Primary air envelopes (**isovels**) show a horizontal, two-jet pattern for the high sidewall and a 360° diffusion pattern for the ceiling outlet. Although variation of vane settings might cause a discharge in one, two, or three jets in the case of the sidewall outlet, or have a smaller diffusion angle for the ceiling outlet, the general effect in each is the same.

During cooling, the total air drops into the occupied zone at a distance from the outlet that depends on air quantity, supply velocity, temperature differential between supply and room air, deflection setting, ceiling effect, and type of loading within the space. Analytical

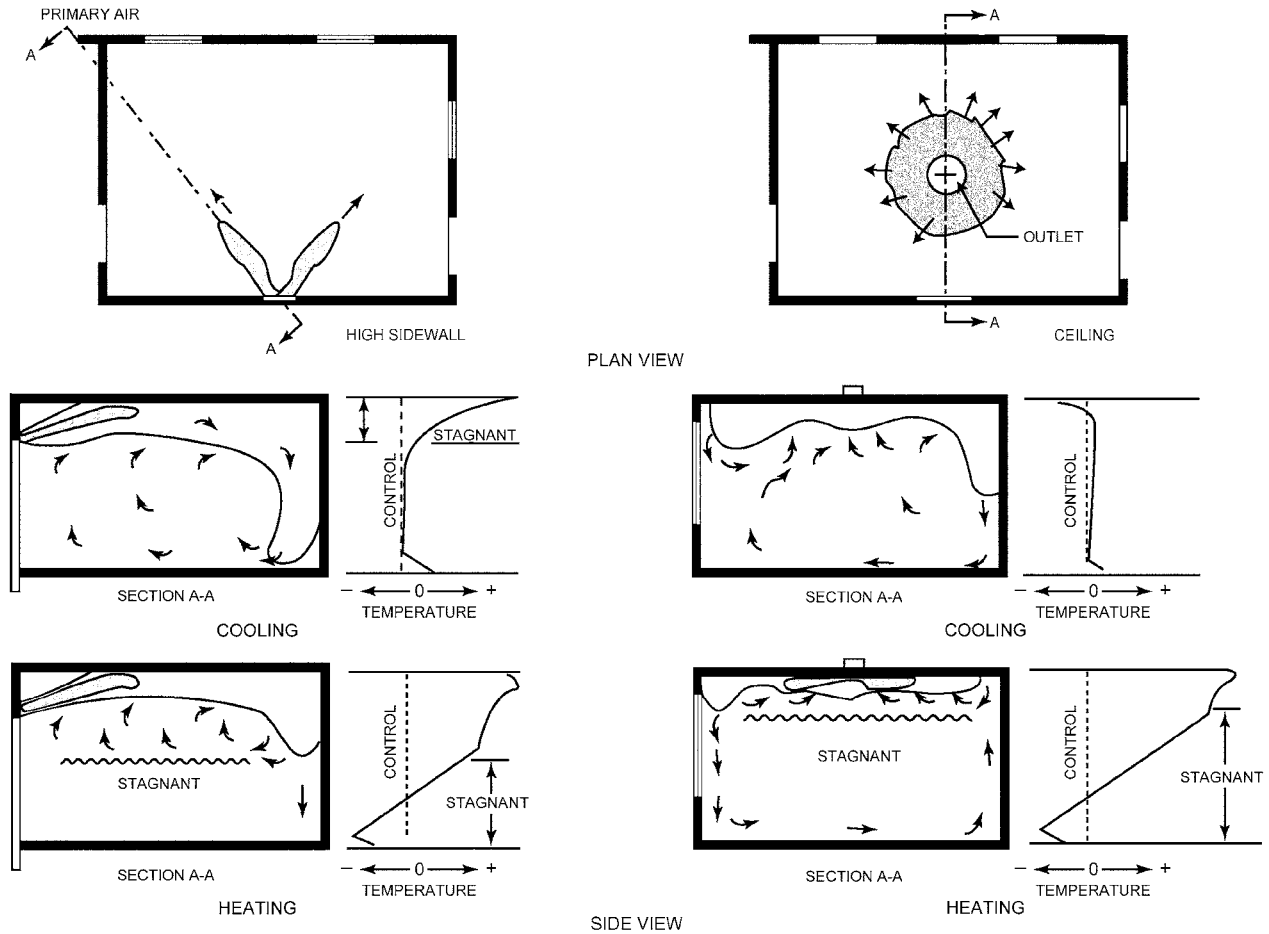

Fig. 5 Air Motion Characteristics of Group A Outlets
(Straub et al. 1956)

methods of relating some of these factors are presented in the section on Principles of Jet Behavior.

The cooling diagram for the high sidewall outlet shows an over-throw condition, which causes the total air to drop along the opposite wall and flow slowly for some distance across the floor. Velocities of about 100 to 150 fpm may be found near the wall but dissipate within about 4 in. of the wall.

The cooling diagram for the ceiling outlet shows that total air movement is counteracted by rising natural convection currents on the heated wall, and, therefore, drops before reaching the wall. On the other hand, the total air reaches the inside wall and descends for some distance along it. With this type of outlet, temperature variations in the room are minimized, with minimal stagnant volume. The maximum velocity and maximum temperature variation occur in and near the total air envelope; therefore, the drop region becomes important because it is an area with high effective draft temperature T_{ed} [see Equation (18)]. Consequently, how far the air drops before velocities and temperatures reach acceptable limits must be known.

Because these outlets discharge horizontally near the ceiling, the warmest air in the room is mixed immediately with cool primary air far above the occupied zone. Therefore, the outlets are capable of handling relatively large quantities of air at large temperature differentials.

During heating, warm supply air introduced at the ceiling can cause stratification in the space if there is insufficient induction of room air at the outlet. Selecting diffusers properly, limiting the room supply temperature differential, and maintaining air supply rates at

a level high enough to ensure air mixing by induction provide adequate air diffusion and minimize stratification.

Several building codes and ASHRAE *Standard* 90.1 require sufficient insulation in exterior walls, so most perimeter spaces can be heated effectively by ceiling air distribution systems. Interior spaces, which generally have only cooling demand conditions, seldom require long-term heating and are seldom a design problem.

Flow rate and velocity for both heating and cooling are the same for the outlets shown in Figure 5. The heating diagram for the sidewall unit shows that, under these conditions, total air does not descend along the wall. Consequently, higher velocities might be beneficial in eliminating the stagnant zone, because high velocity causes some warm air to reach floor level and counteract stratification of the stagnant region.

The heating diagram for the ceiling outlet shows the effect of natural convection currents that produce a larger throw toward the cold exposed wall. The velocity of total air toward the exposed wall complements natural convection currents. However, the warm total air loses its downward momentum at its terminal point, and buoyancy forces cause it to rise toward the primary air. Although these forces are complementary, the heating effect of total air replaces cool natural convection currents with warm total air.

Group B Outlets. This group includes floor registers, baseboard units, low sidewall units, linear-type grilles in the floor or window-sill, and similar outlets. Figure 6 illustrates a floor outlet adjacent to an inside wall.

Because these outlets have no deflecting vanes, primary air is discharged in a single, vertical jet. When total air strikes the ceiling,

Fig. 6 Air Motion Characteristics of Group B Outlets
(Straub et al. 1956)

it fans out in all directions and, during cooling, follows the ceiling for some distance before dropping toward the occupied zone. During heating, the total airflow follows the ceiling across the room, then descends partway down the exterior wall.

The cooling diagram shows that a stagnant zone forms outside the total air region above its terminal point. Below the stagnant zone, air temperature is uniform, effecting complete cooling. Also, the space below the terminal point of total air is cooled satisfactorily. For example, if total airflow is projected upward for 8 ft, the region from this level down to the floor will be cooled satisfactorily. However, this does not apply to an extremely large space. Judgment is needed to determine the acceptable size of the space outside the total air. A distance of 15 to 20 ft between the drop region and the exposed wall is a conservative design value.

Comparison of Figures 5 and 6 for heating shows that the stagnant region is smaller for group B outlets than for group A outlets because air entrained close to the outlet is taken mainly from the stagnant region, which is the coolest air in the room. This results in greater temperature equalization and less buoyancy in the total air than occurs with group A outlets.

Although temperature gradients for both outlet groups are about the same, the stagnant layer is lower for group B than for group A.

Group C Outlets. This group includes floor diffusers, sidewall diffusers, linear-type diffusers, and other outlets installed in the floor or windowsill (Figure 7).

Although group C outlets are related to group B outlets, they are characterized by wide-spreading jets and diffusing action. Total air and room air characteristics are similar to those of group B, although the stagnant zone is larger during cooling and smaller during heating. Primary air diffusion usually causes the total air to fold back on the primary and total air during cooling, instead of following the ceiling. This makes it more difficult to project cool air, but it also provides a greater area for induction of room air. This is

Fig. 7 Air Motion Characteristics of Group C Outlets
(Straub et al. 1956)

beneficial during heating because induced air comes from the lower regions of the room.

Group D Outlets. This group includes baseboard and low sidewall registers and similar outlets (Figure 8) that discharge primary air in single or multiple jets. During cooling, because air is discharged horizontally across the floor, the total air remains near the floor, and a large stagnant zone forms in the entire upper region of the room.

During heating, the total air rises toward the ceiling because of the buoyant effect. Temperature variations are uniform, except in the total air region.

Group E Outlets. This group includes ceiling diffusers, linear grilles, sidewall diffusers and grilles, and similar outlets mounted or designed for vertical downward air projection. Figure 9 shows the heating and cooling diagrams for such a ceiling diffuser.

During cooling, the total air projects to and follows the floor, producing a stagnant region near the ceiling. During heating, the total airflow reaches the floor and folds back toward the ceiling. If projected air does not reach the floor, a stagnant zone results.

Outlet Selection and Location

The design of a mixed-air distribution system is influenced by the same factors that affect design of an air-conditioning plant: building use, size, and construction type. Location and selection of supply outlets is further influenced by the interior design of the building, local sources of heat gain or loss, and outlet performance and design.

Local sources of heat gain or loss promote convection currents or cause stratification; they may, therefore, determine both the type and location of supply outlets. Outlets should be located to neutralize any undesirable convection currents set up by a concentrated load. If a concentrated heat source is located in the occupied zone, the heating effect can be counteracted by (1) directing cool air toward the source

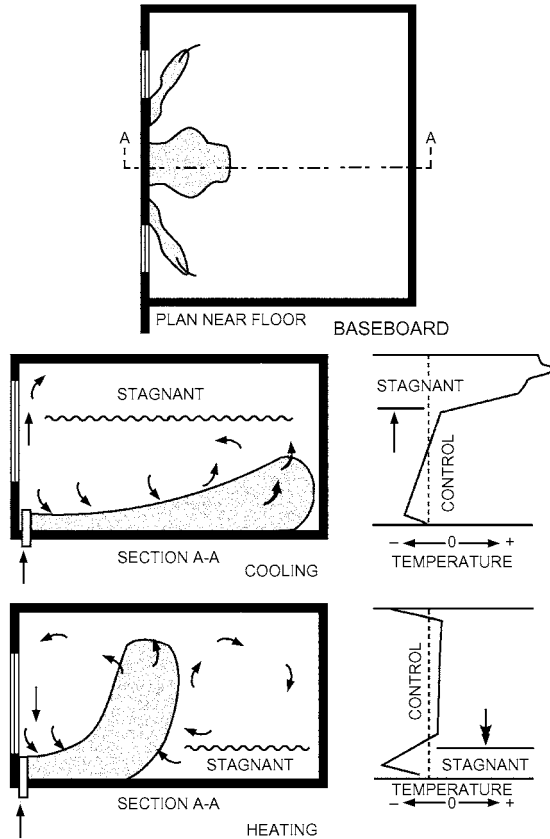

Fig. 8 Air Motion Characteristics of Group D Outlets
(Straub et al. 1956)

or (2) locating an exhaust or return grille adjacent to the source (more economical for cooling applications, because heat is withdrawn at its source rather than dissipated into the space). Where lighting loads are heavy (5 W/ft²) and ceilings relatively high (above 15 ft), outlets should be located below the lighting load, and the stratified warm air should be removed by an exhaust or return fan. An exhaust fan is recommended if the wet-bulb air temperature is above that of the outdoors; a return fan is recommended if the wet-bulb temperature is below this temperature. These methods reduce the requirements for supply air.

The following selection considerations for outlets in groups A through E are based on analysis of outlet performance tests conducted by Straub and Chen (1957) and Straub et al. (1956).

Group A Outlets. Outlets mounted in or near the ceiling with horizontal air discharge should not be used with temperature differentials exceeding 25°F during heating. Hart and Int-Hout (1980) and Lorch and Straub (1983) recommended that temperature differentials not exceed 15°F during heating. Consequently, these outlets should be used for heating buildings in regions where winter heating is only a minor problem and, in northern latitudes, solely for interior spaces. However, these outlets are particularly suited for cooling and can be used with high airflow rates and large temperature differentials. They are usually selected for their cooling characteristics.

Performance is affected by various factors. Vane deflection settings reduce throw and drop by changing air from a single straight jet to a wide-spreading or fanned-out jet. Accordingly, a sidewall outlet with 0° deflection has a longer throw and a greater drop than a ceiling diffuser with a single 360° angle of deflection. Sidewall grilles and similar outlets with other deflection settings may have performance characteristics between these two extremes.

Fig. 9 Air Motion Characteristics of Group E Outlets
(Straub et al. 1956)

Wide deflection settings also cause a ceiling effect, which increases throw and decreases drop. To prevent smudging, total air should be directed away from the ceiling, but this is rarely practicable, except for very high ceilings. For optimum air diffusion in areas with normal ceilings, total air should scrub the ceiling surface.

Drop increases and throw decreases with larger temperature differentials. For constant temperature differential, airflow rate affects drop more than velocity. Therefore, to avoid drop, several small outlets in a room may be better than one large outlet.

With the data in the section on Principles of Jet Behavior, throw may be selected for part of the distance between outlet and wall or, preferably, for the entire distance. For outlets in opposite walls, throw should be one-half the distance between the walls. Following these recommendations, the air drops before striking the opposite wall or the opposing airstream. To counteract specific sources of heat gain or to provide higher air motion in rooms with high ceilings, a longer throw may be necessary. In no case should the drop exceed the distance from the outlet to the 6 ft level.

To maintain maximum ventilation effectiveness with ceiling diffusers, throws should be kept as long as possible. With VAV designs, some overthrow at maximum design volumes is desirable; the highest induction can be maintained at reduced flows. Adequate induction by a ceiling-mounted diffuser prevents short-circuiting unmixed supply air between supply outlet and ceiling-mounted returns.

Group B Outlets. In selecting these outlets, it is important to provide enough throw to project air high enough for proper cooling in the occupied zone. Increased supply air velocity improves air diffusion during both heating and cooling. Also, a terminal velocity of about 150 fpm is found at the same distance from the floor during both heating and cooling. Therefore, outlets should be selected from data given in the section on Principles of Jet Behavior, with throw based on a terminal velocity of 150 fpm.

With outlets installed near the exposed wall, primary air is drawn toward the wall, resulting in a wall effect similar to the ceiling effect for ceiling outlets. This scrubbing of the wall increases heat gain or loss. To reduce scrubbing, outlets should be installed some distance from the wall, or supply air should be deflected away from the wall. However, to prevent air from dropping into the occupied zone before it reaches maximum projection, the distance should not be too large nor the angle too wide. A distance of 6 in. and an angle of 15° is satisfactory.

These outlets do not counteract natural convection currents unless they are installed in sufficient numbers around the space perimeter,

preferably in locations of greatest heat gain or loss (under windows). The effect of drapes and blinds must be considered with outlets installed near windows. Correctly installed, these outlets handle large airflow rates with uniform air motion and temperatures.

Group C Outlets. These outlets can be used for heating, even with severe heat load conditions. Higher supply velocities produce better room air diffusion than lower velocities, but velocity is not critical in selecting these units for heating.

To achieve required projection for cooling, use temperature differentials of less than 15°F. With higher temperature differentials, supply air velocity is not sufficient to project the total air up to the desired level.

These outlets have been used successfully for residential heating, but they may also offer a solution for applications where heating requirements are severe and cooling requirements are moderate. For throw, refer to the section on Principles of Jet Behavior.

Group D Outlets. These outlets direct high-velocity total air into the occupied zone, and, therefore, are not recommended for comfort, particularly for summer cooling. For heating, outlet velocities should not be higher than 300 fpm, so that air velocities in the occupied zone will not be excessive. These outlets have been applied successfully to process installations where controlled air velocities are desired.

Group E Outlets. The different throws shown in the heating and cooling diagrams for these outlets become critical in selecting and applying the outlets. Because the total air enters the occupied zone for both cooling and heating, outlets are used for either cooling or heating, but seldom for both.

During cooling, temperature differential, supply air velocity, and airflow rate strongly influence projection. Therefore, low values of each should be selected.

During heating, it is important to select the correct supply air velocity to project warm air into the occupied zone. Temperature differential is also critical because a small temperature differential reduces variation of throw during cyclic fluctuation of the supply air temperature. Vane setting for deflection is as important here as it is for group B and C outlets.

Investigations by Miller and Nevins (1969) and Nevins and Ward (1968) in full-scale interior test rooms indicate that air temperatures and velocities throughout a room cooled by a ventilating ceiling are a linear function of room load (heat load per unit area), and are not affected significantly by variations in ceiling type, total air temperature differential, or air volumetric flow rate. Higher room loading produces wider room air temperature variations and higher velocities, which decrease performance.

These studies also found no appreciable difference in the performance of air-diffusing ceilings and circular ceiling diffusers for lower room loads (20 Btu/h·ft²). For higher room loads (80 Btu/h·ft²), an air-diffusing ceiling system has only slightly larger vertical temperature variations and slightly lower room air velocities than a ceiling diffuser system.

When the ventilating ceiling is used at exterior exposures, the additional load at the perimeter must be considered. During heating, the designer must provide for the cold-wall effect (radiation, convection, and conduction loads), as with any ceiling supply distribution system. Sound generated by the air supply device must also be considered in total system analysis to ensure that room sound levels do not exceed the design criteria.

Noise. Noise generated by diffusers transmits to the occupied space directly and cannot be attenuated. Therefore, the distribution system design should meet the sound level criteria specified in Chapter 47 of the 2007 *ASHRAE Handbook—HVAC Applications*.

Inlet Selection and Location

Selection. Selection of return and exhaust inlets depends on (1) velocity in the occupied zone near the inlets, (2) permissible pressure drop through the inlets, and (3) noise.

Velocity. Airflow patterns and room air movement are not influenced by the location of return and exhaust inlets beyond a distance of one characteristic length of the return or exhaust inlet (e.g., square root of the inlet area). Air handled by the inlet approaches from all directions, and its velocity decreases rapidly as distance from the inlet increases. Therefore, drafty conditions rarely occur near return inlets.

Permissible pressure drop. Permissible pressure drop depends on the designer's choice. Proper pressure drop allowances should be made for control or directive devices.

Noise. Noise generation and transmission through return inlets should also be taken into account in space acoustical space calculations.

Location. Inlets should be located to minimize short-circuiting of supply air, although tests conducted under ASHRAE *Standard* 129 show little short circuiting with cold ceiling supply and return air. If air is supplied by jets attached to the ceiling, exhaust inlets should be located between the jets or at the side of the room, away from supply air jets. In rooms with vertical temperature stratification, such as foundries, computer rooms, theaters, bars, kitchens, dining rooms, and club rooms, exhaust inlets should be located near the ceiling to collect warm air, odors, and fumes.

For industrial rooms with gas release, selection of exhaust inlet locations depends on the density of released gases and their temperature; locations should be specified for each application.

Exhaust inlets located in walls and doors, depending on their elevation, have the characteristics of either floor or ceiling returns. In large buildings with many small rooms, return air may be brought through door grilles or door undercuts into the corridors and then to a common return or exhaust. If pressure drop through door returns is excessive, air diffusion to the room may be seriously unbalanced by opening or closing doors. Outward leakage through doors or windows cannot be counted on for dependable results.

Ceiling-Based Air Diffusion

For the best thermal comfort conditions and highest ventilation effectiveness in an occupied space (e.g., office or retail store), the entire system performance of air diffusers should be considered. This is particularly true for open spaces, where airstreams from diffusers may interact with each other, and for perimeter spaces, where airstreams from diffusers interact with hot or cold perimeter walls. Although throw data for individual diffusers are used in system design, a mixed-air distribution system should maintain a high quality of air diffusion in the occupied space with low temperature variation, good air mixing, and no objectionable drafts in the occupied space (typically 6 in. to 6 ft above the floor).

Adequate ventilation requires that the selected diffusers effectively mix (by entrainment) the total air in the room with the conditioned supply air, which is assumed to contain adequate ventilation air.

Interior Spaces. An interior space is conditioned exclusively for cooling loads, except after unoccupied periods when the space may have cooled to below a comfortable temperature. Tests by Hart and Int-Hout (1981), Miller (1979), Miller and Nash (1971), and Miller and Nevins (1970) suggest that the air diffusion performance index (ADPI) (see the section on ADPI under System Performance Evaluation) can be improved by moving diffusers closer together (i.e., specifying more diffusers for a given space and air quantity) and by limiting the supply air/room air temperature difference. In a given system of diffusers, these studies found an optimum operating range of air volumetric flow rates at a given thermal load. Operating load varies with diffuser design, ceiling height, thermal load, and diffuser orientation. This information can be obtained by constructing a mock-up representing the proposed building space, with several alternatives tested for ADPI values, in accordance with ASHRAE *Standard* 113. Usually, the diffuser manufacturer performs these tests and can provide the best choice of design options for a particular building. For a VAV system, diffuser spacing selection should

not be based on maximum or design air volumes, but rather on the air volume range in which the system is expected to operate most of the time. For VAV applications, Miller (1979) recommends that the designer consider the expected variation in outlet air volume to ensure that ADPI values remain above a specified minimum. An ADPI of 80% or greater ensures that the space complies with the ASHRAE *Standard 55* limit of 5.4°F in the occupied zone.

For an office environment in cooling mode, the design goal should be an ADPI greater than 80. The ADPI should not be used as a measure of performance for heating conditions. In both cases, ASHRAE *Standard 55* recommends that the maximum temperature gradient (the difference in temperature between any two points) should not exceed 5.4°F.

Perimeter Spaces. Modern office buildings commonly use all-air mechanical systems to handle both heating and cooling thermal loads, instead of baseboards for heating and forced air for cooling. State energy codes (most based on the ASHRAE *Standard 90* series) require that commercial buildings have exterior walls that meet minimum thermal performance criteria for a particular location. Typically, walls of new buildings have design heat losses as low as 100 to 300 Btu/h per linear foot of wall.

A successful all-air heating/cooling mechanical system requires the designer to consider several design variables (Hart and Int-Hout 1980; Lorch and Straub 1983; Rousseau 1983). The most important design variables include

- Supply air/room air temperature difference
- Diffuser type and design
- Design heating and cooling loads
- Supply air volumetric flow rates
- Distance between diffusers and perimeter wall
- Direction of air throw (toward wall, away from wall, or both)
- Ceiling height
- Desired air diffusion performance criteria

Linear diffusers placed parallel to the perimeter wall perform well. For year-round operation, linear diffusers with two-way throw (i.e., both toward and away from the perimeter wall) work best. Lorch and Straub (1983) reported optimum performance with a diffuser that throws warm air toward the perimeter wall during heating and chilled air in both directions during cooling. Performance was less than optimum with high discharge temperatures (greater than 15°F above ambient), both with one-way throw of air away from a cold wall and with one-way throw of chilled air toward the perimeter wall. During heating, the supply air temperature must be limited to avoid excessive thermal stratification. Diffusers should be located such that the published 150 fpm isothermal throw (which is typically unaffected by Δt) extends to within 4.5 ft of the floor. According to ASHRAE *Standard 62.1*, if throw does not meet this requirement, and the discharge-to-room temperature differential exceeds 15°F, the ventilation rate must be increased by 25%. Furthermore, when the room-to-discharge differential exceeds 15°F, it is unlikely that the vertical temperature limitation of ASHRAE *Standard 55* will be met. Figure 10 can be used to predict approximate vertical projection on heated and cooled jets.

To resolve any uncertainty about performance, construct a mock-up with provisions for a cold wall; several variations of the design should be tested so that the best diffuser wall spacing and supply air volumes can be selected. The ADPI, room temperature gradients, or both, measured in accordance with ASHRAE *Standard 113*, can help gage system performance.

The following principles provide the best air diffusion quality and minimum energy use:

- For cooling, return air should exhaust from a location that takes advantage of any thermal stratification design. Often, this should be a high point, to take advantage of rising warm air. Cooling supply air should be introduced as close to the heat sources as

possible. Alternatively, stratification designs may condition only part of the total space. In these cases, conditioned air is supplied and exhausted as close to the occupants as possible. In either case, comfort zone temperature gradients should be maintained within 5°F.

- For heating, thermal stratification should be discouraged. Heat should be introduced at points low in the large space. Ceiling-mounted fans may reduce stratification.

System Performance Evaluation

The object of air diffusion in warm-air heating, ventilating, and air-conditioning is to create the proper combination of temperature, humidity, and air motion in the occupied zone of the conditioned room (from the floor to 6 ft above floor level) (Miller 1989). The effective draft temperature considers the physiological effects on a human body of air temperature, air motion, and relative humidity. Variation from accepted standard limits (see ASHRAE *Standard 55*) may cause occupant discomfort. Lack of uniform conditions in the space or excessive fluctuation of conditions in the same part of the space also produces discomfort. Discomfort can be caused by any of the following conditions:

- Excessive air motion (draft)
- Excessive room air temperature variations (horizontal, vertical, or both)
- Failure to deliver or distribute air according to load requirements at different locations
- Overly rapid fluctuation of room temperature

Draft. Koestel and Tuve (1955) and Reinmann et al. (1959) defined draft as any localized feeling of coolness or warmth of any portion of the body caused by both air movement and air temperature, with humidity and radiation considered constant. The warmth or coolness of a draft was measured above or below a controlled room condition of 76°F db at the center of the room, 30 in. above the floor, with air moving at about 30 fpm.

To define the **effective draft temperature** T_{ed} (difference in temperature between any point in the occupied zone and the control condition), the investigators used the following equation proposed

Fig. 10 Approximate Downward Vertical Projection of Heated and Cooled Jets Along Perimeter Spaces

by Rydberg and Norback (1949) and modified by Straub (Straub and Chen 1957; Straub et al. 1956) in discussion of a paper by Koestel and Tuve (1955):

$$\theta_{ed} = (T_x - T_c) - 0.07(V_x - 30) \tag{15}$$

where

- θ_{ed} = effective draft temperature, °F
- T_x = local airstream dry-bulb temperature, °F
- T_c = average (control) room dry-bulb temperature, °F
- V_x = local airstream centerline velocity, fpm

Equation (15) accounts for the feeling of coolness produced by air motion and is used to establish the neutral line in Figure 11. In summer, the local airstream temperature T_x is below the control temperature T_c . Hence, both temperature and velocity terms are negative when velocity V_x is greater than 30 fpm, and they both add to the feeling of coolness. In winter, if T_x is above T_c , any air velocity above 30 fpm subtracts from the feeling of warmth produced by T_x . Therefore, it is usually possible to have zero difference in effective temperature between location x and the control point in winter, but not in summer.

Houghten et al. (1938) presented data to statistically interpret the percentage of room occupants that will object to a given draft

condition. Figure 11 presents the data in the form used by Koestel and Tuve (1955), showing that a person tolerates higher velocities and lower temperatures at ankle level than at neck level. Because of this, conditions in the zone approximately 30 to 60 in. above the floor are more critical than conditions nearer the floor.

Air Velocity. Room air velocities less than 50 fpm are generally preferred, but even higher velocities may be acceptable to some occupants (Figure 11). ASHRAE *Standard 55* recommends elevated air speeds at elevated air temperatures. No minimum air speeds are recommended for comfort, although air speeds below 20 fpm are usually imperceptible.

Air Diffusion Performance Index (ADPI). A high percentage of people are comfortable in sedentary (office) occupations when the effective draft temperature θ_{ed} , as defined in Equation (18), is between -3 and $+2^\circ\text{F}$ and the air velocity is less than 70 fpm. If several measurements of air velocity and air temperature are made throughout the occupied zone of an office, the ADPI is the percentage of measurement locations where these specifications for effective draft temperature and air velocity were met. An ADPI approaching 100% indicates the most desirable conditions (Miller 1971; Miller and Nash 1971; Miller and Nevins 1969, 1970, 1972; Nevins and Miller 1972; Nevins and Ward 1968).

The ADPI is based only on air velocity and effective draft temperature (a combination of local temperature variations from the room average) and is not directly related to dry-bulb temperature or relative humidity. These and similar effects, such as mean radiant temperature, must be accounted for separately according to ASHRAE *Standard 55*.

ADPI is applicable only for cooling-mode conditions; a measurement technique is specified in ASHRAE *Standard 113*. Heating conditions can be evaluated using ASHRAE *Standard 55* guidelines or ISO *Standard 7730*, and can also be measured using ASHRAE *Standard 113*. The ADPI can be predicted from isothermal throw data determined under ASHRAE *Standard 70* (see Table 3) to predict what will happen under cooling conditions, within the maximum range of room loads presented. These data were obtained, and are therefore most usable, in spaces with ceiling heights between 8 and 10 ft. In a room with a single diffuser, ADPI may be overly sensitive to high airflow rates, because diffuser throws wash the room's walls.

Jet Throw. The throw of a jet is the distance from the outlet to a point where the maximum velocity in the stream cross section has been reduced to a selected terminal velocity. To estimate ADPI, terminal velocity V_T was selected for all diffusers as 50 fpm, except for ceiling slot diffusers, for which it was selected as 100 fpm. Manufacturers give data for jet throw from various diffusers for isothermal conditions and without a boundary wall interfering with the jet.

The throw distance of a jet is denoted by X_{VT} , where subscript VT indicates the terminal velocity for which the throw is given. Characteristic room length L is the distance from the diffuser to the nearest boundary wall in the principle horizontal direction of the airflow. However, where air injected into the room does not impinge on a wall surface but collides with air from a neighboring diffuser, L is one-half the distance between diffusers plus the distance the mixed jet travels downward to reach the occupied zone. Table 2 defines characteristic length for various diffusers.

The midplane between diffusers also can be considered the module line when diffusers serve equal modules throughout a space, and a characteristic length consideration can be based on module dimension.

Load Considerations. Recommendations in Table 3 cover cooling loads of up to 80 Btu/h per square foot of floor surface. The loading is distributed uniformly over the floor up to about 7 Btu/h·ft², lighting contributes about 10 Btu/h·ft², and the remainder is supplied by a concentrated load against one wall that simulates a business machine or a large sun-loaded window. Over this range of data, the maximum ADPI condition is lower for the

Fig. 11 Percentage of Occupants Objecting to Drafts in Air-Conditioned Room

Table 2 Characteristic Room Length for Several Diffusers

Diffuser Type	Characteristic Length L
High sidewall grille	Distance to wall perpendicular to jet
Circular ceiling pattern diffuser	Distance to closest wall or intersecting air jet
Sill grille	Length of room in direction of jet flow
Ceiling slot diffuser	Distance to wall or midplane between outlets
Light troffer diffusers	Distance to midplane between outlets plus distance from ceiling to top of occupied zone
Cross-flow pattern ceiling diffusers	Distance to wall or midplane between outlets

Table 3 Air Diffusion Performance Index (ADPI) Selection Guide

Terminal Device	Room Load, Btu/h·ft ²	X_{50}/L for Maximum ADPI	Maximum ADPI	For ADPI Greater than	Range of X_{50}/L
High sidewall grilles	80	1.8	68	—	—
	60	1.8	72	70	1.5 to 2.2
	40	1.6	78	70	1.2 to 2.3

	11 to 50	2.0	96	80	1.0 to 3.4

highest loads; however, the optimum design condition changes only slightly with load.

Design Conditions. The quantity of air must be known from other design specifications. If it is not known, the solution must be obtained by trial and error.

The devices for which data were obtained are (1) high sidewall grilles; (2) circular pattern ceiling diffusers; (3) sill grilles; (4) two- and four-slot ceiling diffusers; (5) light troffer diffusers; and (6) square-faced one-, two-, three-, and four-jet pattern (cross-flow) ceiling diffusers. Table 3 summarizes recommendations on X_{V7}/L by giving the value of X_{50}/L at which ADPI is maximized for various loads, as well as a range of values of X_{50}/L for which ADPI is above a minimum specified value.

FULLY STRATIFIED SYSTEMS

Fully stratified air distribution systems have been used in industrial applications for many years. In the 1980s, they became a popular alternative for office and classroom HVAC in Europe, and their

popularity has recently spread to North America because of their high contaminant removal efficiencies and their possible energy savings, especially in relatively mild climates. **Thermal displacement ventilation (TDV) systems** are the most widely used variant of these systems.

The main objective of a mixed-air system is to create a homogeneous mixture of supply and room air throughout the space. Contaminants and heat are diluted and then extracted through the return inlet. TDV systems (Figure 12) do not attempt to mix heat and contaminants; instead, they allow them to escape into the upper uninhabited zone, from which they are extracted. With a TDV system, supply air is introduced directly into the occupied zone at low velocity and a temperature lower than that of room air. Contaminants and heat in the space are carried by convective flows (created by space heat sources) into the upper part of the room. Warm air in the upper zone does not recirculate into the occupied zone, so the temperature and concentration of most impurities at the exhaust inlet exceed those in the occupied zone and at the breathing level.

TDV systems offer increased ventilation effectiveness and may reduce HVAC energy consumption. Applications include classrooms, conference rooms, theaters, restaurants, supermarkets, and spaces with high ceilings (10 ft and above) (Skistad et al. 2002).

Sandberg and Blomqvist (1989) suggest that the maximum convective cooling load in office buildings with TDV not exceed about 8 Btu/h·ft², so that the maximum vertical temperature gradient in the occupied zone is not larger than 5°F. Kegel and Schulz (1989) and Svensson (1989) suggested higher cooling load limits of 10 to 13 Btu/h·ft². However, Chen and Glicksman (1999) demonstrated that cooling loads up to 40 Btu/h·ft² can be handled in the office environment if the ventilation rate is increased. Howe et al. (2003) reported successful application of TDV in a telecommunication equipment room with cooling loads up to 108 Btu/h·ft², although thermal comfort was not the primary objective of this application.

Convective Flows Associated with Space Heat Sources

Convective heat flows in the space are the driving forces behind TDV systems. When the surface temperature of a heat source exceeds that of the air surrounding it, heat is transferred to ambient air by convection. This transfer warms the air and causes it to rise because of buoyancy. These rising plumes grow as they entrain room air. Radiant heat transfer does not directly affect heat plume formation, but may indirectly influence development of other heat source plumes by raising the surface temperature of the source.

Each space heat source forms its own thermal plume. Formation of the plume and its vertical travel are determined by several factors:

- Shape and surface area of heat source
- Intensity of heat source
- Air turbulence around heat source (turbulence discourages plume formation)
- Temperature gradient in the space (affects plume volume)

The heat plume rises until it encounters ambient air of similar temperature.

The Archimedes number [Equation (15)] relates the ratio between buoyancy forces and velocity forces of the air surrounding the heat source. Larger Archimedes numbers indicate that buoyancy dominates the air behavior, whereas smaller numbers indicate that inertia (velocity) dominates. Lower Archimedes numbers in mixed-air systems usually inhibit plume formation.

Characteristics of Thermal Plumes

As a thermal plume rises because of natural convection above a heat source, it entrains surrounding air and therefore increases in size and volume, and decreases in velocity (Figure 13). The maximum height to which a plume rises depends primarily on the heat source's strength, and secondarily on stratification in the room (which decreases the rising plume's buoyancy). The **stratified zone**

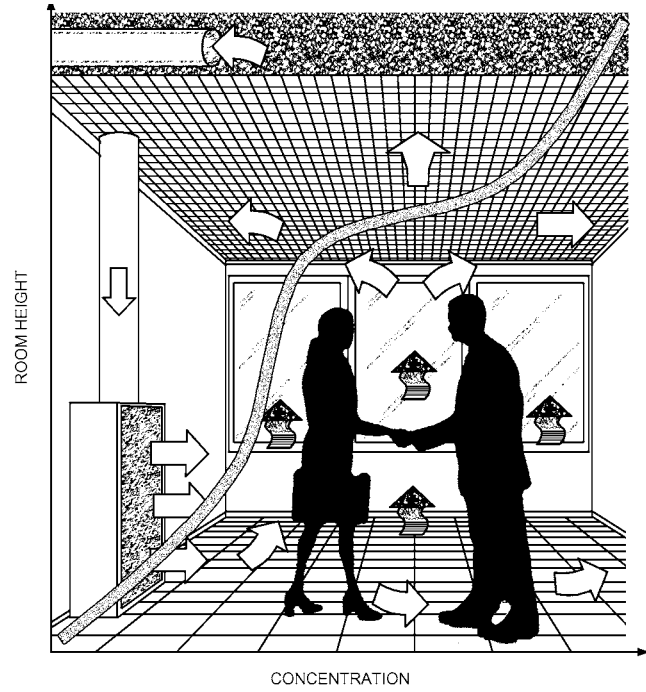

Fig. 12 Displacement Ventilation

Fig. 13 Thermal Plume from Point Source

has little or no recirculation. In this region, cool supply air gradually flows across the room in a thin layer, typically 4 to 6 in. thick. It is drawn horizontally toward the heat sources, where it joins rising air in the plumes and is entrained upward. These plumes expand and rise until they encounter equally warm air in the upper regions of the space. The **upper zone** above the stratification height is characterized by low-velocity recirculation, which produces a fairly well-mixed layer of warm air with greater contaminant concentration than that in the lower levels of the space.

Typically, warmer, more polluted air will not reenter the stratified zone. This principle is the basis for the improved ventilation effectiveness and heat removal efficiency of TDV systems. In some situations (e.g., morning start-up, winter), there are also sources of cooling in the space, such as cold perimeter windows. The resulting

Fig. 14 Schematic Diagram of Major Flow Elements in Room with Displacement Ventilation

cold downdraft may transport some air from the upper zone back down to the stratified zone. Figure 14 shows these basic elements in a simplified schematic of a TDV system. In the figure, q_0 represents the supply airflow into the room from a low sidewall diffuser, q_1 is the upward-moving airflow in thermal plumes that form above heat sources, and q_2 is the downward-moving airflow resulting from cool surfaces. In this simplified configuration, the stratification height occurs at a height SH, where the net upward moving flow $q_1 - q_2$ equals q_0 . An important objective in designing and operating a TDV system is to maintain stratification above the occupied zone.

Vertical Temperature Distribution

Thermal displacement ventilation (TDV) outlets discharge conditioned (typically 60 to 65°F) air at very low outlet velocities (less than 70 fpm). Cool air drops almost immediately to the floor, because of its negative buoyancy. The buoyancy of the supply causes it to remain near the floor until it comes into close contact with a convective heat source. The ascending plume associated with the source creates a stack effect that entrains supply air from the

Fig. 15 Vertical Temperature Gradients in Thermal Displacement System

floor. As it passes vertically over the source, the displaced supply air is warmed and becomes part of the convective plume.

Spaces conditioned by TDV systems can be categorized into two basic zones. Figure 15 illustrates a vertical temperature gradient for a TDV system applied in a space with conventional-height ceilings. In addition, the **adjacent zone** (sometimes referred to as the **near** or **clear zone**) is the portion of the space near the air outlet where horizontal velocities in excess of 40 fpm may be found. This zone is defined as the room volume bordered horizontally by the outlet and the vertical plane corresponding to the furthest extent of an isovel of 40 fpm. Stationary occupants should not normally be located in this zone, because local velocities and supply air temperatures are likely to cause draft sensations. Once the supply air is reduced to a terminal velocity of 40 fpm or less when measured 4 in. above the floor, its temperature has usually increased to a level not likely to produce draft.

Once the conditioned air mixture has passed through the adjacent zone, it pools out across the floor and only moves vertically when entrained by a convective plume associated with a space heat source. The plume rises through the naturally stratified environment (the **stratification zone**) to a level where it encounters equally warm air. The plume then dissipates horizontally across the space. The level at which this occurs is called the **stratification height (SH)**; sometimes also called the **shift height**.

Displaced heat and contaminants (whose buoyancy exceeds that of room air) pool in the space above the stratification height. This is referred to as the **upper zone**.

Contaminant Distribution

One of the key benefits of fully stratified systems is increased removal efficiency of contaminants associated with space heat sources. These contaminants are directly conveyed to the upper zone by thermal plumes associated with the heat sources.

Figure 16 illustrates how stratification height influences indoor air quality in the occupied zone for the idealized case of a TDV system serving a space with a single heat source (person) and its associated contaminant (person's breathing) (Skistad 1994). The figure shows two typical vertical profiles of pollutants (c/c_R) are plotted

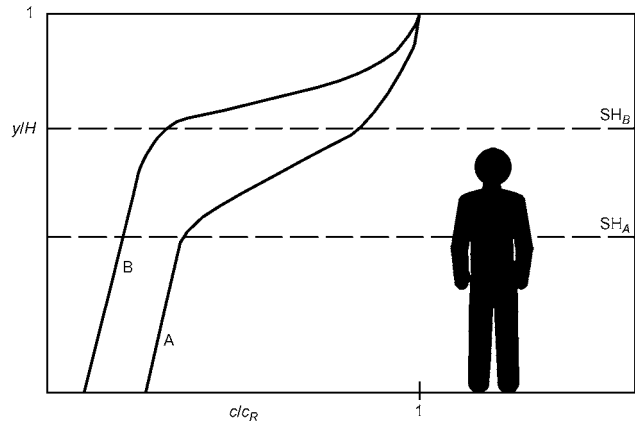

Fig. 16 Vertical Profiles of Pollutant Concentrations in Room with Displacement Ventilation

against normalized room height (y/H), where c_R is the concentration at the return grille near ceiling level and H is room height. Both profiles demonstrate how a large increase in pollutant concentration occurs at the stratification height, with cleaner, less polluted air in the stratified zone and higher pollutant concentrations in the upper zone. Profile A is produced by a lower airflow rate that results in a stratification height (SH_A) somewhat below head height of a standing occupant. By increasing the airflow rate (loads remain constant), stratification height (SH_B) is raised above head height in profile B, producing improved indoor air quality at the breathing height. Stratification height also can be locally displaced about 0.7 ft upward around a person (Nielsen 1996). This represents the entrainment of cleaner air from lower levels in the room by the thermal plume rising around a person up to their breathing height.

Design Methods

Depending on space requirements, there are two options for design. **Temperature-based design** is used when heat removal is the main objective (e.g., in schools, offices, auditoriums, sport facilities). The **shift-zone method** is used when contaminants should be considered, such as in smoking rooms and other facilities with gaseous contaminants (lighter than air or of the same density as air) associated with convective plumes from heat sources. Whereas the objective of the temperature-based method is simply to satisfy temperature conditions in the occupied zone, shift-zone design also seeks to stratify contaminants by maintaining the stratification height above the occupants' breathing level.

Design methods for TDV systems are addressed in Chapter 56 of the 2007 *ASHRAE Handbook—HVAC Applications*.

Ventilation and Heating

Skistad et al. (2002) reported that displacement ventilation can be combined successfully with radiators and convectors at exterior walls to offset space heat losses. Radiant heating panels and heated floors also can be used with displacement ventilation. When the secondary heating system is used, displacement diffusers supply air at 4°F lower than room air temperature. In that case, displacement ventilation performs the same way as in cooling mode and all the benefits associated with better indoor air quality are preserved.

When warm air is supplied through displacement outlets, the system's performance is similar to that of a mixed-air system in heating mode.

Outlet Types

Outlets in TDV systems are designed to limit outlet velocities to about 70 fpm or less. This results in supply airflow capacities of typically 50 to 70 cfm per square foot of discharge area. Therefore,

outlets used in TDV systems tend to be large compared to those used for mixed-air systems. Properly designed TDV outlets also incorporate provisions that create an equal distribution of supply air across their face to minimize discharge velocity variations. Equally distributing flow across the discharge area reduces the length of the outlet's adjacent zone.

TDV system outlets are available in various geometries and capacities. They may be mounted flush in a partition wall, either contained within the wall or extending into a mechanical space behind it. They are also often mounted adjacent to the partition wall (with either a 90° or 180° discharge pattern) or in a corner (with a quarter round discharge pattern). Others are free-standing and column-shaped, with a full radial discharge pattern.

Because TDV outlets discharge the air at such low velocities, they impart very little directional guidance to the supply airstream. This allows them to be mounted behind architectural elements such as louvers or screens and remain visually unobtrusive.

Floor diffusers that discharge supply air horizontally at low air-flow rates can be used to create a fully stratified room environment. Floor diffusers with vertical discharge of turbulent air jets do not create such conditions, and are covered in the section on Partially Mixed Systems.

Much smaller versions of TDV outlets are used for underseat supply in public assembly (theaters, lecture halls, sports arenas, etc.) HVAC applications. These outlets are generally designed for much lower individual supply airflow capacities, and typically use warmer supply air. They may have internal mixing devices to help reduce their adjacent zone length.

Outlet Selection and Location

TDV outlets should be selected and located so that stationary space occupants are not located within their adjacent zone where draft risks are high. The low discharge velocities of TDV terminals create very little noise and thus are only of concern in very sensitive acoustical applications. System noise (noise from fans, dampers, ductwork, etc.) should be considered, however, because it is transmitted with the supply airflow.

Return Inlet Selection and Location

TDV return air inlets used should conform to the same requirements as those for mixed-air systems. They should always be located above the occupied zone, and should be provided within any confined space served by a TDV supply air terminal.

System Performance Evaluation

The primary comfort criterion of TDV systems is maintaining the design room air temperature (usually specified at the head level of the predominant space occupants) while limiting the vertical temperature difference between occupants' ankle and head levels to no more than 5.4°F. Because velocities in the occupied zone are very low, they are of minimal concern. Additional information may be found in ASHRAE *Standard* 113.

ADPI should not be used to evaluate fully stratified systems, because it essentially measures the degree of mixing achieved by the room air distribution system. A fully mixed environment would have the highest ADPI rating.

PARTIALLY MIXED SYSTEMS

Partially mixed room air distribution systems used for space cooling generally discharge conditioned air from a low sidewall or floor location, and the diffuser discharge turbulence is considerably greater than in fully stratified (TDV) systems. This creates a zone of high entrainment near the plane of discharge. A common example of partially mixed systems is **underfloor air distribution (UFAD) systems**.

UFAD systems differ from TDV systems primarily in the way air is delivered to the space: (1) air is supplied at higher velocities

Fig. 17 Underfloor Air Distribution System with Diffuser Throw below Stratification Height

through smaller supply outlets, and (2) local air supply conditions are generally under the control of occupants, allowing comfort conditions to be optimized. By introducing supply air with greater momentum, UFAD systems alter conditions in the lower region of the space by increasing the amount of mixing and reducing the temperature gradient. At higher elevations in the room, above the influence of supply outlets, overall airflow performance is similar to that of TDV systems. Based on recent experimental results (Webster et al. 2002a, 2002b; Yamanaka et al. 2002) and an extension of displacement theory, three distinct zones in the room can be used to describe the room air diffusion for UFAD systems.

Figure 17 shows a schematic of typical airflow patterns in an UFAD system in an office environment. The diagram identifies two characteristic heights in the room that define the three zones in the room: (1) the throw height (X_{50}) of the floor diffusers, and (2) the stratification height (SH), similar to that found in TDV systems. As shown, UFAD diffusers typically create adjacent zones that have excessive draft and cool temperatures, making long-term occupancy not recommended. When under direct individual control by the occupant, however, these local thermal conditions may be acceptable, and even desirable. Increased mixing in the occupied zone diminishes ventilation effectiveness, compared to TDV systems. In any case, control and optimization of stratification is crucial to system design and sizing, energy-efficient operation, and comfort performance of UFAD systems.

Figure 18 compares typical vertical temperature profiles for UFAD, TDV, and conventional overhead mixing systems. The profiles shown are representative of normal operating conditions and are intended to demonstrate key differences and similarities between the three air distribution systems. The UFAD profile is based on temperatures in a space outside the direct influence of supply outlets (outside adjacent zones), and can vary significantly depending on several control factors (see the section on Controlling Stratification) (Webster et al. 2002a). In Figure 18, the nondimensional temperature (temperature ratio) is plotted versus room height, where T_H is room air temperature as a function of height, T_S is supply temperature, and T_E is temperature at the ceiling. The linear profile for TDV systems is based on the 50% rule of thumb that applies to rooms of conventional height and normal heating loads (Skistad 1994); the temperature near the floor is assumed to be halfway between the supply and exhaust temperatures. The TDV profile is assumed to join the UFAD profile at the stratification height. As long as the throw heights of the UFAD diffusers are below the stratification height, the upper zone is assumed to perform in a similar manner for both systems (for the same room-load-to-supply-volume ratio). The fully mixed system profile represents a uniformly mixed room with the temperature equal to the exhaust temperature.

Fig. 18 Comparison of Typical Vertical Temperature Profiles for Underfloor Air Distribution, Displacement Ventilation, and Mixing Systems

Lower (Mixed) Zone

The lower zone is directly adjacent to the floor and varies in depth according to the vertical projection of the floor-based supply outlets used. The air in this layer is relatively well mixed because of the influence of high-velocity jets near the supply air outlets. The upper boundary of the lower zone coincides with the elevation at which supply air reaches a terminal velocity of around 50 fpm. The greater mixing in this zone increases the temperature ratio near floor to about 0.7, and reduces the gradient in comparison to TDV systems. The lower zone always exists, although its height may vary greatly depending on the vertical projection of supply outlets and the ratio of space heat load to supply airflow.

Stratified Zone

The stratified zone is a transition region between the lower and upper zones. Air movement in this zone is entirely buoyant, driven by rising thermal plumes around convective space heat sources. Formation of these plumes is uninhibited in this region, because air movement is not affected by supply air jets. Therefore, the vertical temperature gradient in this zone tends to be greatest, approaching that for TDV systems. The stratified zone only exists when the throw height of supply outlets is below the stratification height.

Upper (Mixed) Zone

The upper zone comprises warm (contaminated) air deposited by rising heat plumes within the space. Although its average air velocities are generally quite low, air in this zone is relatively well mixed as a result of the momentum of thermal plumes penetrating its lower boundary. This zone is analogous to the upper zone found in spaces served by TDV systems. Its bottom boundary, coincident with the stratification height, is primarily a function of the ratio of space heat load to supply airflow rate. If jets from supply outlets penetrate this zone, its depth (or even existence) may be affected, though, if properly controlled, this may be a secondary effect (Figure 19).

Temperature Near Floor

As shown in Figure 18, the greater mixing provided by turbulent supply outlets used in UFAD systems increases the temperature near the floor compared to TDV systems (for the same supply air temperature and volume). This effect is shown more clearly in Figure 20, which plots the nondimensional temperature near the floor as a function of overall room airflow rate, where T_F is the tempera-

Fig. 20 Nondimensional Temperature near Floor Versus Room Airflow Rate

Experimental UFAD data taken from Webster et al. (2002a); TDV results from Mundt (1990).

ture near the floor, T_S is the supply temperature at the floor, and T_e is the temperature at the ceiling. Measurement heights for T_F are in the range of 3 to 4 in. Experimental data for both swirl and variable-area floor diffusers are taken from Webster et al. (2002a). The curve for TDV systems is based on numerous measurements in different rooms (Mundt 1990).

Stratification Height

If vertical throw is equal to or less than the stratification height (see Figure 17), the only airflow crossing it will be from buoyancy effects, similar to TDV systems. As throw and mixing are reduced, UFAD systems tend to approach the operation of TDV systems. If throw height is close to or greater than the stratification height, cooler supply air penetrates the warmer upper layer before dropping back down into the lower region, bringing warm air with it (see Figure 19). Although a subject of ongoing research, recent results indicate that, as long as diffuser throw does not penetrate too far into the upper zone (up to 7 ft in a 10 ft high room), relatively similar comfort conditions are produced in the occupied zone, compared to diffusers with lower throws (Webster et al. 2002a).

The amount of air brought down influences temperatures in the lower region, and can also increase stratification height, but this is a secondary effect. Higher throws that penetrate the stratification height result in slightly warmer temperatures and a smaller gradient in the lower region.

When a very strong supply air jet penetrates far into the upper zone, it is possible to disrupt the stratified airflow pattern. For example, laboratory experiments (Bauman et al. 1991; Fisk et al. 1991) demonstrated that, when a fan-driven floor supply module was operated at higher air supply volumes, cool supply jets were

Fig. 21 Effect of Room Airflow Variation at Constant Heat Input, Swirl Diffusers, Interior Zone

able to reach the ceiling, thereby minimizing stratification and producing close to uniform ventilation conditions. This operating strategy of providing a well-mixed space reduces or eliminates the potential improvements in energy and ventilation performance described. To avoid eliminating a stratified space with UFAD systems, maximum vertical throws of diffusers should be limited to no closer than 2 to 3 ft from the ceiling.

Controlling Stratification

Laboratory experiments have investigated the thermal stratification performance of UFAD systems using floor diffusers (Webster et al. 2002a, 2002b). Figure 21 shows the effect of variations in total room airflow on stratification for swirl diffusers operating in a simulated interior space with total heat input of 18 Btu/h·ft² and a supply air temperature of 64°F. For constant heat input, stratification increases when room airflow is reduced. Figure 21 also demonstrates how a control strategy might optimize stratification performance. At the highest flow rate of 1 cfm/ft², the temperature profile exhibits only a small amount of stratification, with a head/foot temperature difference of 1.3°F. This represents a case where the space is overventilated. On the other hand, at the lowest flow rate of 0.3 cfm/ft², the head/foot temperature difference increases to 6.8°F, exceeding the limit of 5.4°F specified in ASHRAE *Standard* 55. This temperature profile demonstrates the sensitivity to changes in airflow rate, although it is highly unlikely that a system with cooling loads of this magnitude would be operated at such a low airflow rate. To improve energy performance (reduce airflow) while maintaining thermal comfort (avoiding excessive stratification), the middle profile at a flow rate of 0.6 cfm/ft² may be a reasonable target, because it has a head/foot temperature difference of 3.2°F. The difference between the middle and first profiles also demonstrates that, despite a 40% reduction in airflow rate, the temperature in the space only increases by about 1°F up to a height of nearly 4 ft.

Heating Systems

In most applications, heating is primarily needed only near the building envelope, where heat loss to the outdoors can cool spaces and may cause discomfort. Heating may also be needed in some top-floor interior zones and during periods of low occupancy (e.g., nights and weekends).

In operation, delivering warm air from rapidly mixing diffusers near floor level is very effective at providing heat to the conditioned space. Because of buoyancy, the characteristic thermal stratification obtained in cooling operation is replaced with a well-mixed, uniform temperature distribution. Heating load calculation can therefore use the same methods as for conventional overhead air distribution systems.

Effective heating systems isolate the source of warm air from the thermal lag effect of the concrete slab (which is usually slightly

cooler than room temperature). This can be done, for example, by ducting from an underfloor fan-coil unit, or by using baseboard radiation or convection units. Quick response on heating can be very important during morning start-up, particularly if night setback is used.

Outlets Types

Partially mixed systems use a wide variety of outlet types, because they are designed to promote mixing in a designated portion of the space. Most partially mixed systems are floor based, however, and those are the types discussed here.

Floor-based outlets used in partially mixed air distribution systems may be classified as passive or active. **Passive** diffusers are installed in the plenum under the raised access floor in UFAD systems. They are not directly ducted to either the conditioned air source or a fan-assisted terminal in the floor plenum. Instead, their supply airflow rate depends on the pressure in the raised-floor plenum that delivers the HVAC service. **Active** diffusers are connected to either a supply air duct or a fan-assisted terminal.

Both passive and active diffusers can be operated with constant or variable air volume. The supply airflow rate in variable-air-volume diffusers can be either automatically reset in response to a control signal, or manually adjusted by space occupants.

High-induction swirl diffusers are the most common type of UFAD supply air outlet. The swirling air pattern provides rapid mixing of supply air with room air up to the height of the diffuser's vertical throw. Although the discharge pattern for most swirl diffusers is not adjustable, occupants have limited control of the delivered air volume by rotating the face of the diffuser or opening the diffuser and adjusting a volume control damper. The maximum flow rate for most passive swirl diffusers operated at typical UFAD plenum pressures is about 100 cfm at 0.08 in. of water. Most are equipped with a catch basin for dirt and liquid spills.

Linear bar diffusers are also commonly used in UFAD systems. They are often used as active diffusers (supplied by fan-assisted terminals with reheat provisions) for heating and/or cooling perimeter zones adjacent to exterior windows. They may also be used as passive diffusers to supply cooling directly from the pressurized floor plenum. In the latter case, their cooling delivery is usually variable volume and is automatically modulated in accordance with the space thermostat demand.

Passive floor diffusers may also be configured as variable-air-volume diffusers, requiring control and power connections to automatically adjust an integral volume control damper. These terminals may either deliver supply airflow in proportion to a space thermostat signal or use pulse-width modulation to constantly reset an inlet damper from fully open to fully closed (two-position operation). In the latter case, air is supplied through a slotted square floor grill in a jet-type airflow pattern. Occupants can adjust supply jet direction by changing the grille's orientation.

Plenum boxes with integral airflow dampers can also be used to provide automatic variable volume through UFAD floor diffusers. These can be either passive or active in operation, depending on whether they are fan assisted or directly supplied by the pressurized floor plenum.

Outlet Selection and Location

Outlets used in partially mixed air distribution systems should be located such that stationary occupants are not within their prescribed adjacent zone. Outlets that are intended to be manually adjustable by space occupants should be located within a few feet of the occupants.

Return Inlet Selection and Location

As in fully stratified systems, return inlets in partially mixed systems should be located above the occupied zone. These inlets should be of sufficient size to result in inlet velocities no greater than

Fig. 22 Underfloor TAC and Personal HVAC System
(Matsunawa et al. 1995)

500 fpm, and should be located in every confined space with a supply air outlet.

System Performance Evaluation

The primary comfort criterion of UFAD systems is maintenance of the design room air temperature (usually specified at the head level of the predominant space occupants) while limiting the vertical temperature difference between occupants' ankle and head levels to no more than 5.4°F. Because velocities in the occupied zone are very low, they are of minimal concern. Additional information may be found in ASHRAE *Standard* 113.

ADPI should not be used to evaluate partially mixed systems, because it essentially measures the degree of mixing achieved by the room air distribution system. A fully mixed environment would have the highest ADPI rating.

TASK/AMBIENT CONDITIONING (TAC)

Task/ambient conditioning (TAC) is most commonly installed with underfloor air distribution (Arens et al. 1991; Bauman and Arens 1996; Bauman et al. 1991, 1993, 1995, 1998; Faulkner et al. 1993, 1999; Fisk et al. 1991; Matsunawa et al. 1995; Tsuzuki et al. 1999). TAC gives individuals some control over their local environment without adversely affecting that of nearby occupants. Typically, the occupant can control the speed, direction, and, in some cases, temperature of supply air. TAC systems are most frequently installed in open-plan offices to provide supply air and, in some cases, radiant heating directly into workstations. Figure 22 shows an underfloor TAC system with a local (personal HVAC) diffuser located in the partition in front of the office worker (Matsunawa et al. 1995).

Bauman et al. (1998) and de Dear and Brager (1999) found that building occupants who have no individual control capabilities are twice as sensitive to changes in temperature as occupants who do have individual thermal control.

SYMBOLS

A_c	= measured gross (core) area of outlet, ft ²
A_o	= core area or neck area, ft ²
A_R	= cross-sectional area of confined space normal to jet, ft ²
Ar	= Archimedes number [Equation (12)]
c	= pollutant concentration
C_d	= discharge coefficient (usually between 0.65 and 0.90)
c_R	= concentration of pollutant at return grille near ceiling level
g	= gravitational acceleration rate, ft/min ²
H	= height or width of slot (Table 2), or of room
H_o	= width of jet at outlet or at vena contracta, ft

H_s	= width of slot, ft
K_c	= centerline velocity constant
L	= characteristic length, ft
L_o	= length scale of diffuser outlet equal to hydraulic diameter of outlet, ft
ΔP	= diffuser static pressure drop, in. of water
Q_o	= discharge from outlet, cfm
Q_x	= total volumetric flow rate at distance X from face of outlet, cfm
r	= radial distance of point under consideration from centerline of jet
$r_{0.5V}$	= radial distance in same cross-sectional plane from axis to point where velocity is one-half centerline velocity (i.e., $V = 0.5V_x$)
R_{fa}	= ratio of free area to gross (core) area
SH	= stratification height
T	= average absolute room temperature, °R
ΔT	= room/jet temperature difference, °F
T_A	= temperature of ambient air, °F
T_c	= average (control) room dry-bulb temperature, °F
T_E	= temperature at ceiling, °F
T_F	= temperature near floor, °F
T_H	= temperature at given height, °F
T_O	= initial temperature of jet, °F
T_S	= supply temperature, °F
T_x	= local airstream dry-bulb temperature, °F
V	= actual velocity at point being considered
V_c	= nominal velocity of discharge based on core area, fpm
V_o	= initial air velocity of jet, fpm
V_T	= terminal velocity, fpm
V_x	= centerline velocity, fpm
X	= distance from face of outlet to location of centerline velocity V_x , ft
$X_{attached}$	= throw distance of attached jet, ft
X_{free}	= throw distance of free jet, ft
X_H	= throw height from floor outlet, ft
X_{VT}	= distance to given terminal velocity, ft
θ_{ed}	= effective draft temperature, °F

--	---

COMMERCIAL, industrial, and residential air duct system design must consider (1) space availability, (2) space air diffusion, (3) noise levels, (4) air distribution system (duct and equipment), (5) duct heat gains and losses, (6) balancing, (7) fire and smoke control, (8) initial investment cost, and (9) system operating cost.

Deficiencies in duct design can result in systems that operate incorrectly or are expensive to own and operate. Poor design or lack of system sealing can produce inadequate airflow rates at the terminals, leading to discomfort, loss of productivity, and even adverse health effects. Lack of sound attenuation may lead to objectionable noise levels. Proper duct insulation eliminates excessive heat gain or loss.

In this chapter, system design and calculation of a system's frictional and dynamic resistance to airflow are considered. Chapter 18 of the 2008 *ASHRAE Handbook—HVAC Systems and Equipment* examines duct construction and presents construction standards for residential, commercial, and industrial HVAC and exhaust systems.

BERNOULLI EQUATION

The Bernoulli equation can be developed by equating the forces on an element of a stream tube in a frictionless fluid flow to the rate of momentum change. On integrating this relationship for steady flow, the following expression (Osborne 1966) results:

$$\frac{v^2}{2g_c} + \int \frac{dP}{\rho} + \frac{gz}{g_c} = \text{constant, ft} \cdot \text{lb}_f / \text{lb}_m \quad (1)$$

where

- v = streamline (local) velocity, fps
- g_c = dimensional constant, 32.2 lb_m · ft/lb_f · s²
- P = absolute pressure, lb_f/ft²
- ρ = density, lb_m/ft³
- g = acceleration caused by gravity, ft/s²
- z = elevation, ft

Assuming constant fluid density in the system, Equation (1) reduces to

$$\frac{v^2}{2g_c} + \frac{P}{\rho} + \frac{gz}{g_c} = \text{constant, ft} \cdot \text{lb}_f / \text{lb}_m \quad (2)$$

Although Equation (2) was derived for steady, ideal frictionless flow along a stream tube, it can be extended to analyze flow through ducts in real systems. In terms of pressure, the relationship for fluid resistance between two sections is

$$\frac{\rho_1 V_1^2}{2g_c} + P_1 + \frac{g}{g_c} \rho_1 z_1 = \frac{\rho_2 V_2^2}{2g_c} + P_2 + \frac{g}{g_c} \rho_2 z_2 + \Delta p_{t,1-2} \quad (3)$$

where

V = average duct velocity, fps

$\Delta p_{t,1-2}$ = total pressure loss caused by friction and dynamic losses between sections 1 and 2, lb_f/ft²

In Equation (3), V (section average velocity) replaces v (streamline velocity) because experimentally determined loss coefficients allow for errors in calculating $v^2/2g_c$ (velocity pressure) across streamlines.

On the left side of Equation (3), add and subtract p_{z1} ; on the right side, add and subtract p_{z2} , where p_{z1} and p_{z2} are the values of atmospheric air at heights z_1 and z_2 . Thus,

$$\begin{aligned} \frac{\rho_1 V_1^2}{2g_c} + P_1 + (p_{z1} - p_{z1}) + \frac{g}{g_c} \rho_1 z_1 \\ = \frac{\rho_2 V_2^2}{2g_c} + P_2 + (p_{z2} - p_{z2}) + \frac{g}{g_c} \rho_2 z_2 + \Delta p_{t,1-2} \end{aligned} \quad (4)$$

Atmospheric pressure at any elevation (p_{z1} and p_{z2}) expressed in terms of the atmospheric pressure p_a at the same datum elevation is given by

$$p_{z1} = p_a - \frac{g}{g_c} \rho_a z_1 \quad (5)$$

$$p_{z2} = p_a - \frac{g}{g_c} \rho_a z_2 \quad (6)$$

Substituting Equations (5) and (6) into Equation (4) and simplifying yields the total pressure change between sections 1 and 2. Assume no temperature change between sections 1 and 2 (no heat exchanger within the section); therefore, $\rho_1 = \rho_2$. When a heat exchanger is located in the section, the average of the inlet and outlet temperatures is generally used. Let $\rho = \rho_1 = \rho_2$. ($P_1 - p_{z1}$) and ($P_2 - p_{z2}$) are gage pressures at elevations z_1 and z_2 .

$$\Delta p_{t,1-2} = \left(p_{s,1} + \frac{\rho V_1^2}{2} \right) - \left(p_{s,2} + \frac{\rho V_2^2}{2} \right) + g(\rho_a - \rho)(z_2 - z_1) \quad (7a)$$

$$\Delta p_{t,1-2} = \Delta p_t + \Delta p_{se} \quad (7b)$$

$$\Delta p_t = \Delta p_{t,1-2} + \Delta p_{se} \quad (7c)$$

where

$p_{s,1}$ = static pressure, gage at elevation z_1 , lb_f/ft²

The preparation of this chapter is assigned to TC 5.2, Duct Design.

- $p_{s,2}$ = static pressure, gage at elevation z_2 , lb_f/ft^2
 V_1 = average velocity at section 1, fps
 V_2 = average velocity at section 2, fps
 ρ_a = density of ambient air, lb_m/ft^3
 ρ = density of air or gas in duct, lb_m/ft^3
 Δp_{se} = thermal gravity effect, lb_f/ft^2
 Δp_t = total pressure change between sections 1 and 2, lb_f/ft^2
 $\Delta p_{t,1-2}$ = total pressure loss caused by friction and dynamic losses between sections 1 and 2, lb_f/ft^2

HEAD AND PRESSURE

The terms **head** and **pressure** are often used interchangeably; however, head is the height of a fluid column supported by fluid flow, whereas pressure is the normal force per unit area. For liquids, it is convenient to measure head in terms of the flowing fluid. With a gas or air, however, it is customary to measure pressure on a column of liquid.

Static Pressure

The term $\rho g_c/\rho g$ is static head; p is static pressure.

Velocity Pressure

The term $V^2/2g$ refers to velocity head, and $\rho V^2/2g_c$ refers to velocity pressure. Although velocity head is independent of fluid density, velocity pressure [Equation (8)] is not.

$$p_v = \rho(V/1097)^2 \quad (8)$$

where

- p_v = velocity pressure, in. of water
 V = fluid mean velocity, fpm
 1097 = conversion factor to in. of water

For air at standard conditions ($0.075 \text{ lb}_m/\text{ft}^3$), Equation (8) becomes

$$p_v = (V/4005)^2 \quad (9)$$

where $4005 = (1097^2/0.075)^{1/2}$. Velocity is calculated by

$$V = Q/A \quad (10)$$

where

- Q = airflow rate, cfm
 A = cross-sectional area of duct, ft^2

Total Pressure

Total pressure is the sum of static pressure and velocity pressure:

$$p_t = p_s + \rho(V/1097)^2 \quad (11)$$

or

$$p_t = p_s + p_v \quad (12)$$

where

- p_t = total pressure, in. of water
 p_s = static pressure, in. of water

Pressure Measurement

The range, precision, and limitations of instruments for measuring pressure and velocity are discussed in Chapter 36. The manometer is a simple and useful means for measuring partial vacuum and low pressure. Static, velocity, and total pressures in a duct system relative to atmospheric pressure can be measured with a pitot tube connected to a manometer. Pitot tube construction and locations for traversing round and rectangular ducts are presented in Chapter 36.

SYSTEM ANALYSIS

The total pressure change caused by friction, fittings, equipment, and net **thermal gravity effect (stack effect)** for each section of a duct system is calculated by the following equation:

$$\Delta p_{t_i} = \Delta p_{f_i} + \sum_{j=1}^m \Delta p_{ij} + \sum_{k=1}^n \Delta p_{ik} - \sum_{r=1}^{\lambda} \Delta p_{se_{ir}} \quad (13)$$

for $i = 1, 2, \dots, n_{up} + n_{dn}$

where

- Δp_{t_i} = net total pressure change for i -section, in. of water
 Δp_{f_i} = pressure loss due to friction for i -section, in. of water
 Δp_{ij} = total pressure loss due to j -fittings, including fan system effect (FSE), for i -section, in. of water
 Δp_{ik} = pressure loss due to k -equipment for i -section, in. of water
 $\Delta p_{se_{ir}}$ = thermal gravity effect due to r -stacks for i -section, in. of water
 m = number of fittings within i -section
 n = number of equipment within i -section
 λ = number of stacks within i -section
 n_{up} = number of duct sections upstream of fan (exhaust/return air subsystems)
 n_{dn} = number of duct sections downstream of fan (supply air subsystems)

From Equation (7), the thermal gravity effect for each nonhorizontal duct with a density other than that of ambient air is determined by the following equation:

$$\Delta p_{se} = 0.192(\rho_a - \rho)(z_2 - z_1) \quad (14)$$

where

- Δp_{se} = thermal gravity effect, in. of water
 z_1 and z_2 = elevation from datum in direction of airflow (Figure 1), ft
 ρ_a = density of ambient air, lb_m/ft^3
 ρ = density of air or gas within duct, lb_m/ft^3
 0.192 = conversion factor to in. of water

Example 1. For Figure 1, calculate the thermal gravity effect for two cases: (a) air cooled to -30°F , and (b) air heated to 1000°F . Density of air at -30°F is $0.0924 \text{ lb}_m/\text{ft}^3$ and at 1000°F is $0.0271 \text{ lb}_m/\text{ft}^3$. Density of ambient air is $0.075 \text{ lb}_m/\text{ft}^3$. Stack height is 40 ft.

Solution:

$$\Delta p_{se} = 0.192(\rho_a - \rho)z$$

(a) For $\rho > \rho_a$ (Figure 1A),

$$\Delta p_{se} = 0.192(0.075 - 0.0924)40 = -0.13 \text{ in. of water}$$

(b) For $\rho < \rho_a$ (Figure 1B),

$$\Delta p_{se} = 0.192(0.075 - 0.0271)40 = +0.37 \text{ in. of water}$$

Example 2. Calculate the thermal gravity effect for the two-stack system shown in Figure 2, where the air is 250°F and stack heights are 50 and 100 ft. Density of 250°F air is $0.0558 \text{ lb}_m/\text{ft}^3$; ambient air is $0.075 \text{ lb}_m/\text{ft}^3$.

Solution:

$$\Delta p_{se} = 0.192(0.075 - 0.0558)(100 - 50) = 0.18 \text{ in. of water}$$

For the system shown in Figure 3, the direction of air movement created by the thermal gravity effect depends on the initiating force (e.g., fans, wind, opening and closing doors, turning equipment on and off). If for any reason air starts to enter the left stack (Figure 3A), it creates a buoyancy effect in the right stack. On the other hand, if flow starts to enter the right stack (Figure 3B), it creates a buoyancy effect in the left stack. In both cases, the produced thermal gravity effect is stable and depends on stack height and magnitude

Fig. 1 Thermal Gravity Effect for Example 1

Fig. 2 Multiple Stacks for Example 2

Fig. 3 Multiple Stack Analysis

Fig. 4 Illustrative 6-Path, 9-Section System

of heating. The starting direction of flow is important when using natural convection for ventilation.

To determine the fan total pressure requirement for a system, use the following equation:

$$P_t = \sum_{i \in F_{up}} \Delta p_{t_i} + \sum_{i \in F_{dn}} \Delta p_{t_i} \quad \text{for } i = 1, 2, \dots, n_{up} + n_{dn} \quad (15)$$

where

- F_{up} and F_{dn} = sets of duct sections upstream and downstream of fan
- P_t = fan total pressure, in. of water
- ε = symbol that ties duct sections into system paths from exhaust/return air terminals to supply terminals

Figure 4 illustrates the use of Equation (15). This system has three supply and two return terminals consisting of nine sections connected in six paths: 1-3-4-9-7-5, 1-3-4-9-7-6, 1-3-4-9-8, 2-4-9-7-5, 2-4-9-7-6, and 2-4-9-8. Sections 1 and 3 are unequal area; thus, they are assigned separate numbers in accordance with the rules for identifying sections (see step 4 in the section on HVAC Duct Design Procedures). To determine the fan pressure requirement, apply the following six equations, derived from Equation (15).

These equations must be satisfied to attain pressure balancing for design airflow. Relying entirely on dampers is not economical and may create objectionable flow-generated noise.

$$\begin{cases} P_t = \Delta p_1 + \Delta p_3 + \Delta p_4 + \Delta p_9 + \Delta p_7 + \Delta p_5 \\ P_t = \Delta p_1 + \Delta p_3 + \Delta p_4 + \Delta p_9 + \Delta p_7 + \Delta p_6 \\ P_t = \Delta p_1 + \Delta p_3 + \Delta p_4 + \Delta p_9 + \Delta p_8 \\ P_t = \Delta p_2 + \Delta p_4 + \Delta p_9 + \Delta p_7 + \Delta p_5 \\ P_t = \Delta p_2 + \Delta p_4 + \Delta p_9 + \Delta p_7 + \Delta p_6 \\ P_t = \Delta p_2 + \Delta p_4 + \Delta p_9 + \Delta p_8 \end{cases} \quad (16)$$

Example 3. For Figures 5A and 5C, calculate the thermal gravity effect and fan total pressure required when the air is cooled to -30°F . The heat exchanger and ductwork (section 1 to 2) total pressure losses are 0.70 and

0.28 in. of water respectively. Density of -30°F air is $0.0924 \text{ lb}_m/\text{ft}^3$; ambient air is $0.075 \text{ lb}_m/\text{ft}^3$. Elevations are 70 and 10 ft.

Solution:

(a) For Figure 5A (downward flow),

$$\begin{aligned} \Delta p_{se} &= 0.192(\rho_a - \rho)(z_2 - z_1) \\ &= 0.192(0.075 - 0.0924)(10 - 70) \\ &= 0.20 \text{ in. of water} \end{aligned}$$

$$\begin{aligned} P_t &= \Delta p_{t,3-2} - \Delta p_{se} \\ &= (0.70 + 0.28) - (0.20) \\ &= 0.78 \text{ in. of water} \end{aligned}$$

(b) For Figure 5C (upward flow),

$$\begin{aligned} \Delta p_{se} &= 0.192(\rho_a - \rho)(z_2 - z_1) \\ &= 0.192(0.075 - 0.0924)(70 - 10) \\ &= -0.20 \text{ in. of water} \end{aligned}$$

$$\begin{aligned} P_t &= \Delta p_{t,3-2} - \Delta p_{se} \\ &= (0.70 + 0.28) - (-0.20) \\ &= 1.18 \text{ in. of water} \end{aligned}$$

Example 4. For Figures 5B and 5D, calculate the thermal gravity effect and fan total pressure required when air is heated to 250°F . Heat exchanger and ductwork (section 1 to 2) total pressure losses are 0.70 and 0.28 in. of water, respectively. Density of 250°F air is $0.0558 \text{ lb}_m/\text{ft}^3$; ambient air is $0.075 \text{ lb}_m/\text{ft}^3$. Elevations are 70 and 10 ft.

Solution:

(a) For Figure 5B (downward flow),

$$\begin{aligned} \Delta p_{se} &= 0.192(\rho_a - \rho)(z_2 - z_1) \\ &= 0.192(0.075 - 0.0558)(10 - 70) \\ &= -0.22 \text{ in. of water} \end{aligned}$$

$$\begin{aligned} P_t &= \Delta p_{t,3-2} - \Delta p_{se} \\ &= (0.70 + 0.28) - (-0.22) \\ &= 1.20 \text{ in. of water} \end{aligned}$$

(b) For Figure 5D (upward flow),

$$\begin{aligned} \Delta p_{se} &= 0.192(\rho_a - \rho)(z_2 - z_1) \\ &= 0.192(0.075 - 0.0558)(70 - 10) \\ &= 0.22 \text{ in. of water} \end{aligned}$$

DOWNWARD FLOW

UPWARD FLOW

Fig. 5 Single Stack with Fan for Examples 3 and 4

$$\begin{aligned}
 P_t &= \Delta p_{t,3-2} - \Delta p_{se} \\
 &= (0.70 + 0.28) - (0.22) \\
 &= 0.76 \text{ in. of water}
 \end{aligned}$$

Example 5. Calculate the thermal gravity effect for each section of the system in Figure 6 and the system's net thermal gravity effect. Density of ambient air is $0.075 \text{ lb}_m/\text{ft}^3$, and the lengths are as follows: $z_1 = 50 \text{ ft}$, $z_2 = 90 \text{ ft}$, $z_4 = 95 \text{ ft}$, $z_5 = 25 \text{ ft}$, and $z_9 = 200 \text{ ft}$. Pressure required at section 3 is $-0.1 \text{ in. of water}$. Write the equation to determine the fan total pressure requirement.

Solution: The following table summarizes the thermal gravity effect for each section of the system as calculated by Equation (14). The net

thermal gravity effect for the system is $0.52 \text{ in. of water}$. To select a fan, use the following equation:

$$\begin{aligned}
 P_t &= 0.1 + \Delta p_{t,1-7} + \Delta p_{t,8-9} - \Delta p_{se} = 0.1 + \Delta p_{t,1-7} \\
 &\quad + \Delta p_{t,8-9} - 0.52 = \Delta p_{t,1-7} + \Delta p_{t,8-9} - 0.42
 \end{aligned}$$

Path (x-x')	Temp., °F	ρ , lb_m/ft^3	Δz ($z_{x'} - z_x$), ft	$\Delta \rho$ ($\rho_a - \rho_{x-x'}$), lb_m/ft^3	Δp_{se} , in. of water [Eq. (14)]
1-2	1500	0.0202	(90 - 50)	+0.0548	+0.42
3-4	1000	0.0271	0	+0.0479	0
4-5	1000	0.0271	(25 - 95)	+0.0479	-0.64
6-7	250	0.0558	0	+0.0192	0
8-9	250	0.0558	(200 - 0)	+0.0192	+0.74
Net Thermal Gravity Effect					0.52

Fig. 6 Triple Stack System for Example 5

PRESSURE CHANGES IN SYSTEM

Figure 7 shows total and static pressure changes in a fan/duct system consisting of a fan with both supply and return air ductwork. Also shown are total and static pressure gradients referenced to atmospheric pressure.

For all constant-area sections, total and static pressure losses are equal. At diverging transitions, velocity pressure decreases, absolute total pressure decreases, and absolute static pressure can increase. The static pressure increase at these sections is known as **static regain**.

At converging transitions, velocity pressure increases in the direction of airflow, and absolute total and absolute static pressures decrease.

At the exit, total pressure loss depends on the shape of the fitting and the flow characteristics. Exit loss coefficients C_o can be greater than, less than, or equal to one. Total and static pressure grade lines for the various coefficients are shown in Figure 7. Note that, for a loss coefficient less than one, static pressure upstream of the exit is less than atmospheric pressure (negative). Static pressure just upstream of the discharge fitting can be calculated by subtracting the upstream velocity pressure from the upstream total pressure.

Fig. 7 Pressure Changes During Flow in Ducts

At section 1, total pressure loss depends on the shape of the entry. Total pressure immediately downstream of the entrance equals the difference between the upstream pressure, which is zero (atmospheric pressure), and loss through the fitting. Static pressure of ambient air is zero; several diameters downstream, static pressure is negative, equal to the sum of the total pressure (negative) and the velocity pressure (always positive).

System resistance to airflow is noted by the total pressure grade line in Figure 7. Sections 3 and 4 include fan system effect pressure losses. To obtain the fan static pressure requirement for fan selection where fan total pressure is known, use

$$P_s = P_t - p_{v,o} \quad (17)$$

where

$$\begin{aligned} P_s &= \text{fan static pressure, in. of water} \\ P_t &= \text{fan total pressure, in. of water} \\ p_{v,o} &= \text{fan outlet velocity pressure, in. of water} \end{aligned}$$

FLUID RESISTANCE

Duct system losses are the irreversible transformation of mechanical energy into heat. The two types of losses are (1) friction losses and (2) dynamic losses.

FRICITION LOSSES

Friction losses are due to fluid viscosity and result from momentum exchange between molecules (in laminar flow) or between individual particles of adjacent fluid layers moving at different velocities (in turbulent flow). Friction losses occur along the entire duct length.

Darcy and Colebrook Equations

For fluid flow in conduits, friction loss can be calculated by the Darcy equation:

$$\Delta p_f = \frac{12fL}{D_h} \rho \left(\frac{V}{1097} \right)^2 \quad (18)$$

where

$$\begin{aligned} \Delta p_f &= \text{friction losses in terms of total pressure, in. of water} \\ f &= \text{friction factor, dimensionless} \\ L &= \text{duct length, ft} \\ D_h &= \text{hydraulic diameter [Equation (24)], in.} \\ V &= \text{velocity, fpm} \\ \rho &= \text{density, lb}_m/\text{ft}^3 \end{aligned}$$

In the region of laminar flow (Reynolds numbers less than 2000), the friction factor is a function of Reynolds number only.

For completely turbulent flow, the friction factor depends on Reynolds number, duct surface roughness, and internal protuberances (e.g., joints). Between the bounding limits of hydraulically smooth behavior and fully rough behavior is a transitional roughness zone where the friction factor depends on both roughness and Reynolds number. In this transitionally rough, turbulent zone, the friction factor f is calculated by Colebrook's equation (Colebrook 1938-1939). This transition curve merges asymptotically into the curves representing laminar and completely turbulent flow. Because Colebrook's equation cannot be solved explicitly for f , use iterative techniques (Behls 1971).

$$\frac{1}{\sqrt{f}} = -2 \log \left(\frac{\varepsilon}{3.7D_h} + \frac{2.51}{\text{Re}\sqrt{f}} \right) \quad (19)$$

where

$$\begin{aligned} \varepsilon &= \text{material absolute roughness factor, ft} \\ \text{Re} &= \text{Reynolds number} \end{aligned}$$

Reynolds number (Re) may be calculated by using the following equation.

$$\text{Re} = \frac{D_h V}{720\nu} \quad (20)$$

where ν = kinematic viscosity, ft²/s.

For standard air and temperature between 40 and 100°F, Re can be calculated by

$$\text{Re} = 8.50 D_h V \quad (21)$$

Roughness Factors

Roughness factors ε listed in Table 1 are recommended for use with Equation (19). These values include not only material, but also duct construction, joint type, and joint spacing (Griggs and Khodabakhsh-Sharifabad 1992). Idelchik et al. (1994) summarize roughness factors for 80 materials, including metal tubes; conduits made from concrete and cement; and wood, plywood, and glass tubes.

Swim (1978) conducted tests on duct liners of varying densities, surface treatments, transverse joints (workmanship), and methods of attachment to sheet metal ducts. Results suggested using $\varepsilon = 0.015$ ft for spray-coated liners and $\varepsilon = 0.005$ ft for liners with a facing material adhered onto the air side. In both cases, the roughness factor includes resistance offered by mechanical fasteners, and assumes good joints. Liner density does not significantly influence flow resistance.

Figure 8 or Equation (22) (Abushakra et al. 2002, 2004; Culp and Cantrill 2009) provides pressure loss correction factors for compressed flexible ducts ranging in size from 6 to 16 in. Flexible ducts exhibit considerable variation in pressure loss, which can be in the ± 15 to 25% range, because of differences in manufacturing, materials, test setup (compression over the full length of duct), inner liner nonuniformities, installation, and draw-through or blow-through

Table 1 Duct Roughness Factors

Duct Material	Roughness Category	Absolute Roughness ε , ft
Uncoated carbon steel, clean (Moody 1944) (0.00015 ft)	Smooth	0.0001
PVC plastic pipe (Swim 1982) (0.00003 to 0.00015 ft)		
Aluminum (Hutchinson 1953) 0.000015 to 0.0002 ft)		
Galvanized steel, longitudinal seams, 4 ft joints (Griggs et al. 1987) (0.00016 to 0.00032 ft)	Medium-smooth	0.0003
Galvanized steel, continuously rolled, spiral seams, 10 ft joints (Jones 1979) (0.0002 to 0.0004 ft)		
Galvanized steel, spiral seam with 1, 2, and 3 ribs, 12 ft joints (Griggs et al. 1987) (0.00029 to 0.00038 ft)		
Galvanized steel, longitudinal seams, 2.5 ft joints (Wright 1945) (0.0005 ft)	Average	0.0005
Galvanized steel, spiral, corrugated, 10 ft joints (Kulkarni et al. 2009) (0.0024 ft)	Medium-rough	0.003
Fibrous glass duct, rigid		
Fibrous glass duct liner, air side with facing material (Swim 1978) (0.005 ft)		
Flexible duct, fabric and wire, fully extended		
Fibrous glass duct liner, air side spray coated (Swim 1978) (0.015 ft)	Rough	0.01
Flexible duct, metallic (0.004 to 0.007 ft when fully extended)		
Concrete (Moody 1944) (0.001 to 0.01 ft)		

Fig. 8 Pressure Loss Correction Factor for Flexible Duct Not Fully Extended

applications. Pressure drop correction factors should be applied to medium-rough ducts ($\epsilon = 0.003$ ft); they can be obtained by multiplying the values from the friction chart for galvanized ducts (Figure 9) by 1.55, where ($\epsilon = 0.0003$ ft).

For commercial systems, flexible ducts should be

- Limited to connections between duct branches and diffusers or variable-air-volume (VAV) terminal units
- No more than 5 ft in length, fully stretched
- Installed without any radial compression (kinks)
- Not used in lieu of fittings

For 6 to 16 in. ducts that are 70% extended, pressure losses can be three to nine times greater than those for a fully extended flexible duct of the same diameter.

$$PDCF = 1 + 58r_c e^{-0.126D} \quad (22)$$

with

$$r_c = 1 - (L/L_{FE}) \quad (23)$$

where

- PDCF = pressure drop correction factor
- r_c = compression ratio, dimensionless
- D = flexible duct diameter, in.
- L = installed duct length, ft
- L_{FE} = duct length fully extended, ft

Friction Chart

Fluid resistance caused by friction in round ducts can be determined by the friction chart (Figure 9). This chart is based on standard air flowing through round galvanized ducts with beaded slip couplings on 48 in. centers, equivalent to an absolute roughness of 0.0003 ft.

Changes in barometric pressure, temperature, and humidity affect air density, air viscosity, and Reynolds number. No corrections to Figure 9 are needed for (1) duct materials with a medium-smooth roughness factor, (2) temperature variations of $\pm 30^\circ\text{F}$ from

70°F , (3) elevations to 1500 ft, and (4) duct pressures from -20 to $+20$ in. of water relative to ambient pressure. These individual variations in temperature, elevation, and duct pressure result in duct losses within $\pm 5\%$ of the standard air friction chart.

For duct materials not categorized as medium-smooth in Table 1, and for variations in temperature, barometric pressure (elevation), and duct pressures (outside the range listed), calculate friction loss in a duct by the Colebrook and Darcy equations [Equations (19) and (18), respectively].

Noncircular Ducts

A momentum analysis can relate average wall shear stress to pressure drop per unit length for fully developed turbulent flow in a passage of arbitrary shape but uniform longitudinal cross-sectional area. This analysis leads to the definition of **hydraulic diameter**:

$$D_h = 4A/P \quad (24)$$

where

- D_h = hydraulic diameter, in.
- A = duct area, in^2
- P = perimeter of cross section, in.

Although hydraulic diameter is often used to correlate noncircular data, exact solutions for laminar flow in noncircular passages show that this causes some inconsistencies. No exact solutions exist for turbulent flow. Tests over a limited range of turbulent flow indicated that fluid resistance is the same for equal lengths of duct for equal mean velocities of flow if the ducts have the same ratio of cross-sectional area to perimeter. From experiments using round, square, and rectangular ducts having essentially the same hydraulic diameter, Huebscher (1948) found that each, for most purposes, had the same flow resistance at equal mean velocities. Tests by Griggs and Khodabakhsh-Sharifabad (1992) also indicated that experimental rectangular duct data for airflow over the range typical of HVAC systems can be correlated satisfactorily using Equation (19) together with hydraulic diameter, particularly when a realistic experimental uncertainty is accepted. These tests support using hydraulic diameter to correlate noncircular duct data.

Rectangular Ducts. Huebscher (1948) developed the relationship between rectangular and round ducts that is used to determine size equivalency based on equal flow, resistance, and length. This relationship, Equation (25), is the basis for Table 2.

$$D_e = \frac{1.30(ab)^{0.625}}{(a+b)^{0.250}} \quad (25)$$

where

- D_e = circular equivalent of rectangular duct for equal length, fluid resistance, and airflow, in.
- a = length one side of duct, in.
- b = length adjacent side of duct, in.

To determine equivalent round duct diameter, use Table 2. Equations (18) and (19) must be used to determine pressure loss.

Flat Oval Ducts. To convert round ducts to flat oval sizes, use Table 3, which is based on Equation (26) (Heyt and Diaz 1975), the circular equivalent of a flat oval duct for equal airflow, resistance, and length. Equations (18) and (19) must be used to determine friction loss.

$$D_e = \frac{1.55AR^{0.625}}{P^{0.250}} \quad (26)$$

where AR is the cross-sectional area of flat oval duct defined as

$$AR = (\pi a^2/4) + a(A - a) \quad (27)$$

Fig. 9 Friction Chart for Round Duct ($\rho = 0.075 \text{ lb}_m/\text{ft}^3$ and $\epsilon = 0.0003 \text{ ft}$)

and the perimeter P is calculated by

$$P = \pi a + 2(A - a) \quad (28)$$

where

- P = perimeter of flat oval duct, in.
- A = major axis of flat oval duct, in.
- a = minor axis of flat oval duct, in.

DYNAMIC LOSSES

Dynamic losses result from flow disturbances caused by duct-mounted equipment and fittings (e.g., entries, exits, elbows, transitions, and junctions) that change the airflow path's direction and/or area. Idelchik et al. (1994) discuss parameters affecting fluid resistance of fittings and presents local loss coefficients in three forms: tables, curves, and equations.

Local Loss Coefficients

The dimensionless coefficient C is used for fluid resistance, because this coefficient has the same value in dynamically similar streams (i.e., streams with geometrically similar stretches, equal Reynolds numbers, and equal values of other criteria necessary for dynamic similarity). The fluid resistance coefficient represents the ratio of total pressure loss to velocity pressure at the referenced cross section:

$$C = \frac{\Delta p_j}{\rho(V/1097)^2} = \frac{\Delta p_j}{P_v} \quad (29)$$

where

- C = local loss coefficient, dimensionless
- Δp_j = total pressure loss, in. of water
- ρ = density, lb_m/ft³
- V = velocity, fpm
- p_v = velocity pressure, in. of water

Dynamic losses occur along a duct length and cannot be separated from friction losses. For ease of calculation, dynamic losses are assumed to be concentrated at a section (local) and exclude friction. Frictional losses must be considered only for relatively long fittings. Generally, fitting friction losses are accounted for by measuring duct lengths from the centerline of one fitting to that of the next fitting. For fittings closely coupled (less than six hydraulic diameters apart), the flow pattern entering subsequent fittings differs from the flow pattern used to determine loss coefficients. Adequate data for these situations are unavailable.

For all fittings, except junctions, calculate the total pressure loss Δp_j at a section by

$$\Delta p_j = C_o p_{v,o} \quad (30)$$

where the subscript o is the cross section at which the velocity pressure is referenced. Dynamic loss is based on the actual velocity in the duct, not the velocity in an equivalent circular duct. For the cross section to reference a fitting loss coefficient, see step 4 in the section on HVAC Duct Design Procedures. Where necessary (e.g., unequal-area fittings), convert a loss coefficient from section o to section i using Equation (31), where V is the velocity at the respective sections.

$$C_i = \frac{C_o}{(V_i/V_o)^2} \quad (31)$$

For converging and diverging flow junctions, total pressure losses through the straight (main) section are calculated as

$$\Delta p_j = C_{c,s} p_{v,c} \quad (32)$$

For total pressure losses through the branch section,

$$\Delta p_j = C_{c,b} p_{v,c} \quad (33)$$

where $p_{v,c}$ is the velocity pressure at the common section c , and $C_{c,s}$ and $C_{c,b}$ are loss coefficients for the straight (main) and branch flow paths, respectively, each referenced to the velocity pressure at section c . To convert junction local loss coefficients referenced to straight and branch velocity pressures, use the following equation:

$$C_i = \frac{C_{c,i}}{(V_i/V_c)^2} \quad (34)$$

where

- C_i = local loss coefficient referenced to section being calculated (see subscripts), dimensionless
- $C_{c,i}$ = straight ($C_{c,s}$) or branch ($C_{c,b}$) local loss coefficient referenced to dynamic pressure at common section, dimensionless
- V_i = velocity at section to which C_i is being referenced, fpm
- V_c = velocity at common section, fpm

Subscripts:

- b = branch
- s = straight (main) section
- c = common section

The junction of two parallel streams moving at different velocities is characterized by turbulent mixing of the streams, accompanied by pressure losses. In the course of this mixing, momentum is exchanged between particles moving at different velocities, resulting in equalization of the velocity distributions in the common stream. The jet with higher velocity loses part of its kinetic energy by transmitting it to the slower jet. The loss in total pressure before and after mixing is always large and positive for the higher-velocity jet, and increases with an increase in the amount of energy transmitted to the lower-velocity jet. Consequently, the local loss coefficient [Equation (29)] is always positive. Energy stored in the lower-velocity jet increases because of mixing. The loss in total pressure and the local loss coefficient can, therefore, also have negative values for the lower velocity jet (Idelchik et al. 1994).

Duct Fitting Database

A duct fitting database that includes more than 220 round, flat oval, and rectangular fittings is available from ASHRAE (2009).

The fittings are numbered (coded) as shown in Table 4. Entries and converging junctions are only in the exhaust/return portion of systems. Exits and diverging junctions are only in supply systems. Equal-area elbows, obstructions, and duct-mounted equipment are common to both supply and exhaust systems. Transitions and unequal-area elbows can be either supply or exhaust fittings. Fitting ED5-1 (see the section on Fitting Loss Coefficients) is an Exhaust fitting with a round shape (**D**iameter). The number 5 indicates that the fitting is a junction, and 1 is its sequential number. Fittings SR31 and ER3-1 are Supply and Exhaust fittings, respectively. The R indicates that the fitting is **R**ectangular, and the 3 identifies the fitting as an elbow. Note that the cross-sectional areas at sections 0 and 1 are not equal (see the section on Fitting Loss Coefficients). Otherwise, the elbow would be a **C**ommon fitting such as CR3-6. Additional fittings are reproduced in the section on Fitting Loss Coefficients to support the example design problems (see Table 10 for Example 6; see Table 12 for Example 7).

Bends in Flexible Duct

Abushakra et al. (2002) show that loss coefficients for bends in flexible ductwork vary widely from condition to condition, with no uniform or consistent trends. Loss coefficients range from a low of 0.87 to a high of 3.27. Flexible duct elbows should not be used in lieu of rigid elbows.

DUCTWORK SECTIONAL LOSSES

Darcy-Weisbach Equation

Total pressure loss in a duct section is calculated by combining Equations (18) and (29) in terms of Δ*p*, where Σ*C* is the summation of local loss coefficients in the duct section. Each fitting loss coefficient must be referenced to that section's velocity pressure.

$$\Delta p = \left(\frac{12fL}{D_h} + \Sigma C \right) \rho \left(\frac{V}{1097} \right)^2 \tag{35}$$

FAN/SYSTEM INTERFACE

Fan Inlet and Outlet Conditions

Fan performance data measured in the field may show lower performance capacity than manufacturers' ratings. The most common causes of deficient performance of the fan/system combination are improper outlet connections, nonuniform inlet flow, and swirl at the fan inlet. These conditions alter the fan's aerodynamic

characteristics so that its full flow potential is not realized. One bad connection can reduce fan performance far below its rating. No data have been published that account for the effects of fan inlet and outlet flexible vibration connectors.

Normally, a fan is tested with open inlets and a section of straight duct attached to the outlet (ASHRAE *Standard* 51). This setup results in uniform flow into the fan and efficient static pressure recovery on the fan outlet. If good inlet and outlet conditions are not provided in the actual installation, the performance of the fan suffers. To select and apply the fan properly, these effects must be considered, and the pressure requirements of the fan, as calculated by standard duct design procedures, must be increased.

Figure 10 illustrates deficient fan/system performance. System pressure losses have been determined accurately, and a fan has been selected for operation at point 1. However, no allowance has been made for the effect of system connections to the fan on fan performance. To compensate, a fan system effect must be added to the calculated system pressure losses to determine the actual system curve. The point of intersection between the fan performance curve and the actual system curve is point 4. The actual flow volume is, therefore, deficient by the difference from 1 to 4. To achieve design flow volume, a fan system effect pressure loss equal to the pressure difference between points 1 and 2 should be added to the calculated system pressure losses, and the fan should be selected to operate at point 2.

Fan System Effect Coefficients

The system effect concept was formulated by Farquhar (1973) and Meyer (1973); the magnitudes of the system effect, called **system effect factors**, were determined experimentally by the Air Movement and Control Association (AMCA 2007a; Brown 1973; Clarke et al. 1978). The system effect factors, converted to local loss coefficients, are in the *ASHRAE Duct Fitting Database* (2009) for both centrifugal and axial fans. Fan system effect coefficients are only an approximation. Fans of different types and even fans of the same type, but supplied by different manufacturers, do not

necessarily react to a system in the same way. Therefore, judgment based on experience must be applied to any design.

Fan Outlet Conditions. Fans intended primarily for duct systems are usually tested with an outlet duct in place (ASHRAE *Standard 51*). Figure 11 shows the changes in velocity profiles at various

distances from the fan outlet. For 100% recovery, the duct, including transition, must meet the requirements for 100% effective duct length [L_e (Figure 11)], which is calculated as follows:

For $V_o > 2500$ fpm,

$$L_e = \frac{V_o \sqrt{A_o}}{10,600} \quad (36)$$

For $V_o \leq 2500$ fpm,

$$L_e = \frac{\sqrt{A_o}}{4.3} \quad (37)$$

where

- V_o = duct velocity, fpm
- L_e = effective duct length, ft
- A_o = duct area, in²

As illustrated by Fitting SR7-1 in the section on Fitting Loss Coefficients, centrifugal fans should not abruptly discharge to the atmosphere. A diffuser design should be selected from Fitting SR7-2 (see the section on Fitting Loss Coefficients) or SR7-3 [see ASHRAE (2009)].

Fan Inlet Conditions. For rated performance, air must enter the fan uniformly over the inlet area in an axial direction without prerotation. Nonuniform flow into the inlet is the most common cause of reduced fan performance. Such inlet conditions are not equivalent to a simple increase in system resistance; therefore, they cannot be treated as a percentage decrease in the flow and pressure from the fan. A poor inlet condition results in an entirely new fan performance. An elbow at the fan inlet, for example Fitting ED7-2 (see the

Fig. 10 Deficient System Performance with System Effect Ignored

Fig. 11 Establishment of Uniform Velocity Profile in Straight Fan Outlet Duct
(Adapted by permission from AMCA Publication 201)

section on Fitting Loss Coefficients), causes turbulence and uneven flow into the fan impeller. Losses from the fan system effect can be eliminated by including an adequate length of straight duct between the elbow and the fan inlet.

The ideal inlet condition allows air to enter axially and uniformly without spin. A spin in the same direction as the impeller rotation reduces the pressure/volume curve by an amount dependent on the vortex's intensity. A counterrotating vortex at the inlet slightly increases the pressure/volume curve, but the power is increased substantially.

Inlet spin may arise from many different approach conditions, and sometimes the cause is not obvious. Inlet spin can be avoided by providing an adequate length of straight duct between the elbow and the fan inlet. Figure 12 illustrates some common duct connections that cause inlet spin and includes recommendations for correcting spin.

Fans within plenums and cabinets or next to walls should be located so that air may flow unobstructed into the inlets. Fan performance is reduced if the space between the fan inlet and the enclosure is too restrictive. System effect coefficients for fans in an enclosure or adjacent to walls are listed under Fitting ED7-1 (see the section on Fitting Loss Coefficients). How the airstream enters an enclosure in relation to the fan inlets also affects fan performance. Plenum or enclosure inlets or walls that are not symmetrical with the fan inlets cause uneven flow and/or inlet spin.

Testing, Adjusting, and Balancing Considerations

Fan system effects (FSEs) are not only to be used in conjunction with the system resistance characteristics in the fan selection process, but are also applied in the calculations of the results of testing, adjusting, and balancing (TAB) field tests to allow direct comparison to design calculations and/or fan performance data. Fan inlet swirl and the effect on system performance of poor fan inlet and outlet ductwork connections cannot be measured directly. Poor inlet flow patterns affect fan performance within the impeller wheel (centrifugal fan) or wheel rotor impeller (axial fan), while the fan outlet system effect is flow instability and turbulence within the fan discharge ductwork.

The static pressure at the fan inlet and the static pressure at the fan outlet may be measured directly in some systems. In most cases, static pressure measurements for use in determining fan total (or static) pressure will not be made directly at the fan inlet and outlet, but at locations a relatively short distance from the fan inlet and downstream from the fan outlet. To calculate fan total pressure for this case from field measurements, use Equation (38), where Δp_{x-y} is the summation of calculated total pressure losses between the fan inlet and outlet sections noted. Plane 3 is used to determine airflow rate. If necessary, use Equation (17) to calculate fan static pressure knowing fan total pressure. For locating measurement planes and calculation procedures, consult AMCA *Publication 203* (AMCA 2007b).

$$P_t = (p_{s,5} + p_{v,5}) + \Delta p_{2-5} + FSE_2 + (p_{s,4} + p_{v,4}) + \Delta p_{4-1} + FSE_1 + FSE_{1,sw} \tag{38}$$

where

- P_t = fan total pressure, in. of water
- p_s = static pressure, in. of water
- p_v = velocity pressure, in. of water
- FSE = fan system effect, in. of water
- Δp_{x-y} = summarization of total pressure losses between planes x and y , in. of water

Subscripts [numerical subscripts same as used by AMCA (2007b)]:

- 1 = fan inlet
- 2 = fan outlet
- 3 = plane of airflow measurement
- 4 = plane of static pressure measurement upstream of fan
- 5 = plane of static pressure measurement downstream of fan
- sw = swirl

DUCT SYSTEM DESIGN

DESIGN CONSIDERATIONS

Space Pressure Relationships

Space pressure is determined by fan location and duct system arrangement. For example, a supply fan that pumps air into a space increases space pressure; an exhaust fan reduces space pressure. If both supply and exhaust fans are used, space pressure depends on the relative capacity of the fans. Space pressure is positive if supply exceeds exhaust and negative if exhaust exceeds supply (Osborne 1966). System pressure variations caused by wind can be minimized or eliminated by careful selection of intake air and exhaust vent locations (see Chapter 24).

Fire and Smoke Management

Because duct systems can convey smoke, hot gases, and fire from one area to another and can accelerate a fire within the system, fire protection is an essential part of air-conditioning and ventilation system design. Generally, fire safety codes require compliance with the standards of national organizations. NFPA *Standard 90A* examines fire safety requirements for (1) ducts, connectors, and appurtenances; (2) plenums and corridors; (3) air outlets, air inlets, and fresh air intakes; (4) air filters; (5) fans; (6) electric wiring and equipment; (7) air-cooling and -heating equipment; (8) building construction, including protection of penetrations; and (9) controls, including smoke control.

Fire safety codes often refer to the testing and labeling practices of nationally recognized laboratories, such as Factory Mutual and Underwriters Laboratories (UL). UL's annual *Building Materials Directory* lists fire and smoke dampers that have been tested and meet the requirements of UL *Standards 555* and *555S*. This directory also summarizes maximum allowable sizes for individual dampers and assemblies of these dampers. Fire dampers are 1.5 h or 3 h fire-rated. Smoke dampers are classified by (1) temperature degradation [ambient air or high temperature (250°F minimum)] and

Fig. 12 Inlet Duct Connections Causing Inlet Spin and Corrections for Inlet Spin

(Adapted by permission from AMCA *Publication 201*)

(2) leakage at 1 and 4 in. of water pressure difference (8 and 12 in. of water classification optional). Smoke dampers are tested under conditions of maximum airflow. UL's annual *Fire Resistance Directory* lists fire resistances of floor/roof and ceiling assemblies with and without ceiling fire dampers.

For a more detailed presentation of fire protection, see the NFPA (2008) *Fire Protection Handbook*, Chapter 52 of the 2007 *ASHRAE Handbook—HVAC Applications*, and Klote and Milke (2002).

Duct Insulation

In all new construction (except low-rise residential buildings), air-handling ducts and plenums that are part of an HVAC air distribution system should be thermally insulated in accordance with ASHRAE *Standard* 90.1. Duct insulation for new low-rise residential buildings should comply with ASHRAE *Standard* 90.2. Existing buildings should meet requirements of ASHRAE *Standard* 100. In all cases, thermal insulation should meet local code requirements. Insulation thicknesses in these standards are minimum values; economic and thermal considerations may justify higher insulation levels. Additional insulation, vapor retarders, or both may be required to limit vapor transmission and condensation.

Duct heat gains or losses must be known to calculate supply air quantities, supply air temperatures, and coil loads. To estimate duct heat transfer and entering or leaving air temperatures, refer to Chapter 23.

Duct System Leakage

It is recommended that all transverse joints, longitudinal seams, and ductwork penetrations be sealed. **Longitudinal seams** are joints oriented in the direction of airflow. **Duct wall penetrations** are openings made by screws, non-self-sealing fasteners, pipe, tubing, rods, and wire. All other connections are considered **transverse joints**, which are connections of two duct or fitting elements oriented perpendicular to flow (e.g., spin-ins, taps, branch connections, duct connections to equipment). System (ductwork and equipment) leakage should be tested to verify the installing contractor's workmanship and sealing practices.

Leakage in all unsealed ducts varies considerably with the fabricating machinery used, material thickness, assembly methods, and installation workmanship. For sealed ducts, a wide variety of sealing methods and products exists. Sealed and unsealed duct leakage tests (AISI/SMACNA 1972; ASHRAE/SMACNA/TIMA 1985; Swim and Griggs 1995) confirmed that longitudinal seam, transverse joint, and assembled duct leakage can be represented by Equation (39) and that, for the same construction, leakage is not significantly different in negative and positive modes. Table 5 presents a range of leakage rates for longitudinal seams commonly used in metal duct construction. Longitudinal seam leakage for unsealed or unwelded metal ducts is about 10 to 15% of total duct leakage.

$$Q = C \Delta p_n^N \tag{39}$$

where

- Q = duct leakage rate, cfm
- C = constant reflecting area characteristics of leakage path
- Δp_s = static pressure differential from duct interior to exterior, in. of water
- N = exponent relating turbulent or laminar flow in leakage path

The AISI/ASHRAE/SMACNA/TIMA data showed that duct leakage (equipment not included) is best predicted by duct surface area and pressure, because surface area highlights the effect of system size. Duct leakage were grouped into a geometric series of **leakage classes** C_L (Figure 13) based on Equation (40), where the exponent N is assumed to be 0.65. Table 6 shows leakage classes for commonly used duct construction and sealing practices (equipment leakage excluded).

Fig. 13 Duct Leakage Classifications

Table 5 Unsealed Longitudinal Seam Leakage, Metal Ducts

Type of Duct/Seam	Leakage, cfm per ft Seam Length*	
	Range	Average
Rectangular		
Pittsburgh lock		
26 gage	0.01 to 0.02	0.0164
22 gage	0.001 to 0.002	0.0016
Button punch snaplock		
26 gage	0.03 to 0.15	0.0795
22 gage	NA (1 test)	0.0032
Round		
Spiral (26 gage)	NA (1 test)	0.015
Snaplock	0.04 to 0.14	0.11
Grooved	0.11 to 0.18	0.12

*Leakage rate is at 1 in. of water static pressure.

$$C_L = Q / \Delta p_n^{0.65} \tag{40}$$

where

- Q = leakage rate, cfm/100 ft² (surface area)
- C_L = leakage class, cfm per 100 ft duct surface at 1 in. of water static pressure

Effects of equipment leakage (e.g., through dampers, access doors, VAV boxes, diffusers) should be anticipated. Ductwork should not be expected to compensate for equipment leakage. Terminal units may leak 1 to 2% of their maximum flow. Use Table 6 to calculate allowable ductwork leakage for a system. Leakage classes listed in Table 6 are for a specific duct type, not a system with a variety of duct types. When several pressure classifications or shapes occur in a system, ductwork in each class or shape should be evaluated independently to find an aggregate leakage for the system. System leakage (ductwork plus equipment) values for use in specifications should be in terms of cfm at the pressure(s) leakage was determined. The estimated percent leakage for any section of ductwork can be determined from Table 7 (equipment leakage not included).

Limited performance standards for metal duct sealants and tapes exist. For guidance in their selection and use, refer to SMACNA's

Table 6 Duct Leakage Classification^a

Duct Type	Predicted Leakage Class C_L [Eq. (40)]	
	Sealed ^{b,c}	Unsealed ^c
Metal (flexible excluded)		
Round and flat oval	3	30 (6 to 70)
Rectangular	6	48 (12 to 110)
Flexible		
Metal, aluminum	8	30 (12 to 54)
Nonmetal	12	30 (4 to 54)
Fibrous glass		
Round	3	NA
Rectangular	6	NA

^aLeakage classes here are averages based on tests conducted by AISI/SMACNA (1972), ASHRAE/SMACNA/TIMA (1985), and Swim and Griggs (1995).

^b“Sealed” leakage classes assume that, for metal ducts, all transverse joints, seams, and openings in duct wall are sealed.

^cLeakage classes anticipate about 25 joints per 100 linear feet of duct. For systems with a high fitting-to-straight-duct ratio, greater leakage occurs in both sealed and unsealed conditions.

Table 7 Leakage as Percentage of Airflow^{a,b}

Leakage Class	System cfm per ft ² Duct Surface ^c	Static Pressure, in. of water

^aAdapted with permission from *HVAC Air Duct Leakage Test Manual* (SMACNA 1985, Appendix A).

^bPercentage applies to airflow entering a section of duct operating at an assumed pressure equal to average of upstream and downstream pressures.

^cRatios in this column are typical of fan volumetric flow rate divided by total system surface. Portions of systems may vary from these averages.

HVAC Duct Construction Standards (2005). Fibrous glass ducts and their closure systems are covered by UL *Standards* 181 and 181A. For fibrous glass duct construction standards, consult NAIMA (2002) and SMACNA (2003). Flexible duct performance and installation standards are covered by UL *Standards* 181 and 181B and ADC (2003). Soldered or welded duct construction is necessary where sealants are not suitable. Sealants used on exterior ducts must be resistant to weather, temperature cycles, sunlight, and ozone.

Table 8 Typical Design Velocities for HVAC Components

Duct Element	Face Velocity, fpm
Louvers ^a	
Intake	
7000 cfm and greater	400
Less than 7000 cfm	See Figure 14
Exhaust	
5000 cfm and greater	500
Less than 5000 cfm	See Figure 14
Filters ^b	
Panel filters	
Viscous impingement	200 to 800

Shaft and compartment pressure changes affect duct leakage and are important to health and safety in the design and operation of contaminant and smoke control systems. Shafts should not be used for supply, return, and/or exhaust air without accounting for their leakage rates. Airflow around buildings, building component leakage, and the distribution of inside and outside pressures over the height of a building, including shafts, are discussed in Chapters 16 and 24.

System Component Design Velocities

Table 8 summarizes face velocities for HVAC components in built-up systems. In most cases, the values are abstracted from pertinent chapters in the 2008 *ASHRAE Handbook—HVAC Systems and Equipment*; final selection of components should be based on data in these chapters or, preferably, from manufacturers.

Use Figure 14 for preliminary sizing of air intake and exhaust louvers. For air quantities greater than 7000 cfm per louver, the air intake gross louver openings are based on 400 fpm; for exhaust louvers, 500 fpm is used for air quantities of 5000 cfm per louver and greater. For smaller air quantities, refer to Figure 14. These criteria are presented on a per-louver basis (i.e., each louver in a bank of louvers) to include each louver frame. Representative production-run louvers were used in establishing Figure 14, and all data used were based on AMCA *Standard* 500-L tests. For louvers larger than 16 ft², the free areas are greater than 45%; for louvers less than 16 ft², free areas are less than 45%. Unless specific louver data are analyzed, no louver should have a face area less than 4 ft². If debris can collect on the screen of an intake louver, or if louvers are located

Fig. 14 Criteria for Louver Sizing

at grade with adjacent pedestrian traffic, louver face velocity should not exceed 100 fpm.

Louvers require special treatment because the blade shapes, angles, and spacing cause significant variations in louver-free area and performance (pressure drop and water penetration). Selection and analysis should be based on test data obtained from the manufacturer in accordance with AMCA *Standard 500-L*, which presents both pressure drop and water penetration test procedures and a uniform method for calculating the free area of a louver. Tests are conducted on a 48 in. square louver with the frame mounted flush in the wall. For water penetration tests, rainfall is 4 in./h, no wind, and the water flow down the wall is 0.25 gpm per linear foot of louver width.

AMCA *Standard 500-L* also includes a method for measuring water rejection performance of louvers subjected to simulated rain and wind pressures. These louvers are tested at a rainfall of 3 in./h falling on the louver's face with a predetermined wind velocity directed at the face of the louver (typically 29.1 or 44.7 mph). Effectiveness ratings are assigned at various airflow rates through the louver.

System and Duct Noise

The major sources of noise from air-conditioning systems are diffusers, grilles, fans, ducts, fittings, and vibrations. Chapter 47 of the 2007 *ASHRAE Handbook—HVAC Applications* discusses sound control for each of these sources, as well as methods for calculating required sound attenuation. Sound control for terminal devices consists of selecting devices that meet the design goal under all operating conditions and installing them properly so that no additional sound is generated. The sound power output of a fan is determined by the type of fan, airflow, and pressure. Sound control in the duct system requires proper duct layout, sizing, and provision for installing duct attenuators, if required. Noise generated by a system increases with both duct velocity and system pressure.

Testing and Balancing

Each air duct system should be tested, adjusted, and balanced. Detailed procedures are given in Chapter 37 of the 2007 *ASHRAE Handbook—HVAC Applications*. To properly determine fan total (or static) pressure from field measurements taking into account fan system effect, see the section on Fan/System Interface. Equation (38) allows direct comparison of system resistance to design calculations and/or fan performance data. It is important that system effect magnitudes be known prior to testing. If necessary, use Equation (17) to calculate fan static pressure knowing fan total pressure [Equation (38)]. For TAB calculation procedures of numerous fan/system configurations encountered in the field, refer to AMCA (2007b).

DUCT DESIGN METHODS

Duct design methods for HVAC systems and for exhaust systems conveying vapors, gases, and smoke are the equal-friction method, the static regain method, and the T-method. The section on Industrial Exhaust System Duct Design presents the design criteria and procedures for exhaust systems conveying particulates. Equal friction and static regain are nonoptimizing methods, and the T-method is a practical optimization method introduced by Tsal et al. (1988).

To ensure that system designs are acoustically acceptable, noise generation should be analyzed and sound attenuators and/or acoustically lined duct provided where necessary.

Equal-Friction Method

In the equal-friction method, ducts are sized for a constant pressure loss per unit length. The shaded area of the friction chart (see Figure 9) is the suggested range of friction rate and air velocity. When energy cost is high and installed ductwork cost is low, a low-friction-rate design is more economical. For low energy cost and high duct cost, a higher friction rate is more economical. After initial sizing, calculate total pressure loss for all duct sections, and then resize sections to balance pressure losses at each junction.

Static Regain Method

This design method is only applicable to supply air systems. The objective is to obtain the same static pressure at diverging flow junctions by changing downstream duct sizes. This design objective can be developed by rearranging Equation (7a) and setting $p_{s,2}$ equal to $p_{s,1}$ (neglecting thermal gravity effect term). This means that the change in static pressure from one section to another is zero, which is satisfied when the change in total pressure is equal to the change in velocity pressure. Thus,

$$p_{s,1} - p_{s,2} = \Delta p_{t,1-2} - \left[\frac{\rho V_1^2}{2g_c} - \frac{\rho V_2^2}{2g_c} \right] \quad (41)$$

and

$$\Delta p_{t,1-2} = \frac{\rho V_1^2}{2g_c} - \frac{\rho V_2^2}{2g_c} \quad (42)$$

where $\Delta p_{t,1-2}$ is total pressure loss from upstream of junction 1 to upstream of junction 2. Junction 2 can be a terminal section, where the total pressure is zero. For each main section, the straight-through and branch sections immediately downstream of the main duct section are determined by iteration of that section's size until Equation (42) is satisfied. However, there could be cases when the straight or branch sections need to be larger than the upstream section to satisfy Equation (42). Fittings in the 2009 *ASHRAE Duct Fitting Database* have not been tested under these conditions, and making downstream sections larger than upstream sections is not practical. The largest straight-through or branch size should be limited to that of the upstream section. The imbalance that occurs is resolved during total-pressure balancing of the system.

To start system design, a maximum velocity is selected for the root section (duct section downstream of a fan). In Figure 16, section 19 is the root for the supply air subsystem. The shaded area on the friction chart (see Figure 9) is the suggested range of air velocity. When energy cost is high and installed ductwork cost is low, a lower initial velocity is more economical. For low energy cost and high duct cost, a higher velocity is more economical.

Because terminal sections often require additional static pressure to operate VAV terminal boxes properly, that static pressure requirement is added into the section after it is sized using static regain. Otherwise, the downstream section could be larger than the upstream section. For calculating duct sizes, the total pressure losses of grilles, registers, diffusers, or constant-volume (CV) terminal boxes should be included in the sizing iterations.

Total Pressure Balancing. After completing duct sizing by the static regain method, any residual unbalance can be reduced or eliminated by calculating the system's total pressure (pressure required in the critical paths) and changing duct sizes or fittings in other paths to increase the paths' total pressure to approximate what is needed in the critical paths.

T-Method

T-method optimization (Tsal et al. 1988) is a dynamic programming procedure based on Bellman's (1957) tee-staging idea, except that phase-level vector tracing is eliminated by optimizing locally at each stage. This modification reduces the number of calculations, but requires iteration.

Ductwork sizes are determined by minimizing the objective function:

$$E = E_p(\text{PWEF}) + E_s \quad (43)$$

where

E = present-worth owning and operating cost

E_p = first-year energy cost

E_s = initial cost

PWEF = present worth escalation factor (Smith 1968), dimensionless

The objective function includes both initial system cost and present worth of energy. Hours of operation, annual escalation and interest rates, and amortization period are also required for optimization.

The following constraints are necessary for duct optimization (Tsal and Adler 1987):

- *Continuity.* For each node, flow in equals flow out.
- *Pressure balancing.* Total pressure loss in each path must equal fan total pressure; or, in effect, at any junction, total pressure loss for all paths is the same.
- *Nominal duct size.* Ducts are constructed in discrete, nominal sizes. Each diameter of a round duct or height and width of a rectangular duct is rounded to the nearest increment, usually 1 or 2 in. If a lower nominal size is selected, initial cost decreases, but pressure loss increases and may exceed the fan pressure. If a higher nominal size is selected, the opposite is true: initial cost increases, but section pressure loss decreases. However, this lower pressure at one section may allow smaller ducts to be selected for sections that follow. Therefore, optimization must consider size rounding.
- *Air velocity restriction.* Maximum allowable velocity is an acoustic limitation (ductwork regenerated noise).
- *Construction restriction.* Architectural limits may restrict duct sizes. If air velocity or construction constraints are violated during an iteration, a duct size must be calculated. Pressure loss calculated for this preselected duct size is considered a fixed loss.

T-method simulation, developed by Tsal et al. (1990), determines the flow in each duct section of an existing system with a known operating fan performance curve. The simulation version of the T-method converges very efficiently. Usually three iterations are sufficient to obtain a solution with a high degree of accuracy.

Many HVAC problems require duct system simulation. In addition to the following concerns that can be clarified by simulation, the T-method is an excellent design tool for simulating flow distribution within a system with various modes of operation.

- Flow distribution in a VAV system caused by terminal box flow diversity
- Airflow redistribution caused by HVAC system additions and/or modifications
- System airflow analysis for partially occupied buildings
- Necessity to replace fans and/or motors when retrofitting an air distribution system
- Multiple-fan system operating condition when one or more fans shut down
- Pressure differences between adjacent confined spaces in a nuclear facility when a design basis accident (DBA) occurs (Farajian et al. 1992)
- Smoke management system performance during a fire, when some fire/smoke dampers close and others remain open

Availability. Software for T-method optimization is under development to identify optimum duct design, considering energy, operation, and construction costs.

BALANCING DAMPERS

Constant-Volume (CV) Systems

Dampers should be provided throughout CV systems. Systems designed using the inherently non-self-balancing equal-friction method should have balancing dampers at each branch throughout the system, unless sections are resized to balance pressure losses at each junction. Self-balancing design methods, such as static regain and the T-method, produce fairly well-balanced systems and theoretically do not need balancing dampers; however, because of the accuracy limitations of fitting data (loss coefficients), use of fittings for which no data are available, and effects of close-coupled fittings, dampers should be provided.

Variable-Air-Volume (VAV) Systems

VAV systems in balance at design loads will not be in balance at part-load conditions, because there is no single critical path in VAV systems. The critical path is dynamic and continually changing as loads on a building change. In general, balancing dampers are not needed for systems designed by the static regain or T-method, because these design methods are self-balancing at design loads and VAV boxes compensate for inaccuracy in fitting data or data inaccuracy caused by close-coupled fittings (at design loads) and system pressure variation (at part loads). Balancing dampers, however, are required for systems designed using the non-self-balancing equal-friction method. For systems designed using any method, dampers should not be installed in the inlets to VAV boxes.

For any design method, VAV terminal units may have upstream static pressures higher than for which the box is rated, thus possibly introducing noise into occupied spaces. In these cases, control algorithms can poll the VAV boxes and drive the duct static pressure to the minimum set point required to keep at least one unit at starvation (open) at any given time. Upstream static pressure should always be kept at a minimum that is easy for the VAV box to control. Because there may be large differences in static pressure at riser takeoffs serving many floors from a single air handler, manual dampers should be provided at each floor takeoff so that testing, adjusting, and balancing (TAB) contractors can field-adjust them after construction. Alternatively, these takeoff dampers could also be dynamically controlled to adjust the downstream static pressure applied to the VAV boxes, while simultaneously driving the air handler to the lowest possible static pressure set point.

Silencers downstream of VAV terminal units should not be necessary if the VAV box damper is operating at nearly open conditions.

Their use in this location should be based on careful acoustical analysis, because silencers add total pressure to the system and therefore create more system noise by causing air handlers to operate at higher speeds for a given airflow.

HVAC DUCT DESIGN PROCEDURES

The general procedure for HVAC system duct design is as follows:

1. Study the building plans, and arrange supply and return outlets to provide proper distribution of air in each space. Adjust calculated air quantities for duct heat gains or losses and duct leakage. Also, adjust supply, return, and/or exhaust air quantities to meet space pressurization requirements.
2. Select outlet sizes from manufacturers' data (see Chapter 20).
3. Sketch the duct system, connecting supply outlets and return intakes with the air-handling units/air conditioners. Use rigid round ducts, minimize the number of fittings, and avoid close-coupled fittings because little is known about the resulting loss coefficients. If space is restricted and a properly designed

round duct is too large, the next best option to minimize leakage and pressure losses is to use flat oval ductwork. Multiple runs of round duct should also be considered. Limit flexible duct to the final 5 ft of connections to diffusers and terminal boxes, with no more than 5% compression. They should be installed without kinks or crimps, and no more offset between the diffuser and rigid duct than 1/8th the diffuser neck diameter to prevent a significant increase in noise level (see Figure 11 in Chapter 47 of the 2007 ASHRAE Handbook—HVAC Applications).

4. Divide the system into sections and number each section. A duct system should be divided at all points where flow, size, or shape changes. Assign fittings to the section toward the supply and return (or exhaust) terminals. The following examples are for the fittings identified for Example 6 (Figure 15), and system section numbers assigned (Figure 16). For converging flow fitting 3, assign the straight-through flow to section 1 (toward terminal 1), and the branch to section 2 (toward terminal 4). For diverging flow fitting 24, assign the straight-through flow to section 13 (toward terminals 26 and 29) and the branch to section 10

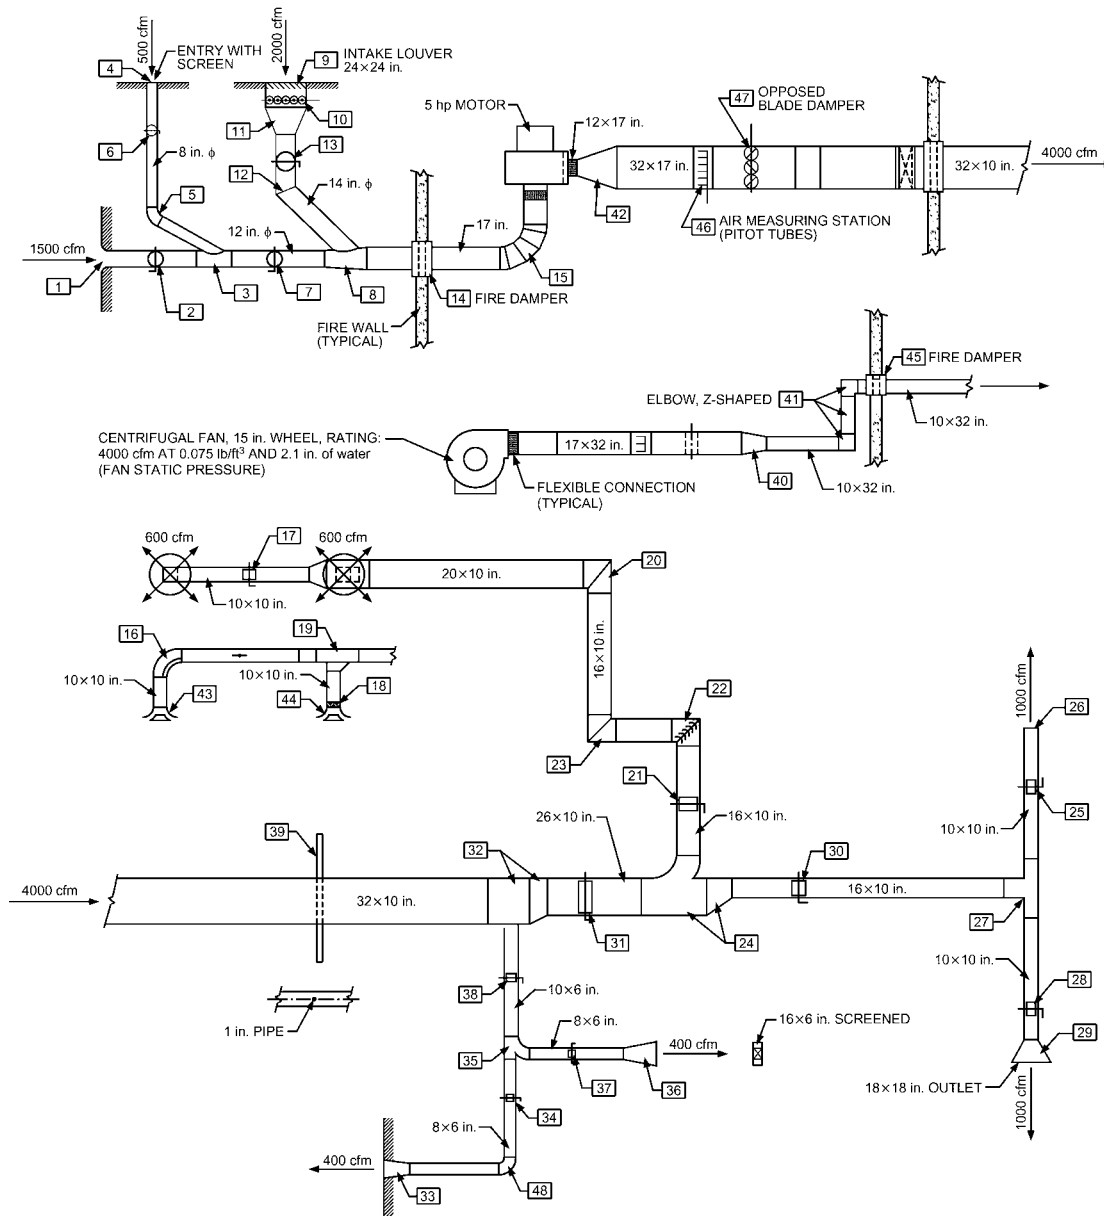

Fig. 15 Schematic for Example 6

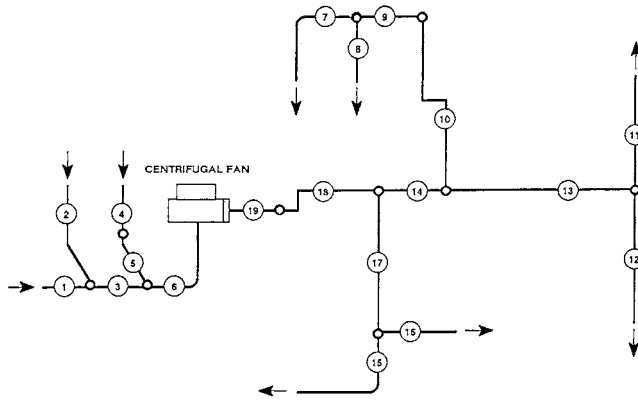

Fig. 16 System Schematic with Section Numbers for Example 6

(toward terminals 43 and 44). For transition fitting 11, assign the fitting to upstream section 4 [toward terminal 9 (intake louver)]. For fitting 20, assign the unequal area elbow to downstream section 9 (toward diffusers 43 and 44). The fan outlet diffuser, fitting 42, is assigned to section 19 (again, toward the supply duct terminals).

5. Size ducts by the selected design method. Calculate system total pressure loss; then select the fan (refer to Chapter 20 of the 2008 ASHRAE Handbook—HVAC Systems and Equipment).
6. Lay out the system in detail. If duct routing and fittings vary significantly from the original design, recalculate pressure losses. Reselect the fan if necessary.
7. Resize duct sections to approximately balance pressures at each junction.
8. Analyze the design for objectionable noise levels, and specify lined duct, double-wall duct, and sound attenuators as necessary. Refer to the section on System and Duct Noise.

Example 6. For the system illustrated by Figures 15 and 16, size the ductwork by the equal-friction method, and pressure-balance the system by changing duct sizes (use 1 in. increments). Determine system resistance and total pressure unbalance at junctions. Airflow quantities are actual values adjusted for heat gains or losses, and ductwork is sealed (assume no leakage), galvanized steel ducts with transverse joints on 4 ft centers ($\epsilon = 0.0003$ ft). Air is at standard conditions ($0.075 \text{ lb}_m/\text{ft}^3$ density).

Because Figure 15 is intended to illustrate calculation procedures, its duct layout is not typical of any real duct system. The layout includes fittings from the local loss coefficient tables, with emphasis on converging and diverging tees and various types of entries and discharges. The supply system is constructed of rectangular ductwork; the return system, round ductwork.

Solution: See Figure 16 for section numbers assigned to the system. Duct sections are sized within the suggested range of friction rate shown on the friction chart (see Figure 9). Tables 9 and 10 give total pressure loss calculations and the supporting summary of loss coefficients by sections. Straight-duct friction factor and pressure loss were calculated by Equations (18) and (19). Fitting loss coefficients are from the 2009 ASHRAE Duct Fitting Database. Loss coefficients were calculated automatically by the database program (not by manual interpolation). Pressure loss values in Table 9 for diffusers (fittings 43 and 44), louver (fitting 9), and air-measuring station (fitting 46) are manufacturers' data.

Pressure unbalance at junctions is shown in Figure 17, the total pressure grade line for the system. System resistance P_t is 2.89 in. of water. Noise levels and the need for sound attenuation were not evaluated. To calculate the fan static pressure, use Equation (17):

$$P_s = 2.89 - 0.50 = 2.39 \text{ in. of water}$$

where 0.50 in. of water is the fan outlet velocity pressure.

Fig. 17 Total Pressure Grade Line for Example 6

INDUSTRIAL EXHAUST SYSTEM DUCT DESIGN

Chapter 30 of the 2007 ASHRAE Handbook—HVAC Applications discusses design criteria, including hood design, for industrial exhaust systems. Exhaust systems conveying vapors, gases, and smoke can be designed by the equal-friction or T-method. Systems conveying particulates are designed by the constant velocity method at duct velocities adequate to convey particles to the system air cleaner. For contaminant transport velocities, see Table 2 in Chapter 30 of the 2007 ASHRAE Handbook—HVAC Applications.

Two pressure-balancing methods can be considered when designing industrial exhaust systems. One method uses balancing devices (e.g., dampers, blast gates) to obtain design airflow through each hood. The other approach balances systems by adding resistance to ductwork sections (i.e., changing duct size, selecting different fittings, and increasing airflow). This self-balancing method is preferred, especially for systems conveying abrasive materials. Where potentially explosive or radioactive materials are conveyed, the prebalanced system is mandatory because contaminants could accumulate at the balancing devices. To balance systems by increasing airflow, use Equation (44) which assumes that all ductwork has the same diameter and that fitting loss coefficients, including main and branch tee coefficients, are constant.

$$Q_c = Q_d(P_h/P_l)^{0.5} \quad (44)$$

where

- Q_c = airflow rate required to increase P_l to P_h , cfm
- Q_d = total airflow rate through low-resistance duct run, cfm
- P_h = absolute value of pressure loss in high-resistance ductwork section(s), in. of water
- P_l = absolute value of pressure loss in low-resistance ductwork section(s), in. of water

For systems conveying particulates, use elbows with a large centerline radius-to-diameter ratio (r/D), greater than 1.5 whenever possible. If r/D is 1.5 or less, abrasion in dust-handling systems can

Fig. 18 Metalworking Exhaust System for Example 7

reduce the life of elbows. Elbows are often made of seven or more gores, especially in large diameters. For converging flow fittings, a 30° entry angle is recommended to minimize energy losses and abrasion in dust-handling systems. For the entry loss coefficients of hoods and equipment for specific operations, see Chapter 30 of the 2007 ASHRAE Handbook—HVAC Applications and ACGIH (2007).

Example 7. For the metalworking exhaust system in Figures 18 and 19, size the ductwork and calculate fan static pressure requirement for an industrial exhaust designed to convey granular materials. Pressure-balance the system by changing duct sizes and adjusting airflow rates. Minimum particulate transport velocity for the chipping and grinding table ducts (sections 1 and 5, Figure 19) is 4000 fpm. For ducts associated with the grinder wheels (sections 2, 3, 4, and 5), minimum duct velocity is 4500 fpm. Ductwork is galvanized steel, with absolute roughness of 0.0003 ft. Assume that air is standard and that duct and fittings are available in the following sizes: 3 to 9.5 in. diameters in 0.5 in. increments, 10 to 37 in. diameters in 1 in. increments, and 38 to 90 in. diameters in 2 in. increments.

The building is one story, and the design wind velocity is 20 mph. For the stack, use design J shown in Figure 2 in Chapter 44 of the 2007 ASHRAE Handbook—HVAC Applications for complete rain protection; stack height, determined by calculations from Chapter 44, is 16 ft above the roof. This height is based on minimized stack downwash; therefore, the stack discharge velocity must exceed 1.5 times the design wind velocity.

Solution: The following table summarizes initial duct sizes and transport velocities for contaminated ducts upstream of the collector. The 4474 fpm velocity in sections 2 and 3 is acceptable because the transport velocity is not significantly lower than 4500 fpm. For the next

Fig. 19 System Schematic with Section Numbers for Example 7

available duct size (4.5 in. diameter), the duct velocity is 5523 fpm, significantly higher than 4500 fpm.

Duct Section	Design Airflow, cfm	Transport Velocity, fpm	Duct Diameter, in.	Duct Velocity, fpm
1	1800	4000	9	4074
2, 3	610 each	4500	5	4474
4	1220	4500	7	4565
5	3020	4500	11	4576

Design calculations up through the junction after sections 1 and 4 are summarized as follows:

Design No.	D_1 , in.	Δp_1 , in. of water	Δp_{2+4} , in. of water	Imbalance, $\Delta p_1 - \Delta p_{2+4}$
1	9	1.46	3.09	-1.63
2	8.5	2.00	3.08	-1.08
3	8	2.79	3.00	-0.21
4	7.5	3.92	2.88	+1.04

$Q_1 = 1800$ cfm
 $Q_2 = 610$ cfm; $D_2 = 5$ in. dia.
 $Q_3 = 610$ cfm; $D_3 = 5$ in. dia.
 $Q_4 = 1220$ cfm; $D_4 = 7$ in. dia.

For (initial) design 1, the imbalance between section 1 and section 2 (or 3) is 1.63 in. of water, with section 1 requiring additional resistance. Decreasing section 1 duct diameter by 0.5 in. increments results in the least imbalance, 0.21 in. of water, when the duct diameter is 8 in. (design 3). Because section 1 requires additional resistance, estimate the new airflow rate using Equation (44):

$$Q_{e,1} = (1800)(3.00/2.79)^{0.5} = 1870 \text{ cfm}$$

At 1870 cfm flow in section 1, 0.13 in. of water imbalance remains at the junction of sections 1 and 4. By trial-and-error solution, balance is attained when the flow in section 1 is 1850 cfm. The duct between the collector and fan inlet is 13 in. round to match the fan inlet (12.75 in. diameter). To minimize downwash, the stack discharge velocity must exceed 2640 fpm, 1.5 times the design wind velocity (20 mph) as stated in the problem definition. Therefore, the stack is 14 in. round, and the stack discharge velocity is 2872 fpm.

Table 11 summarizes the system losses by sections. The straight duct friction factor and pressure loss were calculated by Equations (18) and (19). Table 12 lists fitting loss coefficients and input parameters necessary to determine the loss coefficients. The fitting loss coefficients are from the 2009 *ASHRAE Duct Fitting Database*. The fitting loss coefficient tables are included in the section on Fitting Loss Coefficients for illustration but cannot be obtained exactly by manual interpolation because the coefficients were calculated by the duct fitting database algorithms (more significant figures). Figure 20 shows a pressure grade line of the system. Fan total pressure, calculated by Equation (15), is 7.89 in. of water. To calculate the fan static pressure, use Equation (17):

$$P_s = 7.89 - 0.81 = 7.1 \text{ in. of water}$$

where 0.81 in. of water is the fan outlet velocity pressure. The fan airflow rate is 3070 cfm, and its outlet area is 0.853 ft^2 (10.125 by 12.125 in.). Therefore, the fan outlet velocity is 3600 fpm.

Hood suction for the chipping and grinding table hood is 2.2 in. of water, calculated by Equation (5) from Chapter 30 of the 2007 *ASHRAE Handbook—HVAC Applications* [$P_{s,h} = (1 + 0.25)(1.74) = 2.2$ in. of water, where 0.25 is hood entry loss coefficient C_o , and 1.74 is duct velocity pressure P_v a few diameters downstream from the hood]. Similarly, hood suction for each grinder wheel is 1.7 in. of water:

$$P_{2,3} = (1 + 0.4)(1.24) = 1.7 \text{ in. of water}$$

where 0.4 is the hood entry loss coefficient, and 1.24 in. of water is the duct velocity pressure.

^aSee Figure 15.

^cSee Table 12.

^eCollector manufacturers set fabric bag cleaning mechanism to actuate at a pressure difference of 3.0 in. of water between inlet and outlet plenums. Pressure difference across clean media is approximately 1.5 in. of water.

^bDuct lengths are to fitting centerlines.

^dDuct pressure based on a 0.0003 ft absolute roughness factor.

Table 12 Loss Coefficient Summary by Sections for Example 7

Duct Section	Fitting Number	Type of Fitting	ASHRAE Fitting No. ^a	Parameters	Loss Coefficient
1	1	Hood ^b	—	Hood face area: 3 by 4 ft	0.25
	2	Elbow	CD3-10	90°, 7 gore, $r/D = 2.5$	0.11
	4	Capped wye (45°), with 45° elbow	ED5-6	$A_b/A_c = 1$	0.61 (C_b)
	5	Wye (30°), main	ED5-1	$Q_s/Q_c = 0.60, A_s/A_c = 0.529, A_b/A_c = 0.405$	0.10 (C_s)
	Summation of Section 1 loss coefficients				
2,3	6	Hood ^c	—	Type hood: For double wheels, dia. = 22 in. each, wheel width = 4 in. each; type takeoff: tapered	0.40
	7	Elbow	CD3-12	90°, 3 gore, $r/D = 1.5$	0.34
	8	Symmetrical wye (60°)	ED5-9	$Q_b/Q_c = 0.5, A_{b1}/A_c = 0.51, A_{b2}/A_c = 0.51$	0.32 (C_b)
Summation of Sections 2 and 3 loss coefficients					1.06
4	9	Elbow	CD3-10	90°, 7 gore, $r/D = 2.5$	0.11
	10	Elbow	CD3-13	60°, 3 gore, $r/D = 1.5$	0.19
	5	Wye (30°), branch	ED5-1	$Q_b/Q_c = 0.40, A_s/A_c = 0.529, A_b/A_c = 0.405$	0.21 (C_b)
	Summation of Section 4 loss coefficients				
5	11	Exit, conical diffuser to collector	ED2-1	$L = 24$ in., $L/D_o = 2.0, A_1/A_o \approx 16$	0.22
	Summation of Section 5 loss coefficients				
6	12	Entry, bellmouth from collector	ER2-1	$r/D_1 = 0.23, r = 3$ in., $C_o = 3.30$	0.03 (C_1)
	Summation of Section 6 loss coefficients				
7	13	Diffuser, fan outlet ^d	SD4-2	Fan outlet size: 10.125 by 12.125 in.; $L = 18$ in.	0.19
	14	Capped wye (45°), with 45° elbow	ED5-6	$A_b/A_c = 1$	0.61 (C_b)
	15	Stackhead	SD2-6	$D_e/D = 1$	1.0
	Summation of Section 7 loss coefficients

---	---

THIS CHAPTER includes tables and charts to size piping for various fluid flow systems. Further details on specific piping systems can be found in appropriate chapters of the ASHRAE Handbook.

Two related but distinct concerns emerge when designing a fluid flow system: sizing the pipe and determining the flow-pressure relationship. The two are often confused because they can use the same equations and design tools. Nevertheless, they should be determined separately.

The emphasis in this chapter is on the problem of sizing the pipe, and to this end design charts and tables for specific fluids are presented in addition to the equations that describe the flow of fluids in pipes. Once a system has been sized, it should be analyzed with more detailed methods of calculation to determine the pump head required to achieve the desired flow. Computerized methods are well suited to handling the details of calculating losses around an extensive system.

PRESSURE DROP EQUATIONS

Darcy-Weisbach Equation

Pressure drop caused by fluid friction in fully developed flows of all “well-behaved” (Newtonian) fluids is described by the Darcy-Weisbach equation:

$$\Delta p = f \left(\frac{L}{D} \right) \left(\frac{\rho}{g_c} \right) \left(\frac{V^2}{2} \right) \quad (1)$$

where

- Δp = pressure drop, lb_f/ft²
- f = friction factor, dimensionless (from Moody chart, Figure 13 in Chapter 3)
- L = length of pipe, ft
- D = internal diameter of pipe, ft
- ρ = fluid density at mean temperature, lb_m/ft³
- V = average velocity, fps
- g_c = units conversion factor, 32.2 ft·lb_m/lb_f·s²

This equation is often presented in head or specific energy form as

$$\Delta h = \left(\frac{\Delta p}{\rho} \right) \left(\frac{g_c}{g} \right) = f \left(\frac{L}{D} \right) \left(\frac{V^2}{2g} \right) \quad (2)$$

where

- Δh = head loss, ft
- g = acceleration of gravity, ft/s²

In this form, the density of the fluid does not appear explicitly (although it is in the Reynolds number, which influences f).

The preparation of this chapter is assigned to TC 6.1, Hydronic and Steam Equipment and Systems.

The friction factor f is a function of pipe roughness ϵ , inside diameter D , and parameter Re , the Reynolds number:

$$Re = DV\rho/\mu \quad (3)$$

where

- Re = Reynolds number, dimensionless
- ϵ = absolute roughness of pipe wall, ft
- μ = dynamic viscosity of fluid, lb_m/ft·s

The friction factor is frequently presented on a Moody chart (Figure 13 in Chapter 3) giving f as a function of Re with ϵ/D as a parameter.

A useful fit of smooth and rough pipe data for the usual turbulent flow regime is the **Colebrook equation**:

$$\frac{1}{\sqrt{f}} = 1.74 - 2 \log \left(\frac{2\epsilon}{D} + \frac{18.7}{Re\sqrt{f}} \right) \quad (4)$$

Another form of Equation (4) appears in Chapter 3, but the two are equivalent. Equation (4) is more useful in showing behavior at limiting cases—as ϵ/D approaches 0 (smooth limit), the $18.7/Re\sqrt{f}$ term dominates; at high ϵ/D and Re (fully rough limit), the $2\epsilon/D$ term dominates.

Equation (4) is implicit in f ; that is, f appears on both sides, so a value for f is usually obtained iteratively.

Hazen-Williams Equation

A less widely used alternative to the Darcy-Weisbach formulation for calculating pressure drop is the Hazen-Williams equation, which is expressed as

$$\Delta p = 3.022L \left(\frac{V}{C} \right)^{1.852} \left(\frac{1}{D} \right)^{1.167} \left(\frac{\rho g}{g_c} \right) \quad (5)$$

or

$$\Delta h = 3.022L \left(\frac{V}{C} \right)^{1.852} \left(\frac{1}{D} \right)^{1.167} \quad (6)$$

where C = roughness factor.

Typical values of C are 150 for plastic pipe and copper tubing, 140 for new steel pipe, down to 100 and below for badly corroded or very rough pipe.

Valve and Fitting Losses

Valves and fittings cause pressure losses greater than those caused by the pipe alone. One formulation expresses losses as

$$\Delta p = K \left(\frac{\rho}{g_c} \right) \left(\frac{V^2}{2} \right) \quad \text{or} \quad \Delta h = K \left(\frac{V^2}{2g} \right) \quad (7)$$

where K = geometry- and size-dependent loss coefficient (Tables 1 through 4).

Example 1. Determine the pressure drop for 60°F water flowing at 4 fps through a nominal 1 in., 90° threaded elbow.

Solution: From Table 1, the *K* for a 1 in., 90° threaded elbow is 1.5.

$$\Delta p = 1.5 \times 62.4/32.2 \times 4^2/2 = 23.3 \text{ lb/ft}^2 \text{ or } 0.16 \text{ psi}$$

The loss coefficient for valves appears in another form as *C_v*, a dimensional coefficient expressing the flow through a valve at a specified pressure drop.

$$Q = C_v \sqrt{\Delta p} \tag{8}$$

where

- Q* = volumetric flow, gpm
- C_v* = valve coefficient, gpm at Δ*p* = 1 psi
- Δ*p* = pressure drop, psi

See the section on Control Valve Sizing in Chapter 46 of the 2008 *ASHRAE Handbook—HVAC Systems and Equipment* for more information on valve coefficients.

Example 2. Determine the volumetric flow through a valve with *C_v* = 10 for an allowable pressure drop of 5 psi.

Solution: *Q* = 10√5 = 22.4 gpm.

Alternative formulations express fitting losses in terms of equivalent lengths of straight pipe (Table 8 and Figure 7). Pressure loss data for fittings are also presented in Idelchik (1986).

Equation (7) and data in Tables 1 and 2 are based on the assumption that separated flow in the fitting causes the *K* factors to be independent of Reynolds number. In reality, the *K* factor for most pipe fittings varies with Reynolds number. Tests by Rahmeyer (1999a, 1999b, 2002a, 2002b) (ASHRAE research projects RP-968 and RP-1034) on 2 in. threaded and 4, 12, 16, 20, and 24 in. welded steel fittings demonstrate

Fig. 1 Close-Coupled Test Configurations

the variation and are shown in Tables 4 and 5. The studies also present K factors of diverting and mixing flows in tees, ranging from full through flow to full branch flow. They also examined the variation in K factors caused by variations in geometry among manufacturers and by surface defects in individual fittings.

Hegberg (1995) and Rahmeyer (1999a,b) discuss the origins of some of the data shown in Table 4 and Table 5. The Hydraulic Institute (1979) data appear to have come from Freeman (1941), work that was actually performed in 1895. The work of Giesecke (1926) and Giesecke and Badgett (1931, 1932a,b) may not be representative of present-day fittings.

Further extending the work on determination of fitting K factors to PVC piping systems, Rahmeyer (2003a, 2003b) (ASHRAE research project RP-1193) found the data in Tables 8 and 9 giving K factors for Schedule 80 PVC 2, 4, 6, and 8 in. ells, reducers, expansions, and tees. The results of these tests are also presented in the cited papers in terms of equivalent lengths. In general, PVC fitting geometry varied much more from one manufacturer to another than steel fittings did.

Losses in Multiple Fittings

Typical fitting loss calculations are done as if each fitting is isolated and has no interaction with any other. Rahmeyer (2002c)

Fig. 2 Summary Plot of Effect of Close-Coupled Configurations for 2 in. Ells

Fig. 3 Summary Plot of Effect of Close-Coupled Configurations for 4 in. Ells

(ASHRAE research project RP-1035) tested 2 in. threaded ells and 4 in. ells in two and three fitting assemblies of several geometries, at varying spacings. Figure 1 shows the geometries, and Figures 2 and 3 show the ratio of coupled K values to uncoupled K values (i.e., fitting losses for the assembly compared with losses from the same number of isolated fittings). The most important conclusion is that the interaction between fittings always reduces the loss. Also, although geometry of the assembly has a definite effect, the effects are not the same for 2 in. threaded and 4 in. welded ells. Thus, the traditional practice of adding together losses from individual fittings gives a conservative (high-limit) estimate.

Calculating Pressure Losses

The most common engineering design flow loss calculation selects a pipe size for the desired total flow rate and available or allowable pressure drop.

Because either formulation of fitting losses requires a known diameter, pipe size must be selected before calculating the detailed influence of fittings. A frequently used rule of thumb assumes that the design length of pipe is 50 to 100% longer than actual to account for fitting losses. After a pipe diameter has been selected on this basis, the influence of each fitting can be evaluated.

Table 9 Test Summary for Loss Coefficients K of PVC Tees

Branching		
Schedule 80 PVC Fitting	K_{1-2}	K_{1-3}
2 in. injection molded branching tee, 100% line flow	0.13 to 0.26	—
50/50 flow	0 to 0.12	0.74 to 1.02
100% branch flow	—	0.98 to 1.39
4 in. injection molded branching tee, 100% line flow	0.07 to 0.22	—
50/50 flow	0.03 to 0.13	0.74 to 0.82
100% branch flow	—	0.97 to 1.12
6 in. injection molded branching tee, 100% line flow	0.01 to 0.14	—
50/50 flow	0.06 to 0.11	0.70 to 0.84
100% branch flow	—	0.95 to 1.15

50/50 flow	1.22 to 1.19	0.89 to 1.88
100% mix flow	—	0.89 to 1.54
4 in. injection molded mixing tee, 100% line flow	0.07 to 0.18	—
50/50 flow	1.19 to 1.88	0.98 to 1.88
100% mix flow	—	0.88 to 1.02
6 in. injection molded mixing tee, 100% line flow	0.06 to 0.14	—
50/50 flow	1.26 to 1.80	1.02 to 1.60
100% mix flow	—	0.90 to 1.07
6 in. fabricated mixing tee, 100% line flow	0.19 to 0.21	—
50/50 flow	2.94 to 3.32	2.57 to 3.17
100% mix flow	—	1.72 to 1.98
8 in. injection molded mixing tee, 100% line flow	0.04 to 0.09	—
50/50 flow	1.10 to 1.60	0.96 to 1.32
100% mix flow	—	0.81 to 0.93
8 in. fabricated mixing tee, 100% line flow	0.13 to 0.70	—
50/50 flow	2.36 to 10.62	2.02 to 2.67
100% mix flow	—	1.34 to 1.53

Coefficients based on average velocity of 8 fps. Range of values varies with fitting manufacturers. Line or straight flow is $Q_2/Q_1 = 100\%$. Branch flow is $Q_2/Q_1 = 0\%$.

WATER PIPING

FLOW RATE LIMITATIONS

Stewart and Dona (1987) surveyed the literature relating to water flow rate limitations. Noise, erosion, and installation and operating costs all limit the maximum and minimum velocities in piping systems. If piping sizes are too small, noise levels, erosion levels, and pumping costs can be unfavorable; if piping sizes are too large, installation costs are excessive. Therefore, pipe sizes are chosen to minimize initial cost while avoiding the undesirable effects of high velocities.

A variety of upper limits of water velocity and/or pressure drop in piping and piping systems is used. One recommendation places a

velocity limit of 4 fps for 2 in. pipe and smaller, and a pressure drop limit of 4 ft of water/100 ft for piping over 2 in. Other guidelines are based on the type of service (Table 6) or the annual operating hours (Table 7). These limitations are imposed either to control the levels of pipe and valve noise, erosion, and water hammer pressure or for economic reasons. Carrier (1960) recommends that the velocity not exceed 15 fps in any case.

Noise Generation

Velocity-dependent noise in piping and piping systems results from any or all of four sources: turbulence, cavitation, release of entrained air, and water hammer. In investigations of flow-related noise, Marseille (1965), Ball and Webster (1976), and Rogers (1953, 1954, 1956) reported that velocities on the order of 10 to 17 fps lie within the range of allowable noise levels for residential and commercial buildings. The experiments showed considerable variation in the noise levels obtained for a specified velocity. Generally, systems with longer pipe and with more numerous fittings and valves were noisier. In addition, sound measurements were taken under widely differing conditions; for example, some tests used plastic-covered pipe, while others did not. Thus, no detailed correlations relating sound level to flow velocity in generalized systems are available.

The noise generated by fluid flow in a pipe increases sharply if cavitation or the release of entrained air occurs. Usually the combination of a high water velocity with a change in flow direction or a decrease in the cross section of a pipe causing a sudden pressure drop is necessary to cause cavitation. Ball and Webster (1976) found that at their maximum velocity of 42 fps, cavitation did not occur in straight 3/8 and 1/2 in. pipe; using the apparatus with two elbows, cold water velocities up to 21 fps caused no cavitation. Cavitation did occur in orifices of 1:8 area ratio (orifice flow area is one-eighth of pipe flow area) at 5 fps and in 1:4 area ratio orifices at 10 fps (Rogers 1954).

Some data are available for predicting hydrodynamic (liquid) noise generated by control valves. The International Society for Measurement and Control compiled prediction correlations in an effort to develop control valves for reduced noise levels (ISA 1985). The correlation to predict hydrodynamic noise from control valves is

$$SL = 10 \log C_v + 20 \log \Delta p - 30 \log t + 5 \quad (9)$$

where

- SL = sound level, dB
- C_v = valve coefficient, $\text{gpm}/(\text{psi})^{0.5}$
- Q = flow rate, gpm
- Δp = pressure drop across valve, psi
- t = downstream pipe wall thickness, in.

Air entrained in water usually has a higher partial pressure than the water. Even when flow rates are small enough to avoid cavitation, the release of entrained air may create noise. Every effort should be made to vent the piping system or otherwise remove entrained air.

Erosion

Erosion in piping systems is caused by water bubbles, sand, or other solid matter impinging on the inner surface of the pipe. Generally, at velocities lower than 10 fps, erosion is not significant as long as there is no cavitation. When solid matter is entrained in the fluid at high velocities, erosion occurs rapidly, especially in bends. Thus, high velocities should not be used in systems where sand or other solids are present or where slurries are transported.

Allowances for Aging

With age, the internal surfaces of pipes become increasingly rough, which reduces the available flow with a fixed pressure supply. However, designing with excessive age allowances may result in oversized piping. Age-related decreases in capacity depend on

the type of water, type of pipe material, temperature of water, and type of system (open or closed) and include

- Sliming (biological growth or deposited soil on the pipe walls), which occurs mainly in unchlorinated, raw water systems.
- Caking of calcareous salts, which occurs in hard water (i.e., water bearing calcium salts) and increases with water temperature.
- Corrosion (incrustations of ferrous and ferric hydroxide on the pipe walls), which occurs in metal pipe in soft water. Because oxygen is necessary for corrosion to take place, significantly more corrosion takes place in open systems.

Allowances for expected decreases in capacity are sometimes treated as a specific amount (percentage). Dawson and Bowman (1933) added an allowance of 15% friction loss to new pipe (equivalent to an 8% decrease in capacity). The *HDR Design Guide* (1981) increased the friction loss by 15 to 20% for closed piping systems and 75 to 90% for open systems. Carrier (1960) indicates a factor of approximately 1.75 between friction factors for closed and open systems.

Obrecht and Pourbaix (1967) differentiated between the corrosive potential of different metals in potable water systems and concluded that iron is the most severely attacked, then galvanized steel, lead, copper, and finally copper alloys (i.e., brass). Hunter (1941) and Freeman (1941) showed the same trend. After four years of cold and hot water use, copper pipe had a capacity loss of 25 to 65%. Aged ferrous pipe has a capacity loss of 40 to 80%. Smith (1983) recommended increasing the design discharge by 1.55 for uncoated cast iron, 1.08 for iron and steel, and 1.06 for cement or concrete.

The Plastic Pipe Institute (1971) found that corrosion is not a problem in plastic pipe; the capacity of plastic pipe in Europe and the United States remains essentially the same after 30 years in use.

Extensive age-related flow data are available for use with the Hazen-Williams empirical equation. Difficulties arise in its application, however, because the original Hazen-Williams roughness coefficients are valid only for the specific pipe diameters, water velocities, and water viscosities used in the original experiments. Thus, when the C_s are extended to different diameters, velocities, and/or water viscosities, errors of up to about 50% in pipe capacity can occur (Williams and Hazen 1933, Sanks 1978).

Water Hammer

When any moving fluid (not just water) is abruptly stopped, as when a valve closes suddenly, large pressures can develop. While detailed analysis requires knowledge of the elastic properties of the pipe and the flow-time history, the limiting case of rigid pipe and instantaneous closure is simple to calculate. Under these conditions,

$$\Delta p_h = \rho c_s V / g_c \quad (10)$$

where

- Δp_h = pressure rise caused by water hammer, lb_f/ft^2
- ρ = fluid density, lb_m/ft^3
- c_s = velocity of sound in fluid, fps
- V = fluid flow velocity, fps

The c_s for water is 4720 fps , although the elasticity of the pipe reduces the effective value.

Example 3. What is the maximum pressure rise if water flowing at 10 fps is stopped instantaneously?

Solution:

$$\Delta p_h = 62.4 \times 4720 \times 10 / 32.2 = 91,468 \text{ lb}_f/\text{ft}^2 = 635 \text{ psi}$$

Other Considerations

Not discussed in detail in this chapter, but of potentially great importance, are a number of physical and chemical considerations: pipe and fitting design, materials, and joining methods must be appropriate for working pressures and temperatures encountered, as well as being suitably resistant to chemical attack by the fluid.

Other Piping Materials and Fluids

For fluids not included in this chapter or for piping materials of different dimensions, manufacturers' literature frequently supplies pressure drop charts. The Darcy-Weisbach equation, with the Moody chart or the Colebrook equation, can be used as an alternative to pressure drop charts or tables.

HYDRONIC SYSTEM PIPING

The Darcy-Weisbach equation with friction factors from the Moody chart or Colebrook equation (or, alternatively, the Hazen-Williams equation) is fundamental to calculating pressure drop in hot and chilled water piping; however, charts calculated from these equations (such as Figures 4, 5, and 6) provide easy determination of pressure drops for specific fluids and pipe standards. In addition, tables of pressure drops can be found in Hydraulic Institute (1979) and Crane Co. (1976).

The Reynolds numbers represented on the charts in Figures 4, 5, and 6 are all in the turbulent flow regime. For smaller pipes and/or lower velocities, the Reynolds number may fall into the laminar regime, in which the Colebrook friction factors are no longer valid.

Most tables and charts for water are calculated for properties at 60°F. Using these for hot water introduces some error, although the answers are conservative (i.e., cold water calculations overstate the pressure drop for hot water). Using 60°F water charts for 200°F water should not result in errors in Δp exceeding 20%.

Range of Usage of Pressure Drop Charts

General Design Range. The general range of pipe friction loss used for design of hydronic systems is between 1 and 4 ft of water per 100 ft of pipe. A value of 2.5 ft/100 ft represents the mean to which most systems are designed. Wider ranges may be used in specific designs if certain precautions are taken.

Piping Noise. Closed-loop hydronic system piping is generally sized below certain arbitrary upper limits, such as a velocity limit of 4 fps for 2 in. pipe and under, and a pressure drop limit of 4 ft per 100 ft for piping over 2 in. in diameter. Velocities in excess of 4 fps can be used in piping of larger size. This limitation is generally accepted, although it is based on relatively inconclusive experience with noise in piping. **Water velocity noise** is not caused by water but by free air, sharp pressure drops, turbulence, or a combination of these, which in turn cause cavitation or flashing of water into steam. Therefore, higher velocities may be used if proper precautions are taken to eliminate air and turbulence.

Air Separation

Air in hydronic systems is usually undesirable because it causes flow noise, allows oxygen to react with piping materials, and sometimes even prevents flow in parts of a system. Air may enter a system at an air-water interface in an open system or in an expansion tank in a closed system, or it may be brought in dissolved in makeup water. Most hydronic systems use air separation devices to remove air. The solubility of air in water increases with pressure and decreases with temperature; thus, separation of air from water is best achieved at the point of lowest pressure and/or highest temperature in a system. For more information, see Chapter 12 of the 2008 *ASHRAE Handbook—HVAC Systems and Equipment*.

In the absence of venting, air can be entrained in the water and carried to separation units at flow velocities of 1.5 to 2 fps or more in pipe 2 in. and under. Minimum velocities of 2 fps are therefore recommended. For pipe sizes 2 in. and over, minimum velocities corresponding to a head loss of 0.75 ft/100 ft are normally used. Maintenance of minimum velocities is particularly important in the upper floors of high-rise buildings where the air tends to come out of solution because of reduced pressures. Higher velocities should be used in **downcomer** return mains feeding into air separation units located in the basement.

Example 4. Determine the pipe size for a circuit requiring 20 gpm flow.

Solution: Enter Figure 4 at 20 gpm, read up to pipe size within normal design range (1 to 4 ft/100 ft), and select 1-1/2 in. Velocity is 3.1 fps, which is between 2 and 4. Pressure loss is 2.9 ft/100 ft.

Valve and Fitting Pressure Drop

Valves and fittings can be listed in elbow equivalents, with an elbow being equivalent to a length of straight pipe. Table 10 lists equivalent lengths of 90° elbows; Table 11 lists elbow equivalents for valves and fittings for iron and copper.

Example 5. Determine equivalent feet of pipe for a 4 in. open gate valve at a flow velocity of approximately 4 fps.

Solution: From Table 10, at 4 fps, each elbow is equivalent to 10.6 ft of 4 in. pipe. From Table 11, the gate valve is equivalent to 0.5 elbows. The actual equivalent pipe length (added to measured circuit length for pressure drop determination) will be 10.6 × 0.5, or 5.3 equivalent feet of 4 in. pipe.

Tee Fitting Pressure Drop. Pressure drop through pipe tees varies with flow through the branch. Figure 7 illustrates pressure drops for nominal 1 in. tees of equal inlet and outlet sizes and for the flow patterns illustrated. Idelchik (1986) also presents data for threaded tees.

Different investigators present tee loss data in different forms, and it is sometimes difficult to reconcile results from several sources. As an estimate of the upper limit to tee losses, a pressure or head loss coefficient of 1.0 may be assumed for entering and leaving flows (i.e., $\Delta p = 1.0\rho V_{in}^2/2 + 1.0\rho V_{out}^2/2$).

Example 6. Determine the pressure or head losses for a 1 in. (all openings) threaded pipe tee flowing 25% to the side branch, 75% through. The entering flow is 10 gpm (3.71 fps).

Solution: From Figure 7, bottom curve, the number of equivalent elbows for the through-flow is 0.15 elbows; the through-flow is 7.5 gpm (2.78 fps); and the pressure loss is based on the exit flow rate. Table 10 gives the equivalent length of a 1 in. elbow at 3 fps as 2.7 ft. Using Equations (1) and (2) with friction factor $f = 0.0290$ and diameter $D = 0.0874$ ft,

$$\Delta p = (0.15)(0.0290)(2.7/0.0874)(62.4/32.2)(2.78^2/2)$$

$$= 1.01 \text{ lb/ft}^2 = 0.00699 \text{ psi pressure drop, or}$$

$$\Delta h = (0.15)(0.0290)(2.7/0.0874)(2.78^2)/[(2)(32.2)]$$

$$= 0.0161 \text{ ft head loss}$$

From Figure 7, top curve, the number of equivalent elbows for the branch flow of 25% is 13 elbows; the branch flow is 2.5 gpm (0.93 fps); and the pressure loss is based on the exit flow rate. Table 10 gives the equivalent of a 1 in. elbow at 1 fps as 2.2 ft. Using Equations (1) and (2) with friction factor $f = 0.0350$ and diameter = 0.0874 ft,

$$\Delta p = (13)(0.0350)(2.2/0.0874)(62.4/32.2)(0.93^2/2)$$

$$= 9.60 \text{ lb/ft}^2 = 0.0667 \text{ psi pressure drop, or}$$

$$\Delta h = (13)(0.0350)(2.2/0.0874)(0.93^2)/[(2)(32.2)]$$

$$= 0.154 \text{ ft head loss}$$

- Notes:**
1. Chart is based on straight tees (i.e., branches A, B, and C are the same size).
 2. Pressure loss in desired circuit is obtained by selecting the proper curve according to illustrations, determining the flow at the circled branch, and multiplying the pressure loss for the same size elbow at the flow rate in the circled branch by the equivalent elbows indicated.
 3. When the size of an outlet is reduced, the equivalent elbows shown in the chart do not apply. Therefore, the maximum loss for any circuit for any flow will not exceed 2 elbow equivalents at the maximum flow occurring in any branch of the tee.
 4. Top curve is average of 4 curves, one for each circuit shown.

Fig. 7 Elbow Equivalents of Tees at Various Flow Conditions (Giesecke and Badgett 1931, 1932b)

SERVICE WATER PIPING

Sizing of service water piping differs from sizing of process lines in that design flows in service water piping are determined by the probability of simultaneous operation of a multiplicity of individual loads such as water closets, urinals, lavatories, sinks, and showers. The full flow characteristics of each load device are readily obtained from manufacturers; however, service water piping sized to handle

^cWide range due to variation in design and type of flush valve closets.

all load devices simultaneously would be seriously oversized. Thus, a major issue in sizing service water piping is to determine the diversity of the loads.

The procedure shown in this chapter uses the work of R.B. Hunter for estimating diversity (Hunter 1940, 1941). The present-day plumbing designer is usually constrained by building or plumbing codes, which specify the individual and collective loads to be used for pipe sizing. Frequently used codes (including the BOCA *National Plumbing Code*, *Standard Plumbing Code*, *Uniform Plumbing Code*, and *National Standard Plumbing Code*) contain procedures quite similar to those shown here. The designer must be aware of the applicable code for the location being considered.

Federal mandates are forcing plumbing fixture manufacturers to reduce design flows to many types of fixtures, but these may not yet be included in locally adopted codes. Also, the designer must be aware of special considerations; for example, toilet usage at sports arenas will probably have much less diversity than the codes allow and thus may require larger supply piping than the minimum specified by the codes.

Table 12 gives the rate of flow desirable for many common fixtures and the average pressure necessary to give this rate of flow. The pressure varies with fixture design.

In estimating the load, the rate of flow is frequently computed in **fixture units**, which are relative indicators of flow. Table 13 gives the demand weights in terms of fixture units for different plumbing fixtures under several conditions of service, and Figure 8 gives the estimated demand in gallons per minute corresponding to any total number of fixture units. Figures 9 and 10 provide more accurate estimates at the lower end of the scale.

The estimated demand load for fixtures used intermittently on any supply pipe can be obtained by multiplying the number of each kind

Source: Hunter (1941).
^aFor supply outlets likely to impose continuous demands, estimate continuous supply separately, and add to total demand for fixtures.
^bFor fixtures not listed, weights may be assumed by comparing the fixture to a listed one using water in similar quantities and at similar rates.
^cThe given weights are for total demand. For fixtures with both hot and cold water supplies, the weights for maximum separate demands can be assumed to be 75% of the listed demand for the supply.

Fig. 8 Demand Versus Fixture Units, Mixed System, High Part of Curve (Hunter 1941)

Fig. 9 Estimate Curves for Demand Load
(Hunter 1941)

Fig. 10 Section of Figure 9 on Enlarged Scale

of fixture supplied through that pipe by its weight from Table 13, adding the products, and then referring to the appropriate curve of Figure 8, 9, or 10 to find the demand corresponding to the total fixture units. In using this method, note that the demand for fixture or supply outlets other than those listed in the table of fixture units is not yet included in the estimate. The demands for outlets (e.g., hose connections and air-conditioning apparatus) that are likely to impose continuous demand during heavy use of the weighted fixtures should be estimated separately and added to demand for fixtures used intermittently to estimate total demand.

The Hunter curves in Figures 8, 9, and 10 are based on use patterns in residential buildings and can be erroneous for other usages such as sports arenas. Williams (1976) discusses the Hunter assumptions and presents an analysis using alternative assumptions.

So far, the information presented shows the *design rate of flow* to be determined in any particular section of piping. The next step is to determine the *size of piping*. As water flows through a pipe, the pressure continually decreases along the pipe due to loss of energy from friction. The problem is then to ascertain the minimum pressure in the street main and the minimum pressure required to operate the topmost fixture. (A pressure of 15 psig may be ample for most flush valves, but reference should be made to the manufacturers' requirements. Some fixtures require a pressure up to 25 psig. A minimum of 8 psig should be allowed for other fixtures.) The pressure differential overcomes pressure losses in the distributing system and the difference in elevation between the water main and the highest fixture.

The pressure loss (in psi) resulting from the difference in elevation between the street main and the highest fixture can be obtained

Fig. 12 Variation of Pressure Loss with Flow Rate for Various Faucets and Cocks

by multiplying the difference in elevation in feet by the conversion factor 0.434.

Pressure losses in the distributing system consist of pressure losses in the piping itself, plus the pressure losses in the pipe fittings, valves, and the water meter, if any. Approximate design pressure losses and flow limits for disk-type meters for various rates of flow are given in Figure 11. Water authorities in many localities require compound meters for greater accuracy with varying flow; consult the local utility. Design data for compound meters differ from the data in Figure 11. Manufacturers give data on exact pressure losses and capacities.

Figure 12 shows the variation of pressure loss with rate of flow for various faucets and cocks. The water demand for hose bibbs or other large-demand fixtures taken off the building main frequently

results in inadequate water supply to the upper floor of a building. This condition can be prevented by sizing the distribution system so that the pressure drops from the street main to all fixtures are the same. An ample building main (not less than 1 in. where possible) should be maintained until all branches to hose bibbs have been connected. Where the street main pressure is excessive and a pressure reducing valve is used to prevent water hammer or excessive pressure at the fixtures, the hose bibbs should be connected ahead of the reducing valve.

The principles involved in sizing upfeed and downfeed systems are the same. In the downfeed system, however, the difference in elevation between the overhead supply mains and the fixtures provides the pressure required to overcome pipe friction. Because friction pressure loss and height pressure loss are not additive, as in an upfeed system, smaller pipes may be used with a downfeed system.

Plastic Pipe

The maximum safe water velocity in a thermoplastic piping system under most operating conditions is typically 5 fps; however, higher velocities can be used in cases where the operating characteristics of valves and pumps are known so that sudden changes in flow velocity can be controlled. The total pressure in the system at any time (operating pressure plus surge of water hammer) should not exceed 150% of the pressure rating of the system.

Procedure for Sizing Cold Water Systems

The recommended procedure for sizing piping systems is outlined below.

1. Sketch the main lines, risers, and branches, and indicate the fixtures to be served. Indicate the rate of flow of each fixture.
2. Using Table 13, compute the demand weights of the fixtures in fixture units.
3. Determine the total demand in fixture units and, using Figure 8, 9, or 10, find the expected demand.
4. Determine the equivalent length of pipe in the main lines, risers, and branches. Because the sizes of the pipes are not known, the exact equivalent length of various fittings cannot be determined. Add the equivalent lengths, starting at the street main and proceeding along the service line, the main line of the building, and up the riser to the top fixture of the group served.
5. Determine the average minimum pressure in the street main and the minimum pressure required for the operation of the topmost fixture, which should be 8 to 25 psi.
6. Calculate the approximate design value of the average pressure drop per 100 ft of equivalent length of pipe determined in step 4.

$$\Delta p = (p_s - 0.434H - p_f - p_m)100/L \tag{11}$$

where

- Δp = average pressure loss per 100 ft of equivalent length of pipe, psi
- p_s = pressure in street main, psig
- p_f = minimum pressure required to operate topmost fixture, psig
- p_m = pressure drop through water meter, psi
- H = height of highest fixture above street main, ft
- L = equivalent length determined in step 4, ft

If the system is downfeed supply from a gravity tank, height of water in the tank, converted to psi by multiplying by 0.434, replaces the street main pressure, and the term 0.434H is added instead of subtracted in calculating Δp . In this case, H is the vertical distance of the fixture below the bottom of the tank.

7. From the expected rate of flow determined in step 3 and the value of Δp calculated in step 6, choose the sizes of pipe from Figure 4, 5, or 6.

Example 7. Assume a minimum street main pressure of 55 psig; a height of topmost fixture (a urinal with flush valve) above street main of 50 ft; an equivalent pipe length from water main to highest fixture of 100 ft; a total load on the system of 50 fixture units; and that the water closets are flush valve operated. Find the required size of supply main.

Solution: From Figure 10, the estimated peak demand is 51 gpm. From Table 12, the minimum pressure required to operate the topmost fixture is 15 psig. For a trial computation, choose the 1-1/2 in. meter. From Figure 11, the pressure drop through a 1-1/2 in. disk-type meter for a flow of 51 gpm is 6.5 psi.

The pressure drop available for overcoming friction in pipes and fittings is $55 - 0.434 \times 50 - 15 - 6.5 = 12$ psi.

At this point, estimate the equivalent pipe length of the fittings on the direct line from the street main to the highest fixture. The exact equivalent length of the various fittings cannot be determined since the pipe sizes of the building main, riser, and branch leading to the highest fixture are not yet known, but a first approximation is necessary to tentatively select pipe sizes. If the computed pipe sizes differ from those used in determining the equivalent length of pipe fittings, a recalculation using the computed pipe sizes for the fittings will be necessary. For this example, assume that the total equivalent length of the pipe fittings is 50 ft.

The permissible pressure loss per 100 ft of equivalent pipe is $12 \times 100/(100 + 50) = 8$ psi or 18 ft/100 ft. A 1-1/2 in. building main is adequate.

The sizing of the branches of the building main, the risers, and the fixture branches follows these principles. For example, assume that one of the branches of the building main carries the cold water supply for 3 water closets, 2 bathtubs, and 3 lavatories. Using the permissible pressure loss of 8 psi per 100 ft, the size of branch (determined from Table 13 and Figures 4 and 10) is found to be 1-1/2 in. Items included in the computation of pipe size are as follows:

Fixtures, No. and Type	Fixture Units (Table 13 and Note c)	Demand (Figure 10)	Pipe Size (Figure 4)
3 flush valves	$3 \times 6 = 18$		
2 bathtubs	$0.75 \times 2 \times 2 = 3$		
3 lavatories	$0.75 \times 3 \times 1 = 2.25$		
Total	$= 23.25$	38 gpm	1-1/2 in.

Table 14 is a guide to minimum pipe sizing where flush valves are used.

Velocities exceeding 10 fps cause undesirable noise in the piping system. This usually governs the size of larger pipes in the system, while in small pipe sizes, the friction loss usually governs the selection because the velocity is low compared to friction loss. Velocity is the governing factor in downfeed systems, where friction loss is usually neglected. Velocity in branches leading to pump suction should not exceed 5 fps.

If the street pressure is too low to adequately supply upper-floor fixtures, the pressure must be increased. Constant or variable speed booster pumps, alone or in conjunction with gravity supply tanks, or hydropneumatic systems may be used.

Flow control valves for individual fixtures under varying pressure conditions automatically adjust the flow at the fixture to a predetermined quantity. These valves allow the designer to (1) limit the flow at the individual outlet to the minimum suitable for the

Table 14 Allowable Number of 1 in. Flush Valves Served by Various Sizes of Water Pipe*

Pipe Size, in.	No. of 1 in. Flush Valves
1-1/4	1
1-1/2	2-4
2	5-12
2-1/2	13-25
3	26-40
4	41-100

*Two 3/4 in. flush valves are assumed equal to one 1 in. flush valve but can be served by a 1 in. pipe. Water pipe sizing must consider demand factor, available pressure, and length of run.

purpose, (2) hold the total demand for the system more closely to the required minimum, and (3) design the piping system as accurately as is practicable for the requirements.

STEAM PIPING

Pressure losses in steam piping for flows of dry or nearly dry steam are governed by Equations (1) through (7) in the section on Pressure Drop Equations. This section incorporates these principles with other information specific to steam systems.

Pipe Sizes

Required pipe sizes for a given load in steam heating depend on the following factors:

- The initial pressure and the total pressure drop that can be allowed between the source of supply and the end of the return system
- The maximum velocity of steam allowable for quiet and dependable operation of the system, taking into consideration the direction of condensate flow
- The equivalent length of the run from the boiler or source of steam supply to the farthest heating unit

Initial Pressure and Pressure Drop. Table 15 lists pressure drops commonly used with corresponding initial steam pressures for sizing steam piping.

Several factors, such as initial pressure and pressure required at the end of the line, should be considered, but it is most important that (1) the total pressure drop does not exceed the initial gage pressure of the system (and in practice it should never exceed one-half the initial gage pressure); (2) the pressure drop is not great enough to cause excessive velocities; (3) a constant initial pressure

Table 15 Pressure Drops Used for Sizing Steam Pipe*

Initial Steam Pressure, psig	Pressure Drop per 100 ft	Total Pressure Drop in Steam Supply Piping
Vacuum return	2 to 4 oz/in ²	1 to 2 psi
0	0.5 oz/in ²	1 oz/in ²
1	2 oz/in ²	1 to 4 oz/in ²
2	2 oz/in ²	8 oz/in ²
5	4 oz/in ²	1.5 psi
10	8 oz/in ²	3 psi
15	1 psi	4 psi
30	2 psi	5 to 10 psi
50	2 to 5 psi	10 to 15 psi
100	2 to 5 psi	15 to 25 psi
150	2 to 10 psi	25 to 30 psi

*Equipment, control valves, and so forth must be selected based on delivered pressures.

is maintained, except on systems specially designed for varying initial pressures (e.g., subatmospheric pressure), which normally operate under controlled partial vacuums; and (4) for gravity return systems, the pressure drop to the heating units does not exceed the water column available for removing condensate (i.e., the height above the boiler water line of the lowest point on the steam main, on the heating units, or on the dry return).

Maximum Velocity. For quiet operation, steam velocity should be 8000 to 12,000 fpm, with a maximum of 15,000 fpm. The lower the velocity, the quieter the system. When the condensate must flow against the steam, even in limited quantity, the velocity of the steam must not exceed limits above which the disturbance between the steam and the counterflowing water may (1) produce objectionable sound, such as water hammer, or (2) result in the retention of water in certain parts of the system until the steam flow is reduced sufficiently to permit the water to pass. The velocity at which these disturbances take place is a function of (1) pipe size; (2) the pitch of the pipe if it runs horizontally; (3) the quantity of condensate flowing against the steam; and (4) the freedom of the piping from water pockets that, under certain conditions, act as a restriction in pipe size. Table 16 lists maximum capacities for various size steam lines.

Equivalent Length of Run. All tables for the flow of steam in pipes based on pressure drop must allow for pipe friction, as well as for the resistance of fittings and valves. These resistances are generally stated in terms of straight pipe; that is, a certain fitting produces a drop in pressure equivalent to the stated length of straight run of the same size of pipe. Table 17 gives the length of straight pipe usually allowed for the more common types of fittings and valves. In all pipe sizing tables in this chapter, the *length of run* refers to the *equivalent length of run* as distinguished from the *actual length* of pipe. A common sizing method is to assume the length of run and to check this assumption after pipes are sized. For this purpose, the length of run is usually assumed to be double the actual length of pipe.

Example 8. Using Table 17, determine the equivalent length in feet of pipe for the run illustrated.

Measured length	=	132.0 ft
4 in. gate valve	=	1.9 ft
Four 4 in. elbows	=	36.0 ft
Two 4 in. tees	=	36.0 ft
Equivalent	=	205.9 ft

Sizing Charts

Figure 13 is the basic chart for determining the flow rate and velocity of steam in Schedule 40 pipe for various values of pressure drop per 100 ft, based on 0 psig saturated steam. Using the multiplier chart (Figure 14), Figure 13 can be used at all saturation pressures between 0 and 200 psig (see Example 10).

Figures 13A through 13D present charts for sizing steam piping for systems of 30, 50, 100, and 150 psig at various pressure drops. These charts are based on the Moody friction factor, which considers the Reynolds number and the roughness of the internal pipe surfaces; they contain the same information as the basic chart (Figure 13) but in a more convenient form.

LOW-PRESSURE STEAM PIPING

Values in Table 18 (taken from Figure 13) provide a more rapid means of selecting pipe sizes for the various pressure drops listed and for systems operated at 3.5 and 12 psig. The flow rates shown for 3.5 psig can be used for saturated pressures from 1 to 6 psig, and those shown for 12 psig can be used for saturated pressures from 8 to 16 psig with an error not exceeding 8%.

Both Figure 13 and Table 18 can be used where the flow of condensate does not inhibit the flow of steam. Columns B and C of Table 19 are used in cases where steam and condensate flow in opposite directions, as in risers or runouts that are not dripped. Columns D, E, and F are for one-pipe systems and include risers, radiator valves and vertical connections, and radiator and riser runout sizes, all of which are based on the critical velocity of the steam to permit the counterflow of condensate without noise.

Return piping can be sized using Table 20, in which pipe capacities for wet, dry, and vacuum return lines are shown for several values of pressure drop per 100 ft of equivalent length.

Example 9. What pressure drop should be used for the steam piping of a system if the measured length of the longest run is 500 ft, and the initial pressure must not exceed 2 psig?

Solution: It is assumed, if the measured length of the longest run is 500 ft, that when the allowance for fittings is added, the equivalent length of run does not exceed 1000 ft. Then, with the pressure drop not over one-half of the initial pressure, the drop could be 1 psi or less. With a pressure drop of 1 psi and a length of run of 1000 ft, the drop per 100 ft would be 0.1 psi; if the total drop were 0.5 psi, the drop per

100 ft would be 0.05 psi. In both cases, the pipe could be sized for a desired capacity according to Figure 13.

On completion of the sizing, the drop could be checked by taking the longest line and actually calculating the equivalent length of run from the pipe sizes determined. If the calculated drop is less than that assumed, the pipe size is adequate; if it is more, an unusual number of fittings is probably involved, and either the lines must be straightened, or the next larger pipe size must be tried.

HIGH-PRESSURE STEAM PIPING

Many heating systems for large industrial buildings use high-pressure steam (15 to 150 psig). These systems usually have unit heaters or large built-up fan units with blast heating coils. Temperatures are controlled by a modulating or throttling thermostatic valve or by face or bypass dampers controlled by the room air temperature, fan inlet, or fan outlet.

Use of Basic and Velocity Multiplier Charts

Example 10. Given a flow rate of 6700 lb/h, an initial steam pressure of 100 psig, and a pressure drop of 11 psi/100 ft, find the size of Schedule 40 pipe required and the velocity of steam in the pipe.

Solution: The following steps are illustrated by the broken line on Figures 13 and 14.

1. Enter Figure 13 at a flow rate of 6700 lb/h, and move vertically to the horizontal line at 100 psig
2. Follow along inclined multiplier line (upward and to the left) to horizontal 0 psig line. The equivalent mass flow at 0 psig is about 2500 lb/h.
3. Follow the 2500 lb/h line vertically until it intersects the horizontal line at 11 psi per 100 ft pressure drop. Nominal pipe size is 2-1/2 in. The equivalent steam velocity at 0 psig is about 32,700 fpm.
4. To find the steam velocity at 100 psig, locate the value of 32,700 fpm on the ordinate of the velocity multiplier chart (Figure 14) at 0 psig.
5. Move along the inclined multiplier line (downward and to the right) until it intersects the vertical 100 psig pressure line. The velocity as read from the right (or left) scale is about 13,000 fpm.

Note: Steps 1 through 5 would be rearranged or reversed if different data were given.

STEAM CONDENSATE SYSTEMS

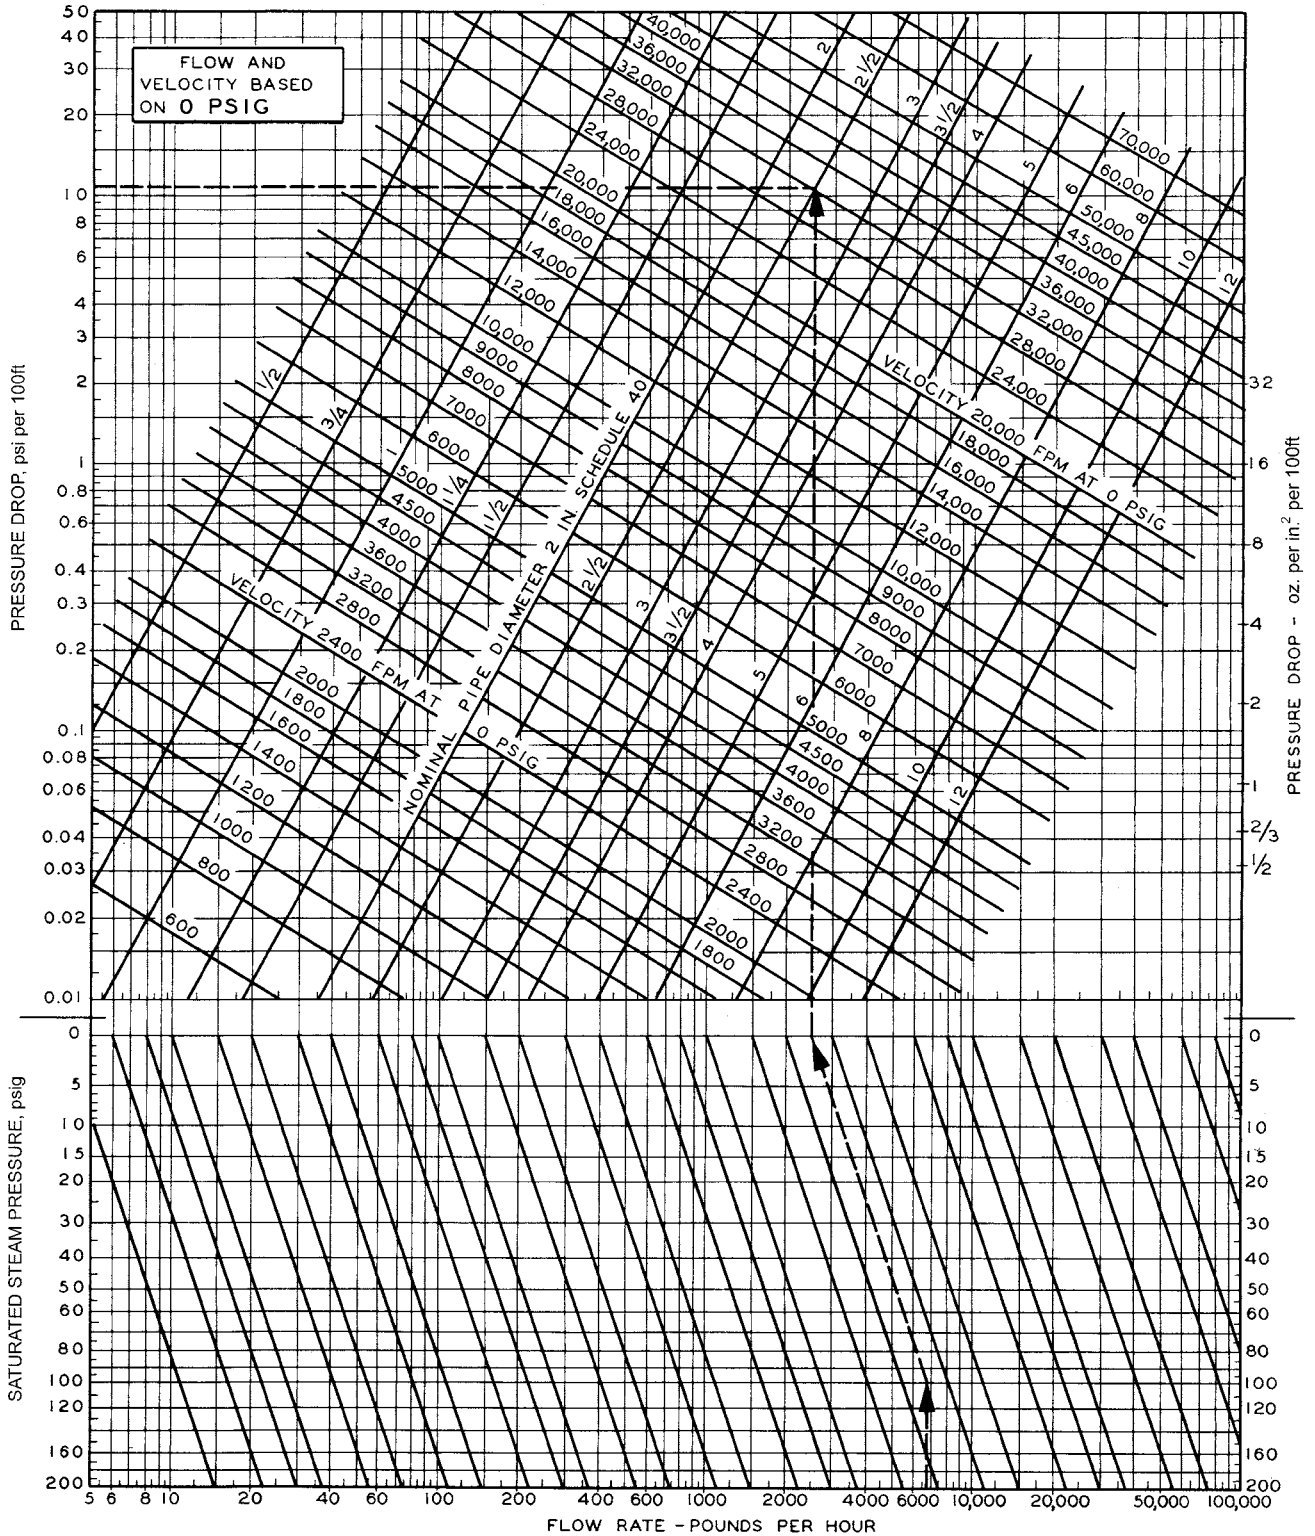

The majority of steam systems used in heating applications are two-pipe systems, in which the two pipes are the “steam” pipe and the “condensate” pipe. This discussion is limited to the sizing of the condensate lines in two-pipe systems.

Two-Pipe Systems

When steam is used for heating a liquid to 215°F or less (e.g., in domestic water heat exchangers, domestic heating water converters, or air-heating coils), the devices are usually provided with a steam control valve. As the control valve throttles, the absolute pressure in the load device decreases, removing all pressure motivation for flow in the condensate return system. In order to ensure the flow of steam condensate from the load device through the trap and into the return system, it is necessary to provide a vacuum breaker on the device ahead of the trap. This ensures a minimum pressure at the trap inlet of atmospheric pressure plus whatever liquid leg the designer has provided. Then, to ensure flow through the trap, it is necessary to design the condensate system so that it will never have a pressure above atmospheric in the condensate return line.

Vented (Open) Return Systems. To achieve this pressure requirement, the condensate return line is usually vented to the atmosphere (1) near the point of entrance of the flow streams from the load traps, (2) in proximity to all connections from drip traps, and (3) at transfer pumps or feedwater receivers.

With this design, the only motivation for flow in the return system is gravity. Return lines that are below the liquid level in the

Notes: Based on Moody Friction Factor where flow of condensate does not inhibit the flow of steam.
 See Figure 14 for obtaining flow rates and velocities of all saturation pressures between 0 and 200 psig; see also Examples 9 and 10.

Fig. 13 Flow Rate and Velocity of Steam in Schedule 40 Pipe at Saturation Pressure of 0 psig

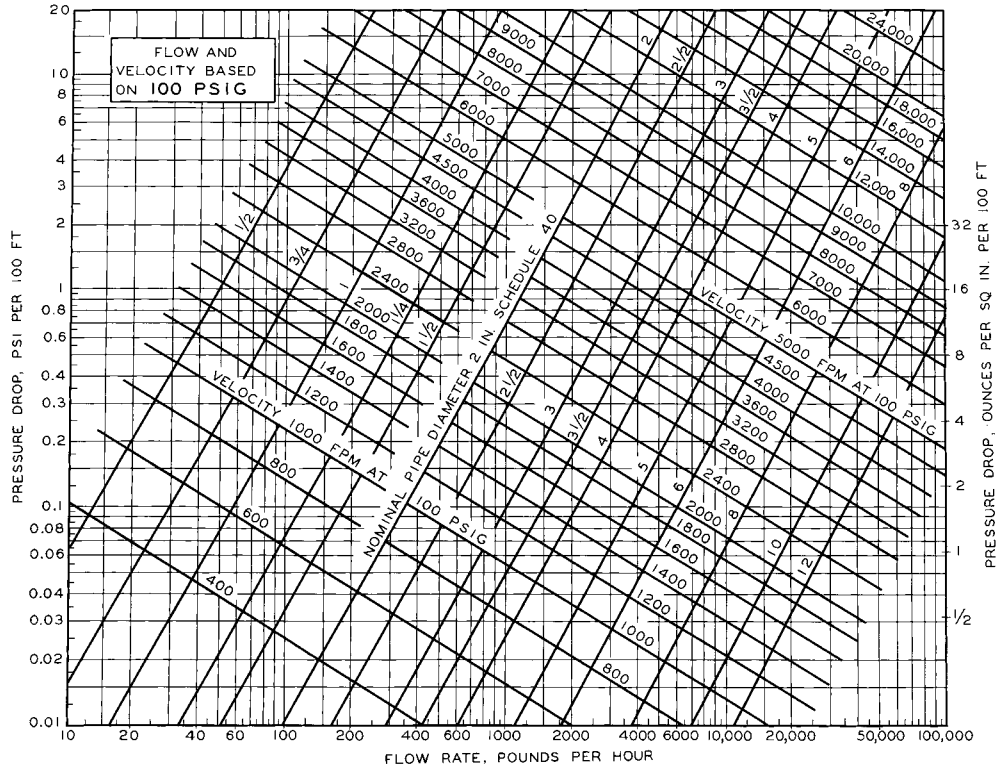

Notes: Based on Moody Friction Factor where flow of condensate does not inhibit the flow of steam.
 May be used for steam pressures from 23 to 37 psig with an error not exceeding 9%.

Fig. 13A Flow Rate and Velocity of Steam in Schedule 40 Pipe at Saturation Pressure of 30 psig

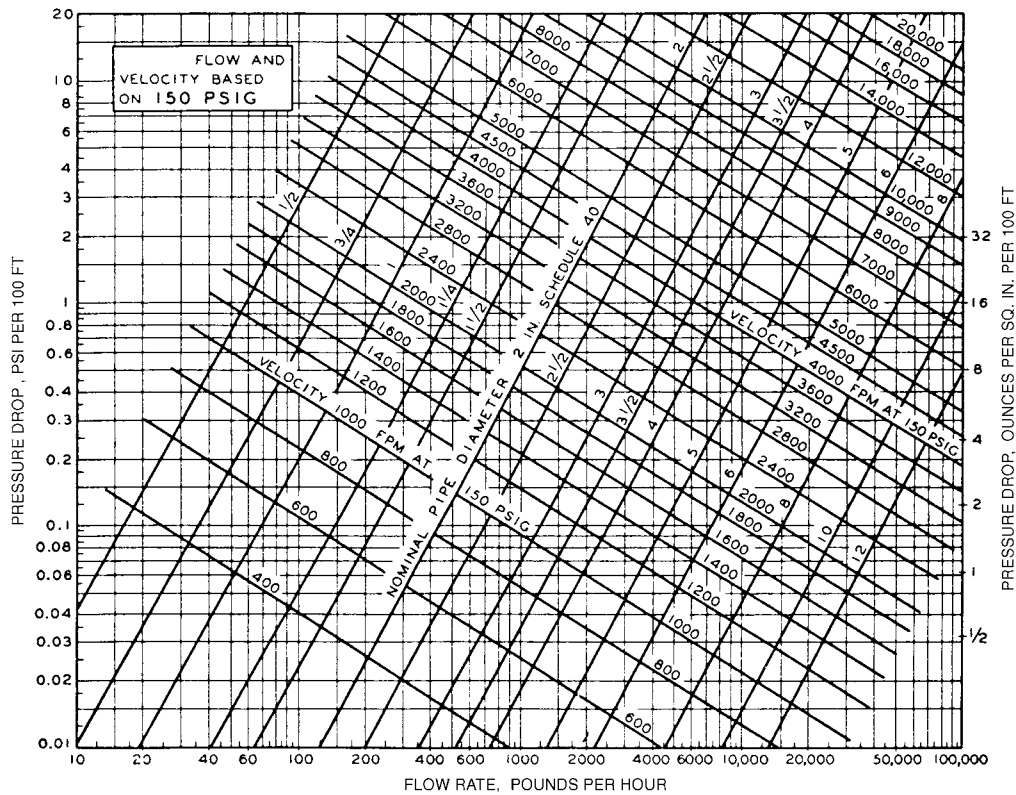

Notes: Based on Moody Friction Factor where flow of condensate does not inhibit the flow of steam.
 May be used for steam pressures from 40 to 60 psig with an error not exceeding 8%.

Fig. 13B Flow Rate and Velocity of Steam in Schedule 40 Pipe at Saturation Pressure of 50 psig

Notes: Based on Moody Friction Factor where flow of condensate does not inhibit the flow of steam. May be used for steam pressures from 85 to 120 psig with an error not exceeding 8%.

Fig. 13C Flow Rate and Velocity of Steam in Schedule 40 Pipe at Saturation Pressure of 100 psig

Notes: Based on Moody Friction Factor where flow of condensate does not inhibit the flow of steam. May be used for steam pressures from 127 to 180 psig with an error not exceeding 8%.

Notes:

1. Flow rate is in lb/h at initial saturation pressures of 3.5 and 12 psig. Flow is based on Moody friction factor, where the flow of condensate does not inhibit the flow of steam.

2. The flow rates at 3.5 psig cover saturated pressure from 1 to 6 psig, and the rates at 12 psig cover saturated pressure from 8 to 16 psig with an error not exceeding 8%.
 3. The steam velocities corresponding to the flow rates given in this table can be found from Figures 13 and 14.

Fig. 14 Velocity Multiplier Chart for Figure 13

downstream receiver or boiler and are thus filled with liquid and are called wet returns; those above the liquid level have both liquid and gas in the pipes and are called dry returns.

The dry return lines in a vented return system have flowing liquid in the bottom of the line and gas or vapor in the top (Figure 15A). The liquid is the condensate, and the gas may be steam, air, or a mixture of the two. The flow phenomenon for these dry return systems is open channel flow, which is best described by the **Manning equation**:

$$Q = \frac{1.49Ar^{2/3}S^{1/2}}{n} \quad (12)$$

where

- Q = volumetric flow rate, cfs
- A = cross-sectional area of conduit, ft²
- r = hydraulic radius of conduit, ft
- n = coefficient of roughness (usually 0.012)
- S = slope of conduit, ft/ft

Table 21 is a solution to Equation (12) that shows pipe size capacities for steel pipes with various pitches. Recommended practice is to size vertical lines by the maximum pitch shown, although they would actually have a capacity far in excess of that shown. As the pitch increases, hydraulic jump that could fill the pipe and other transient effects that could cause water hammer should be avoided. Flow values in Table 21 are calculated for Schedule 40 steel pipe, with a factor of safety of 3.0, and can be used for copper pipes of the same nominal pipe size.

The flow characteristics of **wet return lines** (Figure 15B) are best described by the Darcy-Weisbach equation [Equation (1)]. The motivation for flow is the fluid head difference between the entering section of the flooded line and the leaving section. It is common practice, in addition to providing for the fluid head differential, to slope the return in the direction of flow to a collection point such as a dirt leg in order to clear the line of sediment or solids. Table 22 is a solution to Equation (1) that shows pipe size capacity for steel

Table 21 Vented Dry Condensate Return for Gravity Flow Based on Manning Equation

^a Flow is in lb/h of 180°F water for Schedule 40 steel pipes.

^b Flow was calculated from Equation (12) and rounded.

pipes with various available fluid heads. Table 22 can also be used for copper tubing of equal nominal pipe size.

Nonvented (Closed) Return Systems. For those systems in which there is a continual steam pressure difference between the point where the condensate enters the line and the point where it leaves (Figure 15C), Table 20 or Table 23, as applicable, can be used for sizing the condensate lines. Although these tables express condensate capacity without slope, common practice is to slope the lines in the direction of flow to a collection point similar to wet returns to clear the lines of sediment or solids.

When saturated condensate at pressures above the return system pressure enters the return (condensate) mains, some of the liquid flashes to steam. This occurs typically at drip traps into a vented return system or at load traps leaving process load devices that are not valve-controlled and typically have no subcooling. If the return

Fig. 15 Types of Condensate Return Systems

main is vented, the vent lines will relieve any excessive pressure and prevent a back pressure phenomenon that could restrict the flow through traps from valved loads; the pipe sizing would be as described above for vented dry returns. If the return line is not vented, the flash steam results in a pressure rise at that point and the piping could be sized as described above for closed returns, and in accordance with Table 20 or Table 23, as applicable.

The passage of the fluid through the steam trap is a throttling or constant enthalpy process. The resulting fluid on the downstream side of the trap can be a mixture of saturated liquid and vapor. Thus, in nonvented returns, it is important to understand the condition of the fluid when it enters the return line from the trap.

The condition of the condensate downstream of the trap can be expressed by the quality x , defined as

$$x = \frac{m_v}{m_l + m_v} \tag{13}$$

where

- m_v = mass of saturated vapor in condensate
- m_l = mass of saturated liquid in condensate

Fig. 16 Working Chart for Determining Percentage of Flash Steam (Quality)

Likewise, the volume fraction V_c of the vapor in the condensate is expressed as

$$V_c = \frac{V_v}{V_l + V_v} \tag{14}$$

where

- V_v = volume of saturated vapor in condensate
- V_l = volume of saturated liquid in condensate

The quality and the volume fraction of the condensate downstream of the trap can be estimated from Equations (13) and (14), respectively.

$$x = \frac{h_1 - h_{f_2}}{h_{g_2} - h_{f_2}} \tag{15}$$

$$V_c = \frac{xv_{g_2}}{v_{f_2}(1-x) + xv_{g_2}} \tag{16}$$

where

- h_1 = enthalpy of liquid condensate entering trap evaluated at supply pressure for saturated condensate or at saturation pressure corresponding to temperature of subcooled liquid condensate
- h_{f_2} = enthalpy of saturated liquid at return or downstream pressure of trap
- h_{g_2} = enthalpy of saturated vapor at return or downstream pressure of trap
- v_{f_2} = specific volume of saturated liquid at return or downstream pressure of trap
- v_{g_2} = specific volume of saturated vapor at return or downstream pressure of trap.

Table 24 presents some values for quality and volume fraction for typical supply and return pressures in heating and ventilating systems. Note that the percent of vapor on a mass basis x is small, while the percent of vapor on a volume basis V_c is very large. This indicates that the return pipe cross section is predominantly occupied by vapor. Figure 16 is a working chart to determine the quality of the condensate entering the return line from the trap for various combinations of supply and return pressures. If the liquid is subcooled entering the trap, the saturation pressure corresponding to the liquid temperature should be used for the supply or upstream pressure. Typical pressures in the return line are given in Table 25.

One-Pipe Systems

Gravity one-pipe air vent systems in which steam and condensate flow in the same pipe, frequently in opposite directions, are considered obsolete and are no longer being installed. Chapter 33

of the 1993 *ASHRAE Handbook—Fundamentals* or earlier ASHRAE Handbook volumes include descriptions of and design information for one-pipe systems.

GAS PIPING

Piping for gas appliances should be of adequate size and installed so that it provides a supply of gas sufficient to meet the maximum demand without undue loss of pressure between the

point of supply (the meter) and the appliance. The size of gas pipe required depends on (1) maximum gas consumption to be provided, (2) length of pipe and number of fittings, (3) allowable pressure loss from the outlet of the meter to the appliance, and (4) specific gravity of the gas.

Gas consumption in ft³/h is obtained by dividing the Btu input rate at which the appliance is operated by the average heating value of the gas in Btu/ft³. Insufficient gas flow from excessive pressure losses in gas supply lines can cause inefficient operation

of gas-fired appliances and sometimes create hazardous operations. Gas-fired appliances are normally equipped with a data plate giving information on maximum gas flow requirements or Btu input as well as inlet gas pressure requirements. The gas utility in the area of installation can give the gas pressure available at the utility's gas meter. Using the information, the required size of gas piping can be calculated for satisfactory operation of the appliance(s).

Table 26 gives pipe capacities for gas flow for up to 200 ft of pipe based on a specific gravity of 0.60. Capacities for pressures less than 1.5 psig may also be determined by the following equation from NFPA/IAS *National Fuel Gas Code*:

$$Q = 2313d^{2.623} \left(\frac{\Delta p}{CL} \right)^{0.541} \quad (17)$$

where

Q = flow rate at 60°F and 30 in. Hg, cfh

d = inside diameter of pipe, in.

Δp = pressure drop, in. of water

C = factor for viscosity, density, and temperature

$$= 0.00354(t + 460)^{0.848} \mu^{0.152}$$

t = temperature, °F

s = ratio of density of gas to density of air at 60°F and 30 in. Hg

μ = viscosity of gas, centipoise (0.012 for natural gas, 0.008 for propane)

L = pipe length, ft

Gas service in buildings is generally delivered in the "low-pressure" range of 7 in. of water. The maximum pressure drop allowable in piping systems at this pressure is generally 0.5 in. of water but is subject to regulation by local building, plumbing, and gas appliance codes (see also the NFPA/IAS *National Fuel Gas Code*).

Where large quantities of gas are required or where long lengths of pipe are used (e.g., in industrial buildings), low-pressure limitations result in large pipe sizes. Local codes may allow and local gas companies may deliver gas at higher pressures (e.g., 2, 5, or 10 psig). Under these conditions, an allowable pressure drop of 10% of the initial pressure is used, and pipe sizes can be reduced significantly. Gas pressure regulators at the appliance must be specified to accommodate higher inlet pressures. NFPA/IAS (1992) provides information on pipe sizing for various inlet pressures and pressure drops at higher pressures.

More complete information on gas piping can be found in the *Gas Engineers' Handbook* (1970).

FUEL OIL PIPING

The pipe used to convey fuel oil to oil-fired appliances must be large enough to maintain low pump suction pressure and, in the case of circulating loop systems, to prevent overpressure at the burner oil pump inlet. Pipe materials must be compatible with the fuel and must be carefully assembled to eliminate all leaks. Leaks in suction lines cause pumping problems that result in unreliable burner operation. Leaks in pressurized lines create fire hazards. Cast-iron or aluminum fittings and pipe are unacceptable. Pipe joint compounds must be selected carefully.

Oil pump suction lines should be sized so that at maximum suction line flow conditions, the maximum vacuum will not exceed 10 in. Hg for distillate grade fuels and 15 in. Hg for residual oils. Oil supply lines to burner oil pumps should not be pressurized by circulating loop systems or aboveground oil storage tanks to more than 5 psi, or pump shaft seals may fail. A typical oil circulating loop system is shown in Figure 17.

In assembling long fuel pipe lines, care should be taken to avoid air pockets. On overhead circulating loops, the line should vent air at all high points. Oil supply loops for one or more burners should

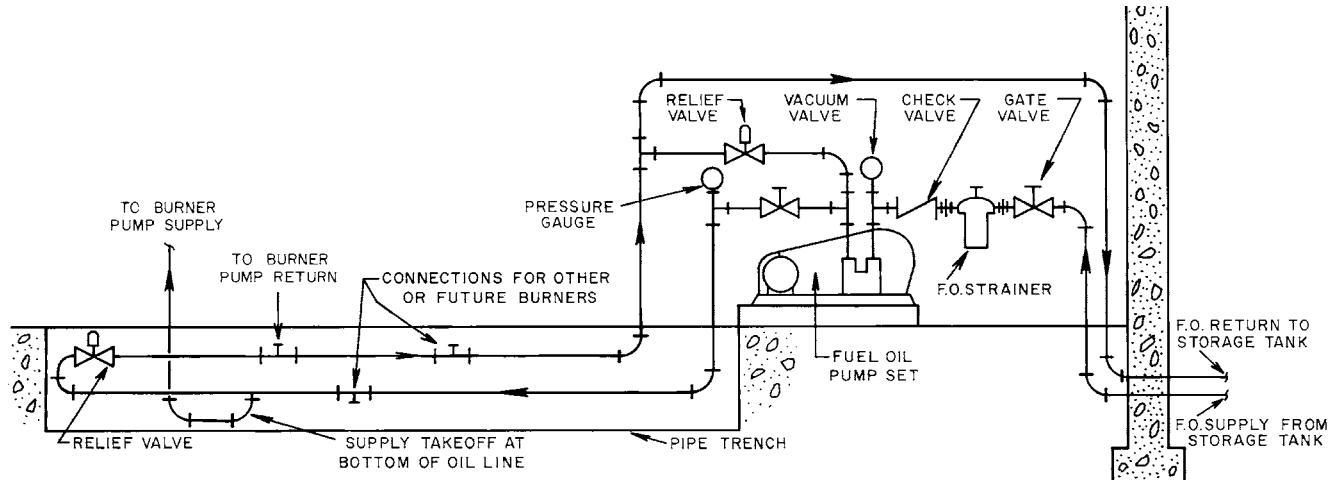

Fig. 17 Typical Oil Circulating Loop

70	1-1/2	2	2	2	2-1/2	2-1/2	2-1/2	2-1/2	3	3
100	2	2	2	2-1/2	2-1/2	3	3	3	3	3
130	2	2	2-1/2	2-1/2	2-1/2	3	3	3	3	4
160	2	2	2-1/2	2-1/2	2-1/2	3	3	3	4	4
190	2	2-1/2	2-1/2	2-1/2	3	3	3	4	4	4
220	2-1/2	2-1/2	2-1/2	3	3	3	4	4	4	4

Notes:

1. Pipe sizes smaller than 1 in. IPS are not recommended for use with residual grade fuel oils.
2. Lines conveying fuel oil from pump discharge port to burners and tank return may be reduced by one or two sizes, depending on piping length and pressure losses.

be the continuous circulation type, with excess fuel returned to the storage tank. Dead-ended pressurized loops can be used, but air or vapor venting is more problematic.

Where valves are used, select ball or gate valves. Globe valves are not recommended because of their high pressure drop characteristics.

Oil lines should be tested after installation, particularly if they are buried, enclosed, or otherwise inaccessible. Failure to perform this test is a frequent cause of later operating difficulties. A suction line can be hydrostatically tested at 1.5 times its maximum operating pressure or at a vacuum of not less than 20 in. Hg. Pressure or vacuum tests should continue for at least 60 min. If there is no noticeable drop in the initial test pressure, the lines can be considered tight.

Pipe Sizes for Heavy Oil

Tables 27 and 28 give recommended pipe sizes for handling No. 5 and No. 6 oils (residual grades) and No. 1 and No. 2 oils (distillate grades), respectively.

Storage tanks and piping and pumping facilities for delivering the oil from the tank to the burner are important considerations in the design of an industrial oil-burning system.

The construction and location of the tank and oil piping are usually subject to local regulations and National Fire Protection Association (NFPA) Standards 30 and 31.

CHAPTER 23

INSULATION FOR MECHANICAL SYSTEMS

<i>Design Considerations</i>	23.1
<i>Materials and Systems</i>	23.7
<i>Installation</i>	23.10
<i>Design Data</i>	23.15
<i>Project Specifications</i>	23.17

THIS chapter deals with applications of thermal and acoustical insulation for mechanical systems in residential, commercial, and industrial facilities. Applications include pipes, tanks, vessels and equipment, and ducts.

Thermal insulation is primarily used to limit heat gain or loss from surfaces operating at temperatures above or below ambient temperature. Insulation may be used to satisfy one or more of the following design objectives:

- **Energy conservation:** minimizing unwanted heat loss/gain from building HVAC systems, as well as preserving natural and financial resources
- **Personnel protection:** controlling surface temperatures to avoid contact burns (hot or cold)
- **Condensation control:** minimizing condensation by keeping surface temperature above the dew point of surrounding air
- **Process control:** minimizing temperature change in process fluids where close control is needed
- **Freeze protection:** minimizing energy required for heat tracing systems and/or extending the time to freezing in the event of system failure
- **Noise control:** reducing/controlling noise in mechanical systems
- **Fire safety:** protecting critical building elements and slowing the spread of fire in buildings

Fundamentals of thermal insulation are covered in Chapter 25; applications in insulated assemblies are discussed in Chapter 27; and data on thermal and water vapor transmission data are in Chapter 26.

DESIGN CONSIDERATIONS

Energy Conservation

Thermal insulation is commonly used to reduce energy consumption of HVAC systems and equipment. Minimum insulation levels for ductwork and piping are often dictated by energy codes, many of which are based on ASHRAE *Standards* 90.1 and 90.2. In many cases, it may be cost-effective to go beyond the minimum levels dictated by energy codes. Thicknesses greater than the optimum economic thickness may be required for other technical reasons such as condensation control, personnel protection, or noise control.

Tables 1 to 3 contain minimum insulation levels for ducts and pipes, excerpted from ANSI/ASHRAE *Standard* 90.1-2007, Energy Standard for Buildings Except Low-Rise Residential Buildings.

Interest in **green buildings** (i.e., those that are environmentally responsible and energy efficient, as well as healthier places to work) is increasing. The LEED® (Leadership in Energy and Environmental Design) Green Building Rating System™, created by the U.S. Green Building Council, is a voluntary rating system that sets out sustainable design and performance criteria for buildings. It evaluates environmental performance from a whole-building perspective and awards points based on satisfying performance criteria in several different

Fig. 1 Determination of Economic Thickness of Insulation

categories. Different levels of green building certification are awarded based on the total points earned. The role of mechanical insulation in reducing energy usage, along with the associated greenhouse gas emissions, can help to contribute to LEED certification and should be considered when designing an insulation system.

Economic Thickness

Economics can be used to (1) select the optimum insulation thickness for a specific insulation, or (2) evaluate two or more insulation materials for least cost for a given level of thermal performance. In either case, economic considerations determine the most cost-effective solution for insulating over a specific period.

Life-cycle costing considers the initial cost of the insulation system plus the ongoing value of energy savings over the expected service lifetime. The economic thickness is defined as the thickness that minimizes the total life-cycle cost.

Labor and material costs of installed insulation increase with thickness. Insulation is often applied in multiple layers (1) because materials are not manufactured in single layers of sufficient thickness and, (2) in many cases, to accommodate expansion and contraction of insulation and system components. Figure 1 shows installed costs for a multilayer application. The slope of the curves is discontinuous and increases with the number of layers because labor and material costs increase more rapidly as thickness increases. Figure 1 shows curves of total annual costs of operation, insulation costs, and lost energy costs. Point A on the total cost

The preparation of this chapter is assigned to TC 1.8, Mechanical Systems Insulation.

^aFor insulation outside the stated conductivity range, the minimum thickness (*T*) shall be determined as follows:

$$T = r\{(1 + t/r)K/k - 1\}$$

where *T* = minimum insulation thickness (in.), *r* = actual outside radius of pipe (in.), *t* = insulation thickness listed in this table for applicable fluid temperature and pipe size, *K* = conductivity of alternate material at mean rating temperature indicated for the applicable fluid temperature (Btu·in/h·ft²·°F); and *k* = the upper value of the conductivity range listed in this table for the applicable fluid temperature.

^bThese thicknesses are based on energy *efficiency* considerations only. Additional insulation is sometimes required relative to safety issues/surface temperature.

^cPiping insulation is not required between the control valve and coil on run-outs when the control valve is located within 4 ft of the coil and the pipe size is 1 in. or less.

^dThese thicknesses are based on energy *efficiency* considerations only. Issues such as water vapor permeability or surface condensation sometimes require vapor retarders or additional insulation.

curve corresponds to the economic insulation thickness, which, in this example, is in the double-layer range. Viewing the calculated economic thickness as a minimum thickness provides a hedge against unforeseen fuel price increases and conserves energy.

Initially, as insulation is applied, the total life-cycle cost decreases because the value of incremental energy savings is greater than the incremental cost of insulation. Additional insulation reduces total cost up to a thickness where the change in total cost is equal to zero. At this point, no further reduction can be obtained; beyond it, incremental insulation costs exceed the additional energy savings derived by adding another increment of insulation.

Economic analysis should also consider the time value of money, which can be based on a desired rate of return for the insulation investment. Energy costs are volatile, and a fuel cost inflation factor

is sometimes included to account for the possibility that fuel costs may increase more quickly than general inflation. Insulation system maintenance costs should also be included, along with cost savings associated with the ability to specify lower capacity equipment, resulting in lower first costs.

Chapter 36 of the 2007 *ASHRAE Handbook—HVAC Applications* has more information on economic analysis.

Personnel Protection

In many applications, insulation is provided to protect personnel from burns. The potential for burns to human skin is a complex function of surface temperature, surface material, and time of contact. ASTM *Standard C1055* has a good discussion of these factors. Standard industry practice is to specify a maximum temperature of 140°F

for surfaces that may be contacted by personnel. For indoor applications, maximum air temperatures depend on the facility and location, and are typically lower than design outdoor conditions. For outdoor installations, base calculations on summer design ambient temperatures with no wind (i.e., the worst case). Surface temperatures increase because of solar loading, but are usually neglected because of variability in orientation, solar intensity, and many other complicating factors. Engineering judgment must be used in selecting ambient and operating temperatures and wind conditions for these calculations.

Note that the choice of jacketing strongly affects a surface’s relative safety. Higher-emittance jacketing materials (e.g., plastic, painted metals) can be selected to minimize the surface temperature. Jacketing material also affects the relative safety at a given surface temperature. For example, at 175°F, a stainless steel jacket blisters skin more severely than a nonmetallic jacket at equal contact time.

Condensation Control

For cold systems, avoiding surface condensation often guides insulation system design. The design goal is to keep the surface temperature above the surrounding air’s dew-point temperature. Calculating surface temperature is relatively simple, but selection of design conditions is often confusing.

To illustrate, Table 4 shows insulation thickness required to prevent condensation on the exterior surface of an insulated tank containing a liquid held at 40°F located in a mechanical room with dry-bulb temperature of 80°F. Note that, at high relative humidities, the thickness required to prevent surface condensation increases dramatically, and becomes impractical above 90% rh.

For outdoor applications (or for unconditioned spaces vented to outdoor air), there are always some hours per year where the ambient air is saturated or nearly saturated. For these times, no amount of insulation will prevent surface condensation. Figure 2 shows the frequency distribution of outdoor relative humidity based on typical meteorological year weather data for Charlotte, NC (Marion and Urban 1995). There are over 1200 h per year when the relative humidity is equal to or greater than 90%, and nearly 600 h per year when the relative humidity is equal to or greater than 95%.

For outdoor applications and mechanical rooms vented to outdoor conditions, it is suggested to design for a relative humidity of 90% at the project’s design dew-point temperature. (Design dew-point data may be found in Chapter 14.) For Charlotte, the 0.4% design dew-point temperature is 74°F. Using a psychrometric chart, the 74°F dew-point temperature line intersects the 90% rh curve at a dry-bulb temperature of approximately 77°F. The recommended design condition for outdoor installations in Charlotte is therefore

Table 4 Insulation Thickness Required to Prevent Surface Condensation

Relative Humidity, %	Thickness, in.
20	—
30	0.1
40	0.2
50	0.3
60	0.5
70	0.7
80	1.3
90	2.9
95	6.0

Note: Calculated using Equation (14), assuming surface conductance of 1.2 Btu/h·ft²·°F and insulation with thermal conductivity of 0.30 Btu-in/h·ft²·°F. Different assumed values yield different results.

Fig. 2 Relative Humidity Histogram for Charlotte, NC

77°F db at 90% rh. Appropriate water-resistant vapor-retarder jacketing or mastics must then be specified to protect the system from the inevitable surface condensation.

Freeze Prevention

It is important to recognize that insulation retards heat flow; it does not stop it completely. If the surrounding air temperature remains low enough for an extended period, insulation cannot prevent freezing of still water or of water flowing at a rate insufficient for the available heat content to offset heat loss. Insulation can prolong the time required for freezing, or prevent freezing if flow is maintained at a sufficient rate. To calculate time θ (in hours) required for water to cool to 32°F with no flow, use the following equation:

Fig. 3 Time to Freeze Nomenclature

$$\theta = \rho C_p \pi (D_1/2)^2 R_T \ln[(t_i - t_a)/(t_f - t_a)] \quad (1)$$

where

- θ = time to freezing, h
- ρ = density of water = 62.4 lb/ft³
- C_p = specific heat of water = 1.0 Btu/lb · °F
- D_1 = inside diameter of pipe, ft (see Figure 3)
- R_T = combined thermal resistance of pipe wall, insulation, and exterior air film (for a unit length of pipe)
- t_i = initial water temperature, °F
- t_a = ambient air temperature, °F
- t_f = freezing temperature, °F

As a conservative assumption for insulated pipes, thermal resistances of pipe walls and exterior air film are usually neglected. Resistance of the insulation layer for a unit length of pipe is calculated as

$$R_T = 12 \ln(D_3/D_2) / (2\pi k) \quad (2)$$

where

- D_3 = outer diameter of insulation, ft
- D_2 = inner diameter of insulation, ft
- k = thermal conductivity of insulation material, Btu · in/ft² · °F

Table 5 shows estimated time to freezing, calculated using these equations for the specific case of still water with $t_i = 42^\circ\text{F}$ and $t_a = -18^\circ\text{F}$.

When unusual conditions make it impractical to maintain protection with insulation or flow, a hot trace pipe or electric resistance heating cable is required along the bottom or top of the water pipe. The heating system then supplies the heat lost through the insulation.

Clean water in pipes usually supercools several degrees below freezing before any ice is formed. Then, upon nucleation, dendritic ice forms in the water and the temperature rises to freezing. Ice can be formed from water only by the release of the latent heat of fusion (144 Btu/lb) through the pipe insulation. Well-insulated pipes may greatly retard this release of latent heat. Gordon (1996) showed that water pipes burst not because of ice crystal growth in the pipe, but because of elevated fluid pressure within a confined pipe section occluded by a growing ice blockage.

Noise Control

Duct Insulation. Without insulation, the acoustical environment of mechanically conditioned buildings can be greatly compromised, resulting in reduced productivity and a decrease in occupant comfort. HVAC ducts act as conduits for mechanical equipment noise, and also carry office noise between occupied spaces. Additionally, some ducts can create their own noise through duct wall vibrations or expansion and contraction. Lined sheet metal ducts and fibrous glass rigid ducts can greatly reduce transmission of HVAC noise

Table 5 Time to Cool Water to Freezing, h

Nominal Pipe Size, NPS	Insulation Thickness, in.					
	0.5	1	1.5	2	3	4
1/2	0.1	0.2	0.2	0.3	—	—
1	0.3	0.4	0.5	0.6	0.8	—
1 1/2	0.4	0.8	1.0	1.3	1.5	—
2	0.6	1.1	1.4	1.7	2.2	2.5
3	0.9	1.7	2.3	2.9	3.7	4.5
4	1.3	2.4	3.3	4.1	5.5	6.6

6	1.9	3.7	5.3	6.9	9.4	11.7
8	—	5.3	7.6	9.6	13.7	16.9
10	—	6.5	10.2	12.9	17.9	22.3
12	—	8.8	12.5	15.8	22.1	27.7

Note: Assumes initial temperature = 42°F, ambient air temperature = -18°F, and insulation thermal conductivity = 0.30 Btu · in/h · ft² · °F. Thermal resistances of pipe and air film are neglected. Different assumed values will yield different results.

through the duct system. The insulation also reduces cross-talk from one room to another through the ducts. A good discussion of duct acoustics is provided in Chapter 47 of the 2007 *ASHRAE Handbook—HVAC Applications*. Duct insulation can be used to provide both attenuation loss and breakout noise reduction.

Attenuation loss is noise absorbed within the duct. In uninsulated ducts, it is a function of duct geometry and dimensions as well as noise frequency. Internal insulation liners are generally available for most duct geometries. Chapter 47 in the 2007 *ASHRAE Handbook—HVAC Applications* provides attenuation losses for square, rectangular, and round ducts lined with fibrous glass, and also gives guidance on the use of insulation in plenums to absorb duct system noise. Internal linings can be very effective in fittings such as elbows, which can have 2 to 8 times more attenuation than an unlined elbow of the same size. For alternative lining materials, consult individual manufacturers.

It is difficult to write specifications for sound attenuation because it changes with every duct dimension and configuration. Thus, insulation materials are generally selected for attenuation based on sound absorption ratings. Sound absorption tests are run per ASTM *Standard C423* in large reverberation rooms with random sound incidence. The test specimens are laid on the chamber floor per ASTM *Standard E795*, Type A mounting. This mode of sound exposure is quite different from the exposure of internal linings installed in an air duct. Therefore, sound absorption ratings for materials can only be used for general comparisons of effectiveness when used in air ducts of varying dimensions (Kuntz and Hoover 1987).

Breakout noise is from vibration of the duct wall caused by air pressure fluctuations in the duct. Absorptive insulation can be used in combination with mass-loaded jacketings or mastics on the duct exterior to reduce breakout noise. This technique is only minimally effective on rectangular ducts, which require the insulation and mass composite to be physically separated from the duct wall to be very effective. For round ducts, as with pipes, absorptive insulation and mass composite can be effective even when directly applied to the duct surface. Chapter 47 in the 2007 *ASHRAE Handbook—HVAC Applications* provides breakout noise guidance data.

Noise Radiating from Pipes. Noise from piping can be reduced by adding an absorptive insulation and jacketing material. By knowing the sound insertion loss of insulation and jacketing material combinations, the expected level of noise reduction in the field can be estimated. A range of jacket weights and insulation thicknesses can be used to reduce noise. Jackets used to reduce noise are typically referred to as being mass-filled. Some products for outdoor applications use mass-filled vinyl (MFV) in combination with aluminum.

Pipe insertion loss is a measurement (in dB) of the reduction in sound pressure level from a pipe as a result of application of insulation and jacketing. Measured at different frequencies, the noise level from the jacketed pipe is subtracted from that of the bare pipe;

Table 6 Insertion Loss for Pipe Insulation Materials, dB

Pipe Size, NPS	Insulation Material	Insulation Thickness, in.	Jacket	Frequency, Hz			
				500	1000	2000	4000
6	Fibrous glass	2	ASJ ^a	2	9	14	16
			0.020 in. aluminum	3	16	24	33
		4	1 lb/ft ² MFV ^b with Al	13	20	32	40
			ASJ	4	21	27	33
	Flexible elastomeric	0.5	0.020 in. aluminum	3	17	27	42
			None	0	2	5	10
		1	None	0	2	5	10
			1 lb/ft ² MFV with Al	0	14	18	20
0.5	None	0	16	20	26		
	1 lb/ft ² MFV with Al	0	16	20	26

			0.016 in. aluminum	0	14	19	30

^aASJ = all-service jacket, a typical factory-applied vapor retarder applied to many products.
^bMFV = mass filled vinyl, a field-installed jacket, which has considerably more mass than ASJ.

Fig. 4 Insertion Loss Versus Weight of Jacket

the larger the insertion loss number, the larger the amount of noise reduction.

ASTM Standard E1222 describes how to determine insertion loss of pipe jacketing systems. A band-limited white noise test signal is produced inside a steel pipe located in a reverberation room, using a loudspeaker or acoustic driver at one end of the pipe to produce the noise. Average sound pressure levels are measured in the room for two conditions: with sound radiating from a bare pipe, and with the same pipe covered with a jacketing system. The insertion loss of the jacketing system is the difference in the sound pressure levels measured, adjusted for changes in room absorption caused by the jacketing system's presence. Results may be obtained in a series of 100 Hz wide bands or in one-third octave bands from 500 to 5000 Hz.

Table 6 gives measured insertion loss values for several pipe insulation and jacket combinations. The weight of the jacket material significantly affects insertion loss of pipe insulation systems. Figure 4 represents insertion loss of typical fibrous pipe insulations with various weights of jacketing (Miller 2001).

It is very important that sound sources be well identified in industrial settings. It is possible to treat a noisy pipe very effectively and have no significant influence on ambient sound measurement after treatment. Is it important that all sources of noise above desired levels receive acoustical treatment, beginning with the largest source, or no improvement will be observed.

Fire Safety

Materials used to insulate mechanical equipment generally must meet the requirements of local codes adopted by governmental

entities having jurisdiction over the project. In the United States, most local codes incorporate or are patterned after model codes developed and maintained by organizations such as the National Fire Protection Association (NFPA) and the more recent International Code Council (International Codes). Refer to local codes to determine specific requirements.

Most codes related to insulation product fire safety refer to the surface burning characteristics as determined by the Steiner tunnel test (ASTM Standard E84, NFPA Standard 255, UL Standard 723, or CAN/ULC Standard S-102). These similar test methods evaluate the flame spread and smoke developed from samples mounted in a 25 ft long tunnel and subsequently exposed to a controlled flame. Results are given in terms of *flame spread* and *smoke developed* indices, which are relative to a baseline index and calibration standards of inorganic reinforced cement board (0) and select grade red oak flooring (100). Samples are normally mounted with the exposed surface face down in the ceiling of the tunnel. Upon ignition, the progress of the flame front is timed while being tracked visually for distance down the tunnel, with the results used to calculate the flame spread index. Smoke index is determined by measuring smoke density with a light cell mounted in the exhaust stream.

Using supporting materials on the underside of the test specimen can lower the flame spread index. Materials that melt, drip, or delaminate to such a degree that the continuity of the flame front is destroyed give low flame spread indices that do not relate directly to indices obtained by testing materials that remain in place. Alternative means of testing may be necessary to fully evaluate some of these materials.

For pipe and duct insulation products, samples are prepared and mounted in the tunnel per ASTM Standard E2231, which directs that "the material, system, composite, or assembly tested shall be representative of the completed insulation system used in actual field installations, in terms of the components, including their respective thicknesses." Samples are constructed to mimic, as closely as possible, the products as they will be used, including any facings and adhesives as appropriate.

Duct insulation generally requires a flame spread index of not more than 25 and a smoke developed index of not more than 50, when tested in accordance with ASTM Standard E84. Codes often require factory-made duct insulations (e.g., insulated flexible ducts, rigid fibrous glass ducts) to be listed and labeled per UL Standard 181, Factory-Made Air Ducts and Air Connectors. This standard specifies a number of other fire tests (e.g., flame penetration and low-energy ignition) as part of the listing requirements.

Some building codes require that duct insulations meet the fire hazard requirements of NFPA *Standard* 90A or 90B, to restrict spread of smoke, heat, and fire through duct systems, and to minimize ignition sources. Local code authorities should also be consulted for specific requirements.

For pipe insulation, the requirement is generally a maximum flame spread index of 25 and a maximum smoke developed index of 450. For insulation materials exposed within supply and return ducts and plenums, the typical requirement is that the materials be noncombustible or have a maximum flame spread index of 25 and maximum smoke developed index of 50. Consult local code authorities for specific requirements.

The term *noncombustible*, as defined by building codes, refers to materials that pass the requirements of ASTM *Standard* E136. This test method involves introducing a small specimen of the material into a furnace initially maintained at a temperature of 1380°F. The temperature rise of the furnace is monitored and the specimen is observed for any flaming. Criteria for passing include limits on temperature rise, flaming, and weight loss of the specimen. Some building codes accept as noncombustible a composite material having a structural base of noncombustible material and a surfacing not more than 1/8 in. thick that has a flame spread index not greater than 50. A related term sometimes referenced in building codes is *limited combustible*, which is an intermediate category that considers the potential heat content of materials determined per the testing requirements of NFPA *Standard* 259.

Mechanical insulation materials are often used as a component in systems or assemblies designed to protect buildings and equipment from the effects or spread of fire (i.e., **fire-resistance assemblies**). They can include walls, roofs, floors, columns, beams, partitions, joints, and through-penetration fire stops. Specific designs are tested and assigned hourly ratings based on performance in full-scale fire tests. Note that insulation materials alone are not assigned hourly fire resistance ratings; ratings are assigned to a system or assembly that may include specific insulation products, along with other elements such as framing members, fasteners, wallboard, etc.

Fire resistance ratings are often developed using ASTM *Standard* E119. This test exposes assemblies (walls, partitions, floor or roof assemblies, and through-penetration fire stops) to a standard fire exposure controlled to achieve specified temperatures throughout a specified time period. The time-temperature curve is intended to be representative of building fires where the primary fuel is solid, and specifies a temperature of 1000°F at 5 min, 1700°F at 1 h, and 2300°F at 8 h. In the hydrocarbon processing industry, liquid hydrocarbon-fueled pool fires are a concern; fire resistance ratings for these applications are tested per ASTM *Standard* E1529. This time-temperature curve rises rapidly to a temperature of 2000°F within 5 min, and remains there for the duration of the test.

Fire-resistant rated designs can be found in the directories of listing agencies. Examples of such not-for-profit agencies include Underwriters Laboratories, Factory Mutual, and UL Canada.

The following standard cross-references are provided for products to be tested in Canada. Although these are parallel Canadian standards, the requirements may differ from those of ASTM standards.

Corrosion Under Insulation

Corrosion of metal pipe, vessels, and equipment under insulation, though not typically caused by the insulation, is still a significant issue that must be considered during the design of any mechanical insulation system. The propensity for corrosion depends on many factors, including the ambient environment and operating temperature of the metal.

Corrosion under insulation (CUI) is most prevalent in outdoor industrial environments such as refineries and chemical plants. Corrosion can be very costly because of forced downtime of processes and can be a health and safety hazard as well. Although insulation itself may not necessarily be the cause of corrosion, it can be a passive component because it is in direct contact with the pipe or equipment surface.

Very little information is published regarding commercial environments. It is not likely that corrosion is a major concern for most insulated surfaces located indoors. Corrosion under insulation could be a concern on indoor systems that are frequently washed down, such as in the food processing industry.

Water from condensation on cold surfaces can be present on both indoor and outdoor insulation systems if there is damage to the vapor retarder. Hot processes can also be subject to condensation during periods of system shutdown.

The following factors may lead to corrosion under insulation.

- **Water** must be present. Water ingress may occur at some point on insulated outdoor surfaces. The entry point for water is through breaks in weatherproofing materials such as mastic, caulk, or adhesives.
- A general lack of **inspection and maintenance** increases the potential for corrosion.
- **Temperature** affects the rate of corrosion. In general, higher temperatures increase the corrosion rate.
- **Contaminants** in the plant environment can accelerate corrosion. For instance, chlorides or sulfates could reside on the insulation's exterior jacket, then be washed into the insulation system by rain or washdown. Other sources of chloride ions include rainwater, ocean mist, and cooling tower spray, each of which can provide a major and virtually inexhaustible supply of ions. Even if the level of chloride ions in the water is low, significant amounts of ions can accumulate at the pipe surface by a continuing cycle of water penetrations and evaporation. Chloride ions only contribute to stress corrosion cracking of stainless steel when water (liquid or vapor) and the ions are present at the surface of a pipe at temperatures above ambient, usually when the surface is above about 140°F and below about 300°F. Exposure of the insulation system to water from some outside source is inevitable, so the key to eliminating stress corrosion cracking lies in preventing moisture and ions, even in small amounts, from reaching the metal surface.
- **Insulation** can contain leachable corrosive agents.
- **Austenitic stainless steels** are particularly susceptible to attack from chlorides. Austenitic stainless steels are generally classified as "18-8s": austenitic alloys containing approximately 18% chromium, 8% nickel, and the balance iron. Besides the basic alloy UNS S30400, these stainless alloys include molybdenum (UNS S31600 and S31700), carbon-stabilized (UNS S321000 and S347000), and low-carbon grades (UNS S30403 and S31603) (NACE 2004).

For outdoor applications, no insulation material alone can prevent penetration of moisture and ions to the metal surface, so additional lines of defense, such as a properly designed, installed, and maintained protective jacket, are necessary. If process temperatures are lower than ambient (even for short periods of time such as during shutdowns), a vapor retarder is also required.

Even with a protective jacket and vapor retarder, it is likely that some moisture and ions will eventually enter the system because of abuse, wear, age, or improper installation. No installation is

ideal in any real-world setting. Because most people only consider the chlorides arising from the insulation material, the crucial issue of water and ions infiltrating the insulation system from the environment and yielding metal corrosion remains unaddressed. Thus, painting the pipe is the second and most important line of defense, and is necessary if pipe temperature is in the 140 to 300°F range for significant periods of time. To minimize the potential for corrosion, metal pipe should be primed with, for example, an epoxy coating. This alternative offers superior protection against corrosion, because priming protects against ions arising from the insulation and, more importantly, from ions that enter the system from the environment.

To minimize corrosion,

- Design, install, and maintain insulation systems to minimize ponding water or penetration of water into the system. Flat sections should be designed with a pitch to shed water. Top sections should overlap the sides to provide a watershed effect, preventing water penetration in the seam. Design should always minimize penetrations; necessary protrusions (e.g., supports, valves, flanges) should be designed to shed rather than capture water. Water from external sources can enter at any discontinuity in the insulation system.
- Insulation should be appropriate for its intended application and service temperature. NACE *Standard* RP0198 states, “CUI of carbon steel is possible under all types of insulation. The insulation type may only be a contributing factor. The insulation characteristics with the most influence on CUI are (1) water-leachable salt content in insulation that may contribute to corrosion, such as chloride, sulfate, and acidic materials in fire retardants; (2) water retention, permeability, and wettability of the insulation; and (3) foams containing residual compounds that react with water to form hydrochloric or other acids. Because CUI is a product of wet metal exposure duration, the insulation system that holds the least amount of water and dries most quickly should result in the least amount of corrosion damage to equipment.”
- Ancillary materials used for weatherproofing (e.g., sealants, caulks, weather stripping, adhesives, mastics) should be appropriate for the application, and be applied following the manufacturer’s recommendations.
- Maintenance should monitor for and immediately repair compromises in the protective jacketing system. Because water may infiltrate the insulation system, inspection ports should be used to facilitate inspection without requiring insulation removal. This is particularly important on subambient systems.
- Because some water will eventually enter the system, a protective pipe coating is necessary for good design. The type of coating depends on temperature (see NACE *Standard* RP0198 for coating guidelines). In Europe, essentially all piping is coated for corrosion protection. This is not necessarily the case in the United States, but should be considered as part of good design practice.
- When using austenitic stainless steel, all insulation products and accessories should meet the requirements of ASTM *Standard* C795. Likewise, any ancillary weatherproofing materials should have low chloride content.

MATERIALS AND SYSTEMS

Categories of Insulation Materials

Turner and Malloy (1981) categorized insulation materials into four types:

- **Fibrous** insulations are composed of small-diameter fibers that finely divide the air space. The fibers may be organic or inorganic, and are normally (but not always) held together by a binder.
- **Granular** insulations are composed of small nodules that contain voids or hollow spaces. These materials are sometimes considered

open-cell materials, because gases can transfer between the individual spaces.

- **Cellular** insulations are composed of small, individual cells, either interconnecting or sealed from each other, to form a cellular structure. Glass, plastics, and rubber may comprise the base material, and various foaming agents are used.

Cellular insulations are often further classified as either open-cell (i.e., cells are interconnecting) or closed-cell (i.e., cells sealed from each other). Generally, materials with greater than 90% closed-cell content are considered to be closed-cell materials.

- **Reflective** insulations and treatments are added to surfaces to lower long-wave emittance, thereby reducing radiant heat transfer from the surface. Low-emittance jackets and facings are often used in combination with other insulation materials.

Another material sometimes called **thermal insulating paint** or **coating** is available for use on pipes ducts and tanks. These products’ performance must be clearly understood before using them as thermal insulation. These paints and coatings have not been extensively tested and additional research is needed to verify their performance. Further discussion of these products can be found in Hart (2006).

Physical Properties of Insulation Materials

Selecting an insulation material for a particular application requires understanding the various physical properties associated with available materials.

Operating temperature is often the primary consideration. Maximum temperature capability is normally assessed using ASTM *Standard* C411 by exposing samples to hot surfaces for an extended time, and assessing the materials for any changes in properties. Evidence of warping, cracking, delamination, flaming, melting, or dripping are indications that the maximum use temperature of the material has been exceeded. There is currently no industry-accepted test method for determining the minimum operating temperature of an insulation material, but minimum temperatures are normally determined by evaluating the material’s integrity and physical properties after exposure to low temperatures.

Thermal conductivity of insulation materials is a function of temperature. Many specifications call for insulation conductivity values evaluated at a mean temperature of 75°F. Most manufacturers provide conductivity data over a range of temperatures to allow evaluations closer to actual operating conditions. Conductivity of flat product is generally measured per ASTM *Standards* C177 or C518, whereas pipe insulation conductivity is generally determined using ASTM *Standard* C335.

Compressive resistance is important where the insulation must support a load without crushing (e.g., insulation inserts in pipe hangers and supports). When insulation is used in an expansion or contraction joint to take up a dimensional change, lower values of compressive resistance are desirable. ASTM *Standard* C165 is used to measure compressive resistance for fibrous materials, and ASTM *Standard* D1621 is used for foam plastic materials.

Water vapor permeability is the water vapor flux through a material induced by a unit vapor pressure gradient across the material. For insulating materials, it is commonly expressed in units of perm·in. A related and often confused term is **water vapor permance** (in perms), which measures water vapor flux through a material of specific thickness and is generally used to define vapor retarder performance. In below-ambient applications, it is important to minimize the rate of water vapor flow to the cold surface. This is normally accomplished by using vapor retarders with low permance, insulation materials with low permeability, or both. ASTM *Standard* E96 is used to measure water vapor transmission properties of insulation materials.

Water absorption is generally measured by immersing a sample of material under a specified head of water for a specified time

Table 7 Performance Property Guide for Insulation Materials

Note: NA = not applicable. NS = not stated (i.e., ASTM Standards do not include a value for this property). Properties not stated do not necessarily indicate that material is not appropriate for a given application depending on that property. See previous editions of *ASHRAE Handbook—Fundamentals* for data on historical insulation materials.

period. It is a useful measure of the amount of liquid water absorbed from water leaks in weather barriers or during construction.

Typical physical properties of interest are given in Table 7. Values in this table are taken from the relevant ASTM material specification with permission from ASTM International. Within each material category, a variety in types and grades of materials exist. A representative type and grade are listed in Table 7 for each material category; refer to ASTM standards or to manufacturers for specific data.

Weather Protection

The importance of weather barriers cannot be overstated. Premature failure can lead to insulation failure, with safety and economic consequences.

Safety consequences

- If insulation is installed for burn protection from a hot pipe or equipment, water entering the insulation system can vaporize into steam and cause a surface temperature well above the expected 140°F, the common design temperature for personnel protection.
- Pipe or equipment can corrode, rupture, and release a hazardous material.

Economic consequences

- Wet insulation has higher thermal conductivity and lower insulation values.
- On a hot system, 1 lb of water entering the system requires 1000 Btu to revaporize. If this vapor cannot vent easily, it can condense, causing interior jacket corrosion; the weather barrier will begin consuming itself from the inside out. Consequently, the system cannot deliver the desired energy and will quickly require an expensive repair.
- On a very cold system, improper vapor retarder selection allows moisture to migrate to the cold surface because of the continuous drive of vapor pressure. A hole in the system allows direct water influx. Either of these entry mechanisms results in ice formation, which separates the insulation and weather protection barrier from the pipe or vessel surface.

Many more scenarios must be considered, especially when the broad range of features required of a weather barrier are considered. Turner and Malloy (1981) define a weather barrier as “a material or

materials, which, when installed on the outer surface of thermal insulation, protects the insulation from . . . rain, snow, sleet, wind, solar radiation, atmospheric contamination and mechanical damage.” With this definition in mind, several service requirements must be considered.

- **Internal mechanical forces:** Expansion and contraction of the pipe or vessel must be considered because the resulting forces are transferred to the external surface of the weather barrier. Ability to slide, elongate, or contract must be provided.
- **External mechanical forces:** Mechanical abuse (i.e., tools being dropped, abrasion from wind-driven sand, personnel walking on the system) inflicted on a pipe or vessel needs to be considered in design. This may affect insulation type, as well as the weather barrier jacketing type.
- **Dimensional stability:** Some cellular materials can show irreversible dimensional change after installation. The manufacturers of these materials provide installation guidelines to minimize the effects of dimensional change. If guidelines are not followed, failure of joint seals can occur, which can lead to system failure.
- **Chemical resistance:** Some industrial environments may have airborne or spilled corrosive agents that accumulate on the weather barrier and chemically attack the pipe or vessel jacketing. Elements that create corrosive issues must be well understood and accounted for. Insulation design of coastal facilities should account for chloride attack.
- **Galvanic corrosion:** Contacts between two different types of metal must be considered for galvanic corrosion potential. Similarly, water can act as an electrolyte, and galvanic corrosion can occur because of the different potential of the pipe and vessel and a metal jacketing.
- **Insulation corrosivity:** Some insulation materials can cause metal jacket corrosion or chemically attack some polymer films. Both of these situations shorten service life.
- **Thermal degradation:** Hot systems are typically designed so that the surface temperature of the insulation and jacketing material do not exceed 140°F. The long-term effect of 140°F on the jacketing material must be considered. Additionally, there may be solar radiation load and perhaps parallel heat loss from an adjacent pipe. Turner and Malloy (1981) suggest that 250°F should be considered as the long-term operating temperature of the jacketing material

selected. This is a critical design consideration, particularly for a nonmetal jacket.

- **Installation and application logistics:** Often, the insulation contractor installs more insulation in a day than can be protected with jacket. If it rains, the exposed insulation gets saturated and, the next day, the jacket is installed over the wet insulation. This creates an obvious potential corrosion issue before the installation is operational, and must be corrected immediately. It should also be understood that the size, shape, and adjacent space available for work may dictate the type of weather barrier used, even if it is a less desirable option. If this is the case, the maintenance schedule must recognize and accommodate for this.
- **Maintenance:** The importance of a maintenance and inspection plan cannot be overemphasized to achieve the service life expected of the design.

Materials Used as Weather Barriers for Insulation. Metal rolls or sheets of various thicknesses are available with embossing, corrugation, moisture barriers, and different banding and closure methods. Elbows and tees are also available for piping. Typical metal jacketing materials are

- Bare aluminum
- Coated aluminum
- Stainless steel
- Painted steel
- Galvanized steel
- Aluminum-zinc coated steel

Polymeric (plastic) rolls or sheets are available at various thicknesses. These materials are glued or solvent-welded, depending on the polymer. Elbows and tees are also available for piping for some type of polymers. Typical polymeric (plastic) jacketing materials include

- Polyvinyl chloride (PVC)
- Polyvinylidene chloride (PVDC)
- Polyisobutylene
- Multiple-layer composite materials (e.g., polymeric/foil/mesh laminates)
- Fabrics (silicone-impregnated fiberglass)

Numerous mastics are available. Mastics are often used with fiberglass cloth or canvas to encapsulate pipes, tanks, or other vessels; they are also used at insulation terminations and at or around protrusions such as valves or supports. It is important to choose the correct mastic for the application, considering surface temperature, insulation type, fire hazard classification, water resistance, and vapor permeability requirements. Mastics are brushed, troweled, or sprayed on the surface at a thickness recommended by the manufacturer.

Importance of Workmanship and Knowledge. Workmanship and knowledge are key to successful insulation weather barrier design. The importance of working with the installing contractor and material manufacturers regarding fitness for use of each material is paramount. The Midwest Insulation Contractors Association (MICA 1999) publishes an excellent resource regarding materials used as weather barriers: the *National Commercial and Industrial Insulation Manual*, in print and CD-ROM, is available from <http://www.micainsulation.org/standards/manual.html>.

Vapor Retarders

Water vapor control is extremely important for piping and equipment operating below ambient temperatures. These systems are typically insulated to prevent surface condensation and control heat gain. Piping and equipment typically create an absolute barrier to passage of water vapor, so any vapor-pressure difference imposed across the insulation system results in the potential for condensation at the cold surface. A high-quality vapor retarder material or system is essential for these systems to perform adequately. Research

(Mumaw 2001) has shown that the design, installation, and performance of the vapor retarder systems are key to an insulation system's ability to minimize water vapor ingress.

Moisture-related problems include thermal performance loss, health and safety issues, structural degradation, and aesthetic issues. Water may enter the insulation system through water vapor diffusion, air leakage carrying water vapor, and leakage of surface water. A vapor retarder is a material or system that will adequately reduce the transmission of water vapor through the insulation system. The vapor retarder system is seldom intended to resist the entry of surface water or prevent air leakage, but can occasionally be considered the second line of defense for these moisture sources.

The performance of the vapor retarder material or system is characterized by its water vapor permeance. Chapter 23 has a thorough description of the physics associated with water vapor transport. Water vapor permeance can be evaluated per ASTM *Standard E96* by imposing a vapor pressure difference across vapor retarder material that has been sealed to a test cup, and gravimetrically measuring the moisture gain or loss.

Faulty application can impair vapor retarder performance. The effectiveness of installation and application techniques must be considered when selecting a vapor retarder system. Factors such as vapor retarder structure, number of joints, mastics and adhesives that are used, and inspection procedures affect performance and durability.

The insulation system should be dry before application of a vapor retarder to prevent trapping water vapor in the system. The system must be protected from undue weather exposure that could introduce moisture into the insulation before the system is sealed.

When selecting a vapor retarder, the vapor pressure difference across the insulation system should be considered. Higher vapor pressure differences typically require a lower-permeance vapor retarder to control the overall moisture pickup of the system. Service conditions affect the direction and magnitude of the vapor pressure difference. Unidirectional flow exists when the water vapor pressure is constantly higher on one side of insulation system. Reversible flow exists when vapor pressure may be higher on either side, typically caused by diurnal or seasonal changes on one side of the system. Properties of insulating materials used should be considered. All materials reduce water vapor flow, but low-permeance insulations can add to the overall water vapor transport resistance of the insulation system. Some low-permeability materials are considered to be vapor retarders without any additional jacket material.

Vapor Retarder Jackets. There is some inconsistency in the nomenclature used for materials used as vapor retarders for pipe, tank, and equipment insulation. Designations such as *jacket*, *jacketing*, *facing*, and *all-service jacket (ASJ)* are all applied to this component, sometimes interchangeably. On the other hand, the vapor retarder component of insulation for air-handling systems, such as duct wrap and duct board, is typically referred to only as *facing*. The term *vapor diffusion retarder (VDR)* is also used to generically describe these materials.

In this chapter, *vapor retarder* denotes the vapor-retarding membrane of the system, but the reader should be aware of the various terms that may be encountered. In addition, some insulation materials (e.g., closed-cell foam materials with low water vapor permeability) are considered vapor retarders in themselves without any additional retarding membrane.

Vapor Retarders for Pipe, Tank, and Equipment Insulation. Materials or combinations of materials used for vapor retarders can take many different forms. Necessarily, one component must be a material that offers significant resistance to vapor passage. A commonly used preformed material for pipe, tank, and equipment vapor retarder applications is the lamination of white paper, reinforcing fiberglass scrim, and aluminum foil or metallized polyester film for the foil component. These products are generally referred to as **all-service jackets (ASJs)**, and meet the requirements of ASTM

Standard C1136, the accepted industry material standard for pipe insulation applications. These facings are commonly used as the outer finish in low-abuse indoor areas; elsewhere, they are covered by a protective metal or plastic jacket. Many types of insulation are supplied with factory-applied ASJ vapor retarders.

Note that ASJs may have service limitations on below-ambient systems in wet environments. Condensation on the surface (possibly caused by inadequate insulation thickness), or moisture migration under the ASJ (through breaches or holes), or liquid or water (from an outside source) can degrade the ASJ by mold growth on the paper and/or corrosion of the aluminum vapor retarder component.

In addition to traditional ASJ vapor retarders, low-permeance monolayer plastic film and sheet, laminations using heavy-gage foil, and other types of sheet structures are used in very-low-temperature applications. These are not typically referred to as ASJ, and are often procured separately from the insulation and applied in fabrication shops or in the field. Examples include polyethylene terephthalate (PET), polyvinyl chloride (PVC), and polyvinylidene chloride (PVDC). They are typically used in more demanding applications, and often are covered by protective jacket. These facings generally meet the requirements of *ASTM Standard* C1136, Type IV, or *ASTM Standard* C921.

The moisture-sensitive nature of paper and the relative frailty of aluminum foil can be problematic in the potentially high-moisture environment of below-ambient applications. Exposure to water, either from condensation caused by inadequate insulation thickness or from ambient sources, can cause degradation and distortion of the paper, higher likelihood of mold growth, and foil corrosion, leading to vapor retarder failure. The presence of leachable chloride in flame-retardant ASJ structures can promote corrosion of the foil or metallized film. The anticipated trend in vapor retarders for pipe insulation is toward nonpaper structures, metallized films, and better-protected foil laminates.

For most common vapor retarder jackets, matching pressure-sensitive tapes are available for making joint and puncture seals. Mastics are available and used where fittings, supports, and other obstructions make a proper vapor seal difficult to achieve. Highly conformable tapes are sometimes used for this purpose, as well. Applied mastic systems are a vapor-retarding layer; they are often called **vapor barriers** by manufacturers, but their vapor resistance is a function of the thickness and quality of the mastic application. Also, some mastic may not be compatible with certain insulation types. For this reason, always consult the insulation manufacturer for recommendations on the correct type of vapor retarder to use in the application.

Below-ambient piping and equipment in general, and below-freezing applications in particular, are the most demanding applications for an insulation vapor retarder. Even though extremely low-permeance (as low as zero) vapor retarder materials exist, a perfect barrier in a system that is field-installed and includes numerous joints and penetrations is extremely difficult to achieve. It follows that adequate system design, proper insulation and jacketing material selection, and careful workmanship are all equally important.

Air-Handling Systems. Vapor retarders for equipment and duct insulation take various forms. Probably because of the relatively less severe and demanding conditions in air-handling systems, current vapor retarder materials seem to adequately meet these performance requirements. In general, moisture problems are not often encountered if insulation design is adequate for the application, and some low-permeability insulation materials are used without separate vapor retarders. For fiberglass duct wrap and duct board, a lamination of aluminum **foil, scrim, and kraft paper (FSK)** has long been the material of choice, although flexible vinyl and other white or black-colored facings are occasionally used. All of these facings can be procured separately in roll form, and used on any type of insulation. *ASTM Standard* C1136, Type II, is a typical

specification for factory-applied vapor retarder on duct insulation (except flexible duct). Flexible (flex) ducting typically incorporates a plastic film or film lamination that contains a metallized substrate as a vapor-retarding component.

Application-specific pressure-sensitive tapes or mastics are usually used to seal joints. As in any cold system where a vapor retarder is required, design, materials, and workmanship must be properly addressed. The insulation manufacturer's recommendations should be followed.

INSTALLATION

Pipe Insulation

Small pipes can be insulated with cylindrical half-sections of rigid insulation or with preformed flexible material. Larger pipes can be insulated with flexible material or with curved, flat segmented, or cylindrical half, third, or quarter sections of rigid insulation, particularly where removal for frequent servicing of the pipe is necessary. Fittings (valves, tees, crosses, and elbows) use preformed fitting insulation, fabricated fitting insulation, individual pieces cut from sectional straight-pipe insulation, or insulating cements. Fitting insulations should always be equal in thermal performance to the pipe insulation.

Securing Methods. The method of securing varies with the type of insulation, size of pipe, form and weight of insulation, and type of jacketing (i.e., field- or factory-applied). Insulation with factory-applied jacketing can be secured on small piping by securing the overlapping jacket, which usually includes an integral sealing tape. Large piping may require supplemental wiring or banding. Insulation on large piping requiring separate jacketing is wired or banded in place, and the jacket is cemented, wired, or banded, depending on the type. Insulation with factory-applied metal or PVC jacketing is secured by specific design of the jacket and its joint closure. Flexible closed-cell materials require no jacket for most applications and are applied using specially formulated contact adhesives.

Insulating Pipe Hangers. All piping is held in place by hangers and supports. Selection and treatment of pipe hangers and supports can significantly affect thermal performance of an insulation system. Thus, it is important that the piping engineer and insulation specifier coordinate during project design to ensure that correct hangers are used and sufficient physical space is maintained to allow for the required thickness of insulation.

A typical **ring or line size** hanger is illustrated in Figure 5A. This type of hanger is commonly used on above-ambient lines at moderate temperature. However, it provides a thermal short circuit through the insulation, and the penetration is difficult to seal effectively against water vapor, so it is not recommended for below-ambient applications.

Pipe shoes (Figure 5B) are used for hot piping of large diameter (heavy weight) and where significant pipe movement is expected. The design allows for pipe movement without damage to the insulation or the finish. The design is not recommended for below-ambient applications because of the thermal short circuit and difficulty in vapor sealing.

A better solution is to use **clevis** hangers (Figure 5C), which are sized to allow clearance for the specified thickness of insulation, and avoid the short circuit associated with ring hangers. Shields (or saddles) spread the load from the pipe, its contents, and the insulation material over an area sufficient to support the system without significantly compressing the insulation material. Table 8 provides guidance on saddle lengths for fiberglass pipe insulation. For pipe sizes above 3 in. NPS, it is recommended that high-density inserts (foam, high-density fiberglass, or wood blocks) be used. Table 9 gives recommended saddle lengths for 2 lb/ft³ polyisocyanurate foam insulation. Preinsulated saddles are available.

are usually governed by location. Appearance and durability are the primary design considerations for indoor applications. For outdoor applications, finishes are provided primarily for weather protection. The finishes may be factory-applied jackets or field-applied metal or polymeric jackets.

Insulation Finish for Below-Ambient Temperatures. Piping at temperatures below ambient is insulated to limit heat gain and prevent condensation of moisture from the ambient air. Because metallic piping is an absolute barrier to water vapor, it becomes the condensing surface. Therefore, the outer surface of the insulation

must be covered by an impervious membrane, or the insulation material itself must be highly resistant to water vapor diffusion.

Vapor retarders for straight pipe insulation are generally designed to meet operating temperature, fire safety, and appearance requirements. Flexible closed-cell materials are often installed without separate vapor retarders, relying on the low permeability of the insulation material to resist vapor flow, and must be carefully sealed or cemented to avoid gaps in insulation. Jacketing used as a vapor retarder may use various materials, alone or in combination, such as paper, aluminum foil, vacuum-metallized or low-permeance plastic films, and reinforcing. The most commonly used products have been ASJ (white), foil-reinforced kraft (FRK), metallized polyester film, or plastic sheeting. An important feature of such jacketing is very low permeance in a relatively thin layer, which provides flexibility for ease of cementing and sealing laps and end-joint strips. This type of jacketing is commonly used indoors without additional treatment. In some cases of operating temperatures below 0°F, multilayer insulation and jacketing may be used. With long lines of piping, insulation should be sealed off every 15 or 20 ft with vapor stops to limit water penetration if vapor retarder damage occurs.

Insulation fittings are usually vapor-sealed by applying suitable materials in the field, and may vary with the type of insulation and operating temperature. For temperatures above 10°F, the vapor seal can be a lapped spiral wrap of plastic film adhesive tape or a relatively thin coat of vapor-seal mastic. For temperatures below 10°F, common practice is to double-wrap a very-low-permeance plastic film adhesive tape or apply two coats of vapor-seal mastic reinforced with open-weave glass or other fabric. Mastic thickness increases with decreasing temperature.

Insulated cold piping should receive special attention when exposed to ambient or unconditioned air. Because cold piping frequently operates year-round, a unidirectional vapor drive may exist. Even with vapor-retarding insulation, jackets, and vapor sealing of joints and fittings, moisture inevitably accumulates in permeable insulations. This not only reduces the thermal resistance of the insulation, it also accelerates condensation on the jacket surface with consequent dripping of water and possible growth of mold and mildew. Depending on local conditions, these problems can arise in less than 3 years, or as many as 30 years. Periodic insulation replacement should be considered, and the piping installation should be accessible for such replacement. Very-low-permeability insulating materials (e.g., materials not exceeding 0.1 perm-in.) have been used to extend system life and reduce replacement frequency. The lower the insulation's permeability, the longer its life, given proper installation.

An alternative approach is to accept the inevitable water vapor ingress, and to provide a means of removing condensed water from the system. One means of accomplishing this is the use of a hydrophilic wicking material to remove condensed water from the surface of cold piping for transport (via the combination of capillary forces

and gravity) outside the system where it can be evaporated to the ambient air (Brower 2000; Crall 2002; Korsgaard 1993). The wick keeps the hydrophobic insulation dry, allowing the thermal insulation to perform effectively. Dripping is avoided if ambient conditions allow evaporation. The concept is limited to pipe temperatures above freezing.

For dual-temperature service, where pipe operating temperatures cycle, the vapor-seal finish, including mastics, must withstand pipe movement and exposure temperatures without deterioration. When flexible closed-cell insulation is used, it should be applied slightly compressed to prevent it from being strained when the piping expands.

Outdoor pipe insulation may be vapor-sealed in the same manner as indoor piping, by applying added weather protection jacketing without damage to the vapor retarder and sealing it to keep out water. In some instances, heavy-duty weather and vapor-seal finish may be used. It is recommended that weather protection jackets installed over vapor retarders use bands or some other closure method that does not penetrate the weather protection jacketing.

Underground Pipe Insulation. Both heated and cooled underground piping systems are insulated. Protecting underground insulated piping is more difficult than protecting aboveground piping. Groundwater conditions, including chemical or electrolytic contributions by the soil and the existence of water pressure, require special design to protect insulated pipes from corrosion and maintain insulation thermal integrity. For optimal performance, walk-through tunnels, conduits, or integral protective coverings are generally provided to protect the pipe and insulation from water. Examples and general design features of conduits, tunnels, and direct burial systems can be found in Chapter 11 of the 2008 *ASHRAE Handbook—HVAC Systems and Equipment*.

Tanks, Vessels, and Equipment

Flat, curved, and irregular surfaces, such as tanks, vessels, boilers, and chimney connectors, are normally insulated with flexible or semirigid sheets or boards or rigid insulation blocks fabricated to fit the specific application. Tank and vessel head segments must be curved or flat cut to fit in single piece or segments per ASTM *Standard C450*. Head segments must be cut to eliminate voids at the head section, and in a minimum number of pieces to minimize joints. Prefabricated flat head sections should be installed in the same number of layers and thickness as the vessel walls, and void areas behind the flat head should be filled with packable insulation. Typically, the curved segments are fabricated to fit the contour of the vessel surface in equal pieces to go around the vessel with a minimum number of joints. Because no general procedure can apply to all materials and conditions, manufacturers' specifications and instructions must be followed for specific applications.

Securing Methods. Insulations are secured in various ways, depending on the form of insulation and contour of the surface to be insulated. Flexible insulations are adhered to tanks, vessels, and equipment using contact adhesive, pressure-sensitive adhesives, or other systems recommended by the manufacturers. The insulation's flexibility lends itself to curved surfaces. Rigid or semirigid insulations on small-diameter, cylindrical vessels can be prefabricated and adhered or mechanically attached, as appropriate. On larger cylindrical vessels, angle iron ledges to support the insulation against slippage can supplement banding. Where diameters exceed 10 to 15 ft, slotted angle iron may be run lengthwise on the cylinder, at intervals around the circumference to secure and avoid an excessive length of banding.

Rigid and semirigid insulations can be secured on large flat and cylindrical surfaces by banding or wiring and can be supplemented by fastening with various welded studs at frequent intervals. On large flat, cylindrical, and spherical surfaces, it is often advantageous to secure the insulation by impaling it on welded studs or pins and fastening it with speed washers. Flexible closed-cell

insulations are adhered directly to these surfaces, using a suitable contact adhesive.

Insulation Finish. Insulation finish is often required to protect insulation against mechanical damage and weather, consistent with acceptable appearance. On smaller indoor equipment, insulation is commonly covered with tightly stretched and secured hexagonal wire mesh. Then, a base and hard finish coat of cement is applied, and sometimes painted. For the same equipment outdoors, insulation can be finished with a coat of hard cement, properly secured hexagonal mesh, and a coat of weather-resistant mastic. A variation is to apply only two coats of weather-resistant mastic reinforced with open-mesh glass or other fabric; however, this finish is limited to an operating temperature of about 300°F, because metal expansion can rupture the finish at insulation joints. Larger equipment may be finished indoors and out with suitable sheet metal.

Outdoor finish is generally metal jacketing, properly flashed around penetrations (e.g., access openings, pipe connections, and structural supports) to maintain weathertightness. Various outdoor finishes are available for different types of insulations.

For below-ambient operating temperatures, insulation is finished, as required, to prevent condensation and protect against mechanical damage and weather, consistent with acceptable appearance. In accordance with the operating temperature, the finish must retard vapor to avoid moisture entry from surrounding air, which can increase the insulation's thermal conductivity or deterioration, or corrode the metal equipment surface.

Whenever a vapor retarder is required, all penetrations such as access openings, pipe connections, and structural supports must be properly treated with an appropriate vapor-retarder film, mastic, or other sealant. Equipment must be insulated from structural steel by isolating supports of high compressive strength and reasonably low thermal conductivity, such as a rigid insulation material or a hardwood block. The vapor retarder must carry over this insulation from the equipment to the supporting steel to ensure proper sealing.

If the equipment rests directly on steel supports, the supports must be insulated for some distance from the points of contact. Commonly, insulation and vapor retarder are extended 8 to 10 times the thickness of the insulation applied to the equipment.

For dual-temperature service, where vessels are alternately cold and hot, vapor retarder finish materials and design must withstand movement caused by temperature change.

Ducts

Ducts are used to convey air or process gases for several purposes. In general, their uses can be divided into process ducts and HVAC ducts. **Process ducts** can range from industrial hot exhaust to subambient process gases, and can be outdoors or inside. They can need insulation for various reasons, including thermal energy conservation, personnel protection, process control, condensation control and noise attenuation. Because of the wide range of possible operating temperatures and environmental conditions, selection of duct insulation and jacketings for industrial processes requires careful consideration of all operational, environmental, and human safety factors. Issues of energy conservation, personnel protection, condensation control, and process control can be solved by careful analysis of heat flow. Computer programs are available for calculating heat transfer, surface temperatures for personnel protection, condensation control, and economic thickness.

HVAC ducts carry air to conditioned spaces inhabited by people, animals, sensitive equipment, or a combination thereof. Thermal and acoustical duct insulation is one of the keys to a well-designed system that provides both occupant comfort and acceptable indoor air quality (IEQ). These insulation products help maintain a consistent air temperature throughout the system, reduce condensation, absorb system operation noise, and conserve energy.

Typical air temperatures for HVAC applications are 40 to 120°F. Because of the more moderate temperature ranges associated with HVAC applications, there is a wide range of insulation materials available. Where acoustical and thermal considerations are significant, sheet metal ducts are often internally insulated, or the ducts themselves are constructed of materials that form both the air-conveying duct and the insulation. Where acoustical concerns are not significant, sheet metal ducts can be externally insulated with rigid, semirigid, or flexible insulation materials. Again, another alternative is to use ducts that incorporate insulation as part of their construction. The determining factor in duct construction and insulation materials selection is often a combination of performance criteria and budgetary limitations.

The need for duct insulation is influenced by the

- Duct location (e.g., indoors or outdoors; conditioned, semiconditioned, or unconditioned space)
- Effect of heat loss or gain on equipment size and operating cost
- Need to prevent condensation on low-temperature ducts
- Need to control temperature change in long duct lengths
- Need to control noise transmitted within the duct or through the duct wall

All HVAC ducts exposed to outdoor conditions, as well as those passing through unconditioned or semiconditioned spaces, should be insulated. Analyses of temperature change, heat loss or gain and other factors affecting the economics of thermal insulation are essential for large commercial and industrial projects. ASHRAE *Standard* 90.1 and building codes set minimum standards for thermal efficiency, but economic thickness is often greater than the minimum. Additionally, the standards and codes do not address surface condensation issues. These considerations are often the primary driver of minimum thickness in unconditioned or semiconditioned locations subject to moderate or greater relative humidity.

Duct thermal efficiencies are generally regulated by local or national codes by specifying minimum thermal resistances, or R-values. These R-values are most often determined by testing per ASTM *Standards* C518 or C177, as required by the Federal Trade Commission (FTC) for reporting R-values of duct wrap insulations. Neither method allows for increased thermal resistance caused by convective or radiative surface effects. To comply with current code language, it is recommended that R-value requirements in specifications for duct insulation be based on *Standards* C177 or C518 testing at 75°F mean temperature and at the installed thickness of the insulation. Insulation products for ducts are available in a range of R-values, dependent predominantly on insulation thickness, but also somewhat on insulation density.

Temperature Control Calculations for Air Ducts. Duct heat gains or losses must be known for the calculation of supply air quantities, supply air temperatures, and coil loads (see Chapter 17 of this volume and Chapter 4 of the 2008 *ASHRAE Handbook—HVAC Systems and Equipment*). Heat loss programs based on ASTM *Standard* C680 may be used to calculate thermal energy transfer through the duct walls. Duct air exit temperatures can then be estimated using the following equations:

$$t_{drop} \text{ or } t_{gain} = 0.2 \left(\frac{qPL}{VC_p \rho A} \right) \quad (3)$$

then, for warm air ducts,

$$t_{exit} = t_{enter} - t_{drop} \quad (4)$$

and for cold air ducts,

$$t_{exit} = t_{enter} + t_{gain} \quad (5)$$

where

- t_{drop} = temperature loss for warm air ducts, °F
- t_{enter} = entering air temperature, °F
- t_{gain} = temperature rise for cool air ducts, °F
- t_{exit} = exit temperature for either warm or cool air ducts, °F
- q = heat loss through duct wall, Btu/h · ft²
- P = duct perimeter, in.
- L = length of duct run, ft
- V = air velocity in duct, ft/min
- C_p = specific heat of air, Btu/lb_m · °F
- ρ = density of air, 0.075 lb/ft³
- A = area of duct, in²
- 0.2 = conversion factor for length, time units

Example 1. A 65 ft length of 24 by 36 in. uninsulated sheet metal duct, freely suspended, conveys heated air through a space maintained at 40°F. The ASTM *Standard* C680 heat loss calculation gives a heat transfer rate of 140.8 Btu/h · ft². Based on heat loss calculations for the heated zone, 17,200 cfm of standard air ($c_p = 0.24$ Btu/lb_m · °F) at a supply air temperature of 122°F is required. The duct is connected directly to the heated zone. Determine the temperature of the air entering the duct.

Solution: The area of the duct is $24 \times 36 = 864$ in². Air velocity V is calculated as

$$\frac{\text{Volumetric flow}}{\text{Area}} \times 144 = \frac{17,200}{864} \times 144 = 2867 \text{ fpm}$$

Duct perimeter P is

$$(24 + 36) \times 2 = 120 \text{ in.}$$

Temperature drop t_{drop} is

$$0.2 \left(\frac{140.8 \times 120 \times 65}{2867 \times 0.24 \times 0.075 \times 864} \right) = 4.9^\circ\text{F}$$

Temperature of air entering the duct is thus

$$122 + 4.9 = 126.9^\circ\text{F}$$

Example 2. Repeat Example 1, except the duct is insulated externally with 1 in. thick insulation material having a heat transfer rate of 14.2 Btu/h · ft².

Solution: All values except q remain the same as in the previous example. Therefore, t_{drop} is

$$0.2 \left(\frac{14.2 \times 120 \times 65}{2867 \times 0.24 \times 0.075 \times 864} \right) = 0.5^\circ\text{F}$$

Temperature of air entering the duct is thus

$$122 + 0.5 = 122.5^\circ\text{F}$$

Preventing Surface Condensation on Cool Air Ducts. Insulation also can prevent surface condensation on cool air ducts operating in warm and humid environments. This reduces the opportunity for microbial growth as well as other moisture-related building damage. Condensation forms on cold air-conditioning ducts anywhere the exterior surface temperature reaches the dew point. The moisture may remain in place or drip, causing moisture damage and creating a potential for microbial contamination.

Preventing surface condensation requires that sufficient thermal resistance be installed for the condensation design conditions. Figures 6 and 7 give installed R-value requirements to prevent surface condensation on insulated air ducts. The first chart (for emittance = 0.1) should be used for foil-faced insulation products. The second chart is based on materials with a surface emittance of 0.9. The

Fig. 6 R-Value Required to Prevent Condensation on Surface with Emittance $\epsilon = 0.1$

Fig. 7 R-Value Required to Prevent Condensation on Surface with Emittance $\epsilon = 0.9$

designer must choose the appropriate environmental conditions for the location. It may be financially imprudent to design for the most extreme condition that could occur during a system's life, but it is also important to be aware that the worst-case condition for condensation control is not the maximum design load of coincident dry bulb and wet bulb. Rather, the worst case for condensation occurs when relative humidity is high, such as when the dry bulb is only very slightly above the wet bulb. This condition often occurs in the early morning in many climates.

For cold-duct applications, it is critical that water vapor not be allowed to enter the insulation system and condense on the cold duct surface. Once water begins to condense, loss of thermal efficiency is inevitable. This leads to further surface condensation on the surface of the insulation. To prevent this, exterior duct insulations must have a low vapor permeance. Permeance values of 0.1 perms or less are generally recommended for cold-duct applications. It is equally important that all exterior duct insulation joints are well sealed. Areas of special concern are often found around duct flanges, hangers, and other fittings.

Insulation Materials for HVAC Ducts. Insulated ducts in buildings can consist of insulated sheet metal, fibrous glass, or insulated flexible ducts, all of which provide combined air barrier, thermal insulation, and some degree of sound absorption. Ducts embedded in or below floor slabs may be of compressed fiber, ceramic tile, or other rigid materials. Depending on the insulation material, there are a number of standards that specify the material requirements.

Duct insulations include semirigid boards and flexible blanket types, composed of organic and inorganic materials in fibrous, cellular, or bonded particle forms. Insulations for exterior surfaces may have attached vapor retarders or facings, or vapor retarders may be applied separately. When applied to the duct interior as a liner, insulation both insulates thermally and absorbs sound. Duct liner insulations have sound-permeable surfaces on the side facing the

airstream capable of withstanding duct design air velocities or duct cleaning without deterioration.

Abuse Resistance. One important consideration in the choice of external insulations for air ducts is abuse resistance. Some insulation materials have more abuse resistance than others, but most rigid insulations will not withstand high abuse such as foot traffic. In high-traffic locations, a combination of insulation and protective jacketings is required. In areas where the insulation is generally inaccessible to human contact, less rigid insulations are acceptable.

One important consideration for internal insulation abuse resistance is that, in large commercial units, it is common for maintenance personnel to enter and move around. In these instances, it is critical that structural elements be provided to keep foot traffic off the insulation.

Duct Airstream Surface Durability. One of the most important considerations in choosing internal duct insulations is resistance to air erosion. Each material has a maximum airflow velocity rating, which should be determined using an erosion test methodology in accordance with either UL *Standard* 181 or ASTM *Standard* C1071. Under these methods, the liner material is subjected to velocities that are two and one-half times the maximum rated air velocity. Air erosion testing should include evaluation of the insulation for evidence of erosion, cracking, or delamination.

Additionally, internal insulation must be resistant to aging effects in the air duct environment. Insulation materials have maximum temperatures for prolonged exposure, some codes impose temperature requirements. Ensure that the material selected will have no aging effects at either the anticipated maximum duct temperature or the temperature specified by the code bodies for the local jurisdiction.

Another durability concern is ultraviolet (UV) resistance. Ultraviolet-generating equipment is used to mitigate microbial activity. Determine, both from the UV equipment manufacturer as well as the insulation manufacturer, whether the anticipated UV exposure poses a threat to the insulation.

Duct Airflow Characteristics. Internal duct insulations and ducts that have insulation as part of their construction have increased frictional pressure loss characteristics compared to bare sheet metal. Generally, duct dimensions are oversized to compensate for the increased frictional pressure losses and the decrease in internal cross section caused by the insulation thickness. However, frictional losses are only part of the total static pressure loss in a duct; dynamic fitting losses should also be considered in any required resizing. Generally, internal linings conform to the shape of the fitting in which they are installed. For this reason, the insulated fitting is assumed to have the same dynamic pressure loss as the uninsulated fitting of the same dimension. See Chapter 21 for further details on frictional pressure loss characteristics of internal linings and how they affect pressure drop and duct-sizing requirements.

Securing Methods. Exterior rigid or flexible duct insulation can be attached with adhesive, with supplemental preattached pins and clips, or with wiring or banding. Individual manufacturers of these materials should be consulted for their installation requirements. Flexible duct wraps do not require attachment except on bottom duct panels more than 24 in. wide. For larger ducts, pins placed at a maximum spacing of 24 in. or less are sufficient. Internal liners are attached with adhesive and pins, in accordance with industry standards.

Leakage Considerations. To achieve the full thermal benefits of insulation, air ducts should be substantially sealed against leakage under operating pressure. The insulation material should not be counted on to provide leakage resistance, unless the insulation is part of the actual duct. Using the case in Example 1, 10% air leakage from an unsealed duct represents an energy loss of 1.66 times the energy lost through heat transfer through the entire 65 ft of uninsulated duct. When that same 10% leakage is compared against an insulated duct, the energy lost through leakage is 15.3 times the

losses through heat transfer through the insulation over the entire duct length.

Outdoor Applications. Insulated air ducts located outdoors generally require specific protection against the elements, including water, ice, hail, wind, ultraviolet exposure, vermin, birds, other animals, and mechanical abuse. Strategies for protecting externally insulated ducts located outdoors include protective metal jackets and glass fabric with weather barrier mastic. Note that most of these protective weather treatments do not replace the need for a vapor retarder for cold-duct applications.

Special Considerations.

Cooling-only ducts in cold climates. These applications generally occur in northern climates with ducts that run through unconditioned spaces such as attics. Warm air from the conditioned space enters through registers and into the unused ducts. This relatively moist air then condenses in the cold portions of the duct. Condensation encourages odor problems, mold growth, and degradation of the insulation. In the worst cases, water build-up becomes so excessive that water-soaked or frozen ducts can collapse and break through ceilings. The solution is to completely seal all entry points into the ducts, generally by sealing behind all registers, using a very good vapor retarder such as 7 mil (0.007 in.) polyethylene sheet.

Covering ducts with insulation in attics in hot and humid climates. In an effort to conserve energy, attic insulation levels have been increasing. Often, these attics are insulated with pneumatically applied loose fill insulation. If this insulation comes into contact with duct insulation, it could lower surface temperatures on the facing of the duct insulation below dew point during humid conditions. For this reason, it is important that the ducts be supported so that they are above the attic insulation. Many building codes in humid areas (e.g., Florida) require this, and it should be considered good practice in all humid climates.

DESIGN DATA

Estimating Heat Loss and Gain

Fundamentals of heat transfer are covered in Chapter 4, and the concepts are extended to insulation systems in Chapter 25. Steady-state, one-dimensional heat flow through insulation systems is governed by Fourier’s law:

$$Q = -kA \, dT/dx \tag{6}$$

where

- Q = rate of heat flow, Btu/h
- A = cross-sectional area normal to heat flow, ft²
- k = thermal conductivity of insulation material, Btu/h·ft·°F
- dT/dx = temperature gradient, °F/ft

For flat geometry of finite thickness, the equation reduces to

$$Q = kA(T_1 - T_2) \, \S \, L \tag{7}$$

where L is insulation thickness, in ft.

For radial geometry, the equation becomes

$$Q = kA_2(T_1 - T_2)/[r_2 \ln(r_2/r_1)] \tag{8}$$

where

- r_1 = outer radius, ft
- r_2 = inner radius, ft
- A_2 = area of outer surface, ft²

The term $r_2 \ln(r_2/r_1)$ is sometimes called the **equivalent thickness** of the insulation layer. Equivalent thickness is the thickness of insulation that, if installed on a flat surface, would equal the heat flux at the outer surface of the cylindrical geometry.

Heat transfer from surfaces is a combination of convection and radiation. Usually, these modes are assumed to be additive, and

Table 10 Emittance Data of Commonly Used Materials

Material	Emittance ϵ at ~80°F
All-service jacket (ASJ)	0.9
Aluminum paint	0.5
Aluminum	
Anodized	0.8
Commercial sheet	0.1
Embossed	0.2
Oxidized	0.1 to 0.2
Polished	0.04
Aluminum-zinc coated steel	0.06
Canvas	0.7 to 0.9
Colored mastic	0.9
Copper	
Highly polished	0.03
Oxidized	0.8
Elastomeric or polyisobutylene	0.9
Galvanized steel	
Dipped or dull	0.3
New, bright	0.1
Iron or steel	0.8
Painted metal	0.8
Plastic pipe or jacket (PVC, PVDC, or PET)	0.9
Roofing felt and black mastic	0.9
Rubber	0.9
Silicon-impregnated fiberglass fabric	0.9
Stainless steel, new, cleaned	0.2

therefore a combined surface coefficient can be used to estimate the heat flow to and from a surface:

$$h_s = h_c + h_r \tag{9}$$

where

- h_s = combined surface coefficient, Btu/h·ft²·°F
- h_c = convection coefficient, Btu/h·ft²·°F
- h_r = radiation coefficient, Btu/h·ft²·°F

Assuming the radiant environment is equal to the ambient air temperature, the heat loss/gain at a surface can be calculated as

$$Q = h_s A(T_{surf} - T_{amb}) \tag{10}$$

The radiation coefficient is usually estimated as

$$h_r = \epsilon \sigma (T_{surf}^4 - T_{amb}^4) / (T_{surf} - T_{amb}) \tag{11}$$

where

- ϵ = surface emittance
- σ = Stephen-Boltzmann constant, 0.1712×10^{-8} Btu/h·ft²·°R⁴

Table 10 gives the approximate emittance of commonly used materials.

Controlling Surface Temperatures

A common calculation associated with mechanical insulation systems involves determining the thickness of insulation required to control the surface temperature to a certain value given the operating temperature of the process and the ambient temperature. For example, it may be desired to calculate the thickness of tank insulation required to keep the outside surface temperature at or below 140°F when the fluid in the tank is 450°F and the ambient temperature is 80°F.

At steady state, the heat flow through the insulation to the outside surface equals heat flow from the surface to the ambient air:

$$Q_{ins} = Q_{surf} \tag{12}$$

or

$$(k/X)A(T_{hot} - T_{surf}) = hA(T_{surf} - T_{amb}) \tag{13}$$

Rearranging this equation yields

$$X = (k/h)[(T_{hot} - T_{surf}) / (T_{surf} - T_{amb})] \quad (14)$$

Because the ratio of temperature differences is known, the required thickness can be calculated by multiplying by the ratio of the insulation material conductivity to the surface coefficient.

For this example, assume the surface coefficient can be estimated as 1.0 Btu/h·ft²·°F, and the conductivity of the insulation to be used is 0.25 Btu·in/h·ft²·°F. The required thickness can then be estimated as

$$X = \left(\frac{0.25}{1.0}\right) \left[\frac{(450 - 140)}{(140 - 80)}\right] = 1.29 \text{ in.} \quad (15)$$

This estimated thickness would be rounded up to the next available size, probably 1.5 in.

For radial heat flow, the thickness calculated represents the equivalent thickness; the actual thickness ($r_2 - r_1$) is less, per Equation (8).

This simple procedure can be used as a first-order estimate. In reality, the surface coefficient is not constant, but varies as a function of surface temperature, air velocity, orientation, and surface emittance.

When performing these calculations, it is important to use the actual dimensions for the pipe and tubing insulation. Many (but not all) pipe and tubing insulation products conform to dimensional standards originally published by the U.S. Navy in *Military Standard MIL-I-2781* and since adopted by other organizations, including ASTM. Standard pipe and insulation dimensions are given for reference in Table 11, and standard tubing and insulation dimensions in Table 12. Corresponding dimensional data for flexible closed-cell insulations are given in Tables 13 and 14.

For mechanical insulation systems, it is also important to realize that the thermal conductivity k of most insulation products varies significantly with temperature. Manufacturer's literature usually provides curves or tabulations of conductivity versus temperature. When performing heat transfer calculations, it is important to use the effective thermal conductivity, which can be obtained by integration of the conductivity versus temperature curve, or (as an approximation) using the conductivity evaluated at the mean temperature

across the insulation layer. ASTM *Standard* C680 provides the algorithms and calculation methodologies for incorporating these equations in computer programs.

These complications are readily handled for a variety of boundary conditions using available computer programs, such as the NAIMA 3E Plus® program [available as a download from the Web site of the North American Insulation Manufacturers Association (NAIMA), www.naima.org].

Estimates of the heat loss from bare pipe and tubing are given in Tables 15 and 16. These are useful for quickly estimating the cost of lost energy from uninsulated piping.

PROJECT SPECIFICATIONS

The importance of a well-prepared specification to meet energy conservation objectives is paramount. Specifications should

- Identify systems and equipment that must be insulated
- Identify precisely the materials selected, including thickness and jacketing, etc.
- Define the procedure for submitting alternative materials and systems
- Specify installation requirements
- Describe procedures to ensure the job is done correctly
- Comply with regional and national building codes

Although each of these steps is important, identifying systems that must be insulated is critical. When defining the materials to be used, it is important to specify them exactly, while allowing for submission of generic equivalents or value-engineered materials. Overspecifying materials limits potentially good options, and underspecifying may allow underperforming materials to be used. A proper balance is needed, and specifying key properties is required. Specifying installation requirements is as important as specifying the correct materials. Specifying procedures for submittals and quality control at the job will ensure correctness.

Reference standards from ASHRAE, ASTM, MICA, and others should be incorporated into the specifications; this practice saves time with respect to specification development, and shortens the specification considerably. Specifications that are not reviewed and updated periodically can perpetuate old technologies, obsolete materials, and fall out of code compliance.

Essentially all manufacturers of mechanical insulation products offer guide specifications for their products. These documents are insightful and offer credible information about specific products and the accessories commonly used with them. These documents are widely available on manufacturers' Web sites.

ASHRAE Learning Institute (ALI) offers training on mechanical insulation to assist in system design and specification construction. The program closely relates to this chapter and provides information on how to design and specify the insulation systems for mechanical equipment, piping, and ductwork. Specifically, the training is designed to familiarize students with

- The concept of insulation as a “system,” one that requires careful design and specificity to perform to expectations.
- The multiple, detailed steps involved in insulation system design and product selection.
- Critical installation requirements to include in the specification.
- Using ASHRAE tools and other software programs to quantify economic, energy, and environmental benefits of well-designed and specified insulation systems.

More information on ALI training can be found at <http://www.ashrae.org/education/page/554>.

CHAPTER 24

AIRFLOW AROUND BUILDINGS

Flow Patterns	24.1
Wind Pressure on Buildings	24.3
Wind Effects on System Operation	24.7
Building Pressure Balance and Internal Flow Control.....	24.9
Physical and Computational Modeling.....	24.9
Symbols	24.12

AIRFLOW around buildings affects worker safety, process and building equipment operation, weather and pollution protection at inlets, and the ability to control indoor temperature, humidity, air motion, and contaminants. Wind causes variable surface pressures on buildings that change intake and exhaust system flow rates, natural ventilation, infiltration and exfiltration, and interior pressures. The mean flow patterns and turbulence of wind passing over a building can recirculate exhaust gases to air intakes. This chapter provides basic information for evaluating windflow patterns, estimating wind pressures, and identifying problems caused by the effects of wind on intakes, exhausts, and equipment. In most cases, detailed solutions are addressed in other chapters. Related information can be found in Chapters 11, 14, 16, and 36 of this volume; in Chapters 29, 30, 44, 46, and 52 of the 2007 *ASHRAE Handbook—HVAC Applications*; and in Chapters 29, 34, and 39 of the 2008 *ASHRAE Handbook—HVAC Systems and Equipment*.

FLOW PATTERNS

Buildings having even moderately complex shapes, such as L- or U-shaped structures, can generate flow patterns too complex to generalize for design. To determine flow conditions influenced by surrounding buildings or topography, wind tunnel or water channel tests of physical scale models, tests of existing buildings, or careful computational modeling efforts are required (see the section on

Physical and Computational Modeling). Only isolated, rectangular block buildings are discussed here. English and Fricke (1997), Hosker (1984, 1985), Khanduri et al. (1998), Saunders and Melbourne (1979), and Walker et al. (1996) review the effects of nearby buildings.

As wind impinges on a building, airflow separates at the building edges, generating recirculation zones over downwind surfaces (roof, side and downwind walls) and extending into the downwind wake (Figure 1). On the upwind wall, surface flow patterns are largely influenced by approach wind characteristics. Figure 1 shows that the mean speed of wind U_H approaching a building increases with height H above the ground. Higher wind speed at roof level causes a larger pressure on the upper part of the wall than near the ground, which leads to **downwash** on the lower one-half to two-thirds of the building. On the upper one-quarter to one-third of the building, windflow is directed upward over the roof (**upwash**). For a building with height H three or more times width W of the upwind face, an intermediate stagnation zone can exist between the upwash and downwash regions, where surface streamlines pass horizontally around the building, as shown in Figures 1 (inset) and 2. (In Figure 2, the upwind building surface is “folded out” to illustrate upwash, downwash, and stagnation zones.) Downwash on the lower surface of the upwind face separates from the building before it reaches ground level and moves upwind to form a vortex that can generate high velocities close to the ground (“area of strong surface wind” in

Fig. 1 Flow Patterns Around Rectangular Building

The preparation of this chapter is assigned to TC 4.3, Ventilation Requirements and Infiltration.

Fig. 2 Surface Flow Patterns for Normal and Oblique Winds
(Wilson 1979)

Fig. 3 Flow Recirculation Regions and Exhaust-to-Intake Stretched-String Distances (S_A, S_B)

Figure 1, inset). This ground-level upwind vortex is carried around the sides of the building in U shape and suspends dust and debris that can contaminate air intakes close to ground level.

The downwind wall of a building exhibits a region of low average velocity and high turbulence (i.e., a **flow recirculation region**) extending a distance L_r downwind. If the building has sufficient length L in the windward direction, the flow reattaches to the building and may generate two distinct regions of separated recirculation flow, on the building and in its wake, as shown in Figures 2 and 3. Figure 3 also illustrates a rooftop recirculation cavity of length L_c at the upwind roof edge and a recirculation zone of length L_r downwind of the rooftop penthouse. Velocities near the downwind wall are typically one-quarter of those at the corresponding upwind wall location. Figures 1 and 2 show that an upward flow exists over most of the downwind walls.

Streamline patterns are independent of wind speed and depend mainly on building shape and upwind conditions. Because of the three-dimensional flow around a building, the shape and size of the recirculation airflow are not constant over the surface. Airflow reattaches closer to the upwind building face along the edges of the building than it does near the middle of the roof and sidewalls (Figure 2). Recirculation cavity height H_c (Figures 1 and 3) also

decreases near roof edges. Calculating characteristic dimensions for recirculation zones $H_c, L_c,$ and L_r is discussed in Chapter 44 of the 2007 ASHRAE Handbook—HVAC Applications.

For wind perpendicular to a building wall, height H and width W of the upwind building face determine the **scaling length R** that characterizes the building’s influence on windflow. According to Wilson (1979),

$$R = B_s^{0.67} B_L^{0.33} \tag{1}$$

where

- B_s = smaller of upwind building face dimensions H and W
- B_L = larger of upwind building face dimensions H and W

When B_L is larger than $8B_s$, use $B_L = 8B_s$ in Equation (1). For buildings with varying roof levels or with wings separated by at least a distance of B_s , only the height and width of the building face below the portion of the roof in question should be used to calculate R .

Flow accelerates as the streamlines compress over the roof and decelerates as they spread downward over the wake on the downwind side of the building. The distance above roof level where a building influences the flow is approximately 1.5R, as shown in

Figure 1. In addition, roof pitch also begins to affect flow when it exceeds about 15° (1:4). When roof pitch reaches 20° (1:3), flow remains attached to the upwind pitched roof and produces a recirculation region downwind of the roof ridge that is larger than that for a flat roof.

If the angle of the approach wind is not perpendicular to the upwind face, complex flow patterns result. Strong vortices develop from the upwind edges of a roof, causing strong downwash onto the roof (Figure 2). High speeds in these vortices (vorticity) cause large negative pressures near roof corners that can be a hazard to roof-mounted equipment during high winds. When the angle between the wind direction and the upwind face of the building is less than about 70°, the upwash/downwash patterns on the upwind face of the building are less pronounced, as is the ground-level vortex shown in Figure 1. Figure 2 shows that, for an approach flow angle of 45°, streamlines remain close to the horizontal in their passage around the sides of the building, except near roof level, where the flow is sucked upward into the roof edge vortices (Cochran 1992).

Both the upwind velocity profile shape and its turbulence intensity strongly influence flow patterns and surface pressures (Melbourne 1979).

WIND PRESSURE ON BUILDINGS

In addition to flow patterns described previously, the turbulence or gustiness of approaching wind and the unsteady character of separated flows cause surface pressures to fluctuate. Pressures discussed here are time-averaged values, with an averaging period of about 600 s. This is approximately the shortest time period considered to be a “steady-state” condition when considering atmospheric winds; the longest is typically 3600 s. Instantaneous pressures may vary significantly above and below these averages, and peak pressures two or three times the mean values are possible. Although peak pressures are important with regard to structural loads, mean values are more appropriate for computing infiltration and ventilation rates. Time-averaged surface pressures are proportional to wind velocity pressure p_v given by Bernoulli’s equation:

$$p_v = \frac{\rho_a U_H^2}{2g_c} \quad (2)$$

where

- U_H = approach wind speed at upwind wall height H [see Equation (4)]
- ρ_a = ambient (outdoor) air density
- g_c = gravitational proportionality constant

The proportional relationship is shown in the following equation, in which the difference p_s between the pressure on the building surface and the local outdoor atmospheric pressure at the same level in an undisturbed wind approaching the building is

$$p_s = C_p p_v \quad (3)$$

where C_p is the local wind pressure coefficient at a point on the building surface.

The local wind speed U_H at the top of the wall that is required for Equation (2) is estimated by applying terrain and height corrections to the hourly wind speed U_{met} from a nearby meteorological station.

U_{met} is generally measured in flat, open terrain (i.e., category 3 in Table 1). The anemometer that records U_{met} is located at height H_{met} , usually 33 ft above ground level. The hourly average wind speed U_H (Figures 1 and 3) in the undisturbed wind approaching a building in its local terrain can be calculated from U_{met} as follows:

$$U_H = U_{met} \left(\frac{\delta_{met}}{H_{met}} \right)^{a_{met}} \left(\frac{H}{\delta} \right)^a \quad (4)$$

Table 1 Atmospheric Boundary Layer Parameters

Terrain Category	Description	Exponent a	Layer Thickness δ , ft
1	Large city centers, in which at least 50% of buildings are higher than 80 ft, over a distance of at least 0.5 mi or 10 times the height of the structure upwind, whichever is greater	0.33	1500
2	Urban and suburban areas, wooded areas, or other terrain with numerous closely spaced obstructions having the size of single-family dwellings or larger, over a distance of at least 0.5 mi or 10 times the height of the structure upwind, whichever is greater	0.22	1200
3	Open terrain with scattered obstructions having heights generally less than 30 ft, including flat open country typical of meteorological station surroundings	0.14	900
4	Flat, unobstructed areas exposed to wind flowing over water for at least 1 mi, over a distance of 1500 ft or 10 times the height of the structure inland, whichever is greater	0.10	700

The atmospheric boundary layer thickness δ and exponent a for the local building terrain and a_{met} and δ_{met} for the meteorological station are determined from Table 1. Typical values for meteorological stations (category 3 in Table 1) are $a_{met} = 0.14$ and $\delta_{met} = 900$ ft. The values and terrain categories in Table 1 are consistent with those adopted in other engineering applications (e.g., ASCE *Standard 7*). Equation (4) gives the wind speed at height H above the average height of local obstacles, such as buildings and vegetation, weighted by the plan-area. At heights at or below this average obstacle height (e.g., at roof height in densely built-up suburbs), speed depends on the geometrical arrangement of the buildings, and Equation (4) is less reliable.

An alternative mathematical description of the atmospheric boundary layer, which uses a logarithmic function, is given by Deaves and Harris (1978). Although their model is more complicated than the power law used in Equation (4), it more closely models the real physics of the atmosphere and has been adopted by several foreign codes (e.g., SA/SNZ *Standard AS/NZS 1170.2* from Australia).

Example 1. Assuming a 23 mph anemometer wind speed for a height H_{met} of 33 ft at a nearby airport, determine the wind speed U_H at roof level $H = 50$ ft for a building located in a city suburb.

Solution: From Table 1, the atmospheric boundary layer properties for the anemometer are $a_{met} = 0.14$ and $\delta_{met} = 900$ ft. The atmospheric boundary layer properties at the building site are $a = 0.22$ and $\delta = 1200$ ft. Using Equation (4), wind speed U_H at 50 ft is

$$U_H = 23 \left(\frac{900}{33} \right)^{0.14} \left(\frac{50}{1200} \right)^{0.22} = 18.2 \text{ mph}$$

Local Wind Pressure Coefficients

Values of the mean local wind pressure coefficient C_p used in Equation (3) depend on building shape, wind direction, and influence of nearby buildings, vegetation, and terrain features. Accurate determination of C_p can be obtained only from wind tunnel model tests of the specific site and building or full-scale tests. Ventilation rate calculations for single, unshielded rectangular buildings can be reasonably estimated using existing wind tunnel data. Many wind load codes (e.g., ASCE *Standard ASCE/SEI 7-05*, SA/SNZ *Standard AS/NZS 1170.2*) give mean pressure coefficients for common building shapes.

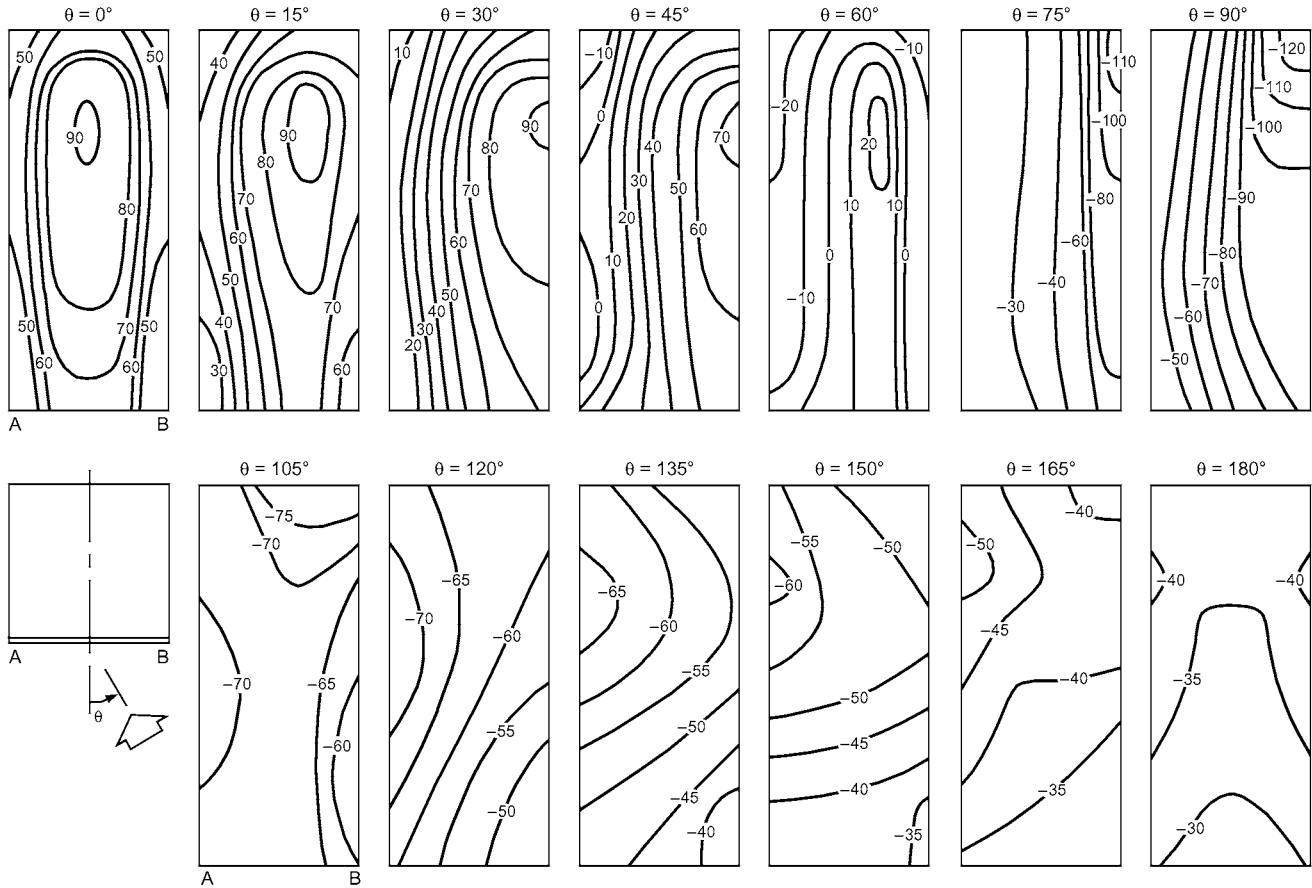

Fig. 4 Local Pressure Coefficients ($C_p \times 100$) for Tall Building with Varying Wind Direction
(Davenport and Hui 1982)

Figure 4 shows pressure coefficients for walls of a tall rectangular cross section building (high-rise) sited in urban terrain (Davenport and Hui 1982). Figure 5 shows pressure coefficients for walls of a low-rise building (Holmes 1986). Generally, for high-rise buildings, height H is more than three times the crosswind width W . For $H > 3W$, use Figure 4; for $H < 3W$, use Figure 5. At a wind angle $\theta = 0^\circ$ (e.g., wind perpendicular to the face in question), pressure coefficients are positive, and their magnitudes decrease near the sides and the top as flow velocities increase.

As seen in Figure 4, C_p generally increases with height, which reflects increasing velocity pressure in the approach flow as wind speed increases with height. As wind direction moves off normal ($\theta = 0^\circ$), the region of maximum pressure occurs closer to the upwind edge (B in Figure 4) of the building. At a wind angle of $\theta = 45^\circ$, pressures become negative at the downwind edge (A in Figure 4) of the front face. At some angle θ between 60° and 75° , pressures become negative over the whole front face. For $\theta = 90^\circ$, maximum suction (negative) pressure occurs near the upwind edge (B in Figure 4) of the building side and then recovers towards a lower-magnitude negative coefficient as the downwind edge (A in Figure 4) is approached. The degree of this recovery depends on the length of the side in relation to the width W of the structure. For wind angles larger than $\theta = 100^\circ$, the side is completely within the separated flow of the wake and spatial variations in pressure over the face are not as great. The average pressure on a face is positive for wind angles from $\theta = 0^\circ$ to almost 60° and negative (suction) for $\theta = 60^\circ$ to 180° .

A similar pattern of behavior in wall pressure coefficients for a low-rise building is shown in Figure 5. Here, recovery from strong suction with distance from the upwind edge is more rapid.

Surface-Averaged Wall Pressures

Surface-averaged pressure coefficients may be used to determine ventilation and/or infiltration rates, as discussed in Chapter 16. Figure 6 shows the surface pressure coefficient C_s averaged over a complete wall of a low-rise building (Swami and Chandra 1987). The figure also includes values calculated from pressure distributions in Figure 5. Similar results for a tall building are shown in Figure 7 (Akins et al. 1979).

The wind-induced indoor/outdoor pressure difference is found using the coefficient C_p (*in-out*), which is defined as

$$C_p \text{ (in-out)} = C_p - C_{in} \quad (5)$$

where C_{in} is the internal wind-induced pressure coefficient. For uniformly distributed air leakage sites in all the walls, C_{in} is about -0.2 , as can be found easily by integration.

Roof Pressures

Surface pressures on the roof of a low-rise building depend strongly on roof slope. Figure 8 shows typical distributions for a wind direction normal to a side of the building. Note that the direction and magnitude of pressure coefficients are indicated by the direction and length of the arrows. For very low slopes (less than about 10°), pressures are negative over the whole roof surface. The magnitude is greatest within the separated flow zone near the leading edge and recovers toward the free stream pressure downwind of the edge. For intermediate slopes (about 10 to 20°), two large-magnitude low-pressure regions are formed, one at the leading roof edge and one at the roof peak. For steeper slopes (greater than about 20°), pressures are weakly positive on the upwind slope and

Fig. 5 Local Pressure Coefficients for Walls of Low-Rise Building with Varying Wind Direction

Fig. 6 Variation of Surface-Averaged Wall Pressure Coefficients for Low-Rise Buildings
 Courtesy of Florida Solar Energy Center
 (Swami and Chandra 1987)

negative within the separated flow over the downwind slope. With a wind angle of about 45°, the vortices originating at the leading corner of a roof with a low slope can induce very large, localized negative pressures (see Figure 2). A similar vortex forms on the

 (Akins et al. 1979)

Fig. 8 Local Roof Pressure Coefficients for Roof of Low-Rise Buildings
 (Holmes 1983)

Fig. 9 Surface-Averaged Roof Pressure Coefficients for Tall Buildings
 (Akins et al. 1979)

downwind side of a leading ridge end on a steep roof, as discussed in Cochran et al. (1999). Roof corner vortices and how to disrupt their influence are discussed in Cochran and Cermak (1992) and Cochran and English (1997). Figure 9 shows the average pressure coefficient over the roof of a tall building (Akins et al. 1979).

Interference and Shielding Effects on Pressures

Nearby structures strongly influence surface pressures on both high- and low-rise buildings, particularly for spacing-to-height ratios less than five, where distributions of pressure shown in Figures 4 to 9 do not apply. Although the effect of shielding for low-rise buildings is still significant at larger spacing, it is largely accounted

for by the reduction in p , with increased terrain roughness. Bailey and Kwok (1985), Khanduri et al. (1998), Saunders and Melbourne (1979), Sherman and Grimsrud (1980), and Walker et al. (1996) discuss interference. English and Fricke (1997) discuss shielding through use of an interference index, and Walker et al. (1996) present a wind shadow model for predicting shelter factors. Chapter 16 gives shielding classes for air infiltration and ventilation applications.

Sources of Wind Data

To design for effects of airflow around buildings, wind speed and direction frequency data are necessary. The simplest forms of wind data are tables or charts of climatic normals, which give hourly average wind speeds, prevailing wind directions, and peak gust wind speeds for each month. This information can be found in sources such as *The Weather Almanac* (Bair 1992) and the *Climatic Atlas of the United States* (DOC 1968). Climatic design information, including wind speed at various frequencies of occurrence, is included in Chapter 14. A current source, which contains information on wind speed and direction frequencies, is the *International Station Meteorological Climatic Summary* CD from the National Climatic Data Center (NCDC) in Asheville, NC. Where more detailed information is required, digital records of hourly winds and other meteorological parameters are available (on magnetic tape or CD-ROM) from the NCDC for stations throughout the world. Most countries also have weather services that provide data. For example, in Canada, the Atmospheric Environment Service in Downsview, Ontario, provides hourly meteorological data and summaries.

When an hourly wind speed U_{met} at a specified probability level (e.g., the wind speed that is exceeded 1% of the time) is desired, but only the average annual wind speed U_{annual} is available for a given meteorological station, U_{met} may be estimated from Table 2. The ratios U_{met}/U_{annual} are based on long-term data from 24 weather stations widely distributed over North America. At these stations, U_{annual} ranges from 7 to 14 mph. The uncertainty ranges listed in Table 2 are one standard deviation of the wind speed ratios. The following example demonstrates the use of Table 2.

Example 2. The wind speed U_{met} that is exceeded 1% of the time (88 hours per year) is needed for a building pressure or exhaust dilution calculation. If $U_{annual} = 9$ mph, find U_{met} .

Solution: From Table 2, the wind speed U_{met} exceeded 1% of the time is 2.5 ± 0.4 times U_{annual} . For $U_{annual} = 9$ mph, U_{met} is 23 mph with an uncertainty range of 19 to 26 mph at one standard deviation.

Using a single prevailing wind direction for design can cause serious errors. For any set of wind direction frequencies, one direction always has a somewhat higher frequency of occurrence. Thus, it is often called the **prevailing wind**, even though winds from other directions may be almost as frequent.

When using long-term meteorological records, check the anemometer location history, because the instrument may have been relocated and its height varied. This can affect its directional

Table 2 Typical Relationship of Hourly Wind Speed U_{met} to Annual Average Wind Speed U_{annual}

Percentage of Hourly Values That Exceed U_{met}	Wind Speed Ratio U_{met}/U_{annual}
90%	0.2 ± 0.1
75%	0.5 ± 0.1
50%	0.8 ± 0.1
25%	1.2 ± 0.15
10%	1.6 ± 0.2
5%	1.9 ± 0.3
1%	2.5 ± 0.4

exposure and the recorded wind speeds. Equation (4) can be used to correct wind data collected at different mounting heights. Poor anemometer exposure caused by obstructions or mounting on top of a building cannot be easily corrected, and records for that period should be deleted.

If an estimate of the probability of an extreme wind speed outside the range of the recorded values at a site is required, the observations may be fit to an appropriate probability distribution (e.g., a Weibull distribution) and the particular probabilities calculated from the resulting function (Figure 10). This process is usually repeated for each of 16 wind directions (e.g., 22.5° intervals). Note that most recent wind data records are provided in 10° intervals, for which the same method may be used, except that the process is repeated for each of 36 wind directions. If both types of data are to be used, one data set must be transformed to match the other.

Where estimates at extremely low probability (high wind speed) are required, curve fitting at the tail of the probability distribution is very important and may require special statistical techniques applicable to extreme values (see Chapter 14). Building codes for wind loading on structures contain information on estimating extreme wind conditions. For ventilation applications, extreme winds are usually not required, and the 99 percentile limit can be accurately estimated from airport data averaged over less than 10 years.

Estimating Wind at Sites Remote from Recording Stations

Many building sites are located far from the nearest long-term wind recording site, which is usually an airport meteorological station. To estimate wind conditions at such sites, the terrain surrounding both the anemometer site and the building site should be checked. In the simplest case of flat or slightly undulating terrain

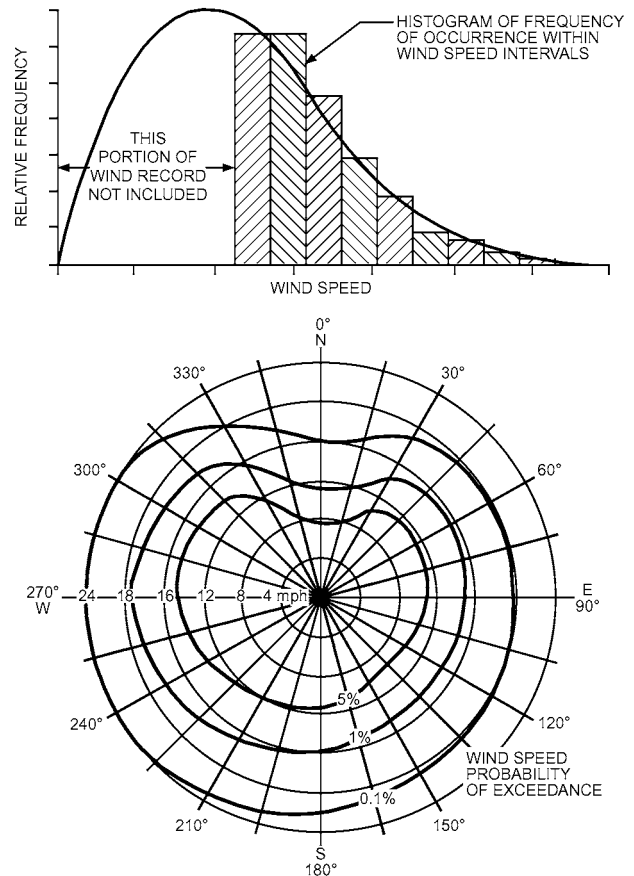

Fig. 10 Frequency Distribution of Wind Speed and Direction

with few obstructions extending for large distances around and between the anemometer site and building site, recorded wind data can be assumed to be representative of that at the building site. Wind direction occurrence frequency at a building site should be inferred from airport data only if the two locations are on the same terrain, with no terrain features that could alter wind direction between them.

In cases where the only significant difference between the anemometer site terrain and the building site terrain is surface roughness, the mean wind speed can be adjusted using Equation (4) and Table 1, to yield approximate wind velocities at the building site. Wind direction frequencies at the site are assumed to be the same as at the recording station.

In using Equation (4), cases may be encountered where, for a given wind direction, the terrain upwind of either the building or recording site does not fall into just one of the categories in Table 1. The terrain immediately upwind of the site may fall into one category, while that somewhat further upwind falls into a different category. For example, at a downtown airport the terrain may be flat and open (category 3) immediately around the recording instrument, but urban or suburban (category 2) a relatively short distance away. This difference in terrains also occurs when a building or recording site is in an urban area near open water or at the edge of town. In these cases, the suggested approach is to use the terrain category most representative of the average condition within approximately 1 mile upwind of the site (Deaves 1981). If the average condition is somewhere between two categories described in Table 1, the values of a and δ can be interpolated from those given in the table.

Several other factors are important in causing wind speed and direction at a building site to differ from values recorded at a nearby meteorological station. Wind speeds for buildings on hillcrests or in valleys where the wind is accelerated or channeled can be 1.5 times higher than meteorological station data. Wind speeds for buildings sheltered in the lee of hills and escarpments can be reduced to 0.5 times the values at nearby flat meteorological station terrain.

Solar heating of valley slopes can cause light winds of 2 to 9 mph to occur as warm air flows upslope. At night, radiant cooling of the ground can produce similar speeds as cold air drains downslope. In general, rolling terrain experiences a smaller fraction of low speeds than nearly flat terrain.

When wind is calm or light in the rural area surrounding a city, urban air tends to rise in a buoyant plume over the city center. This rising air, heated by anthropogenic sources and higher solar absorption in the city, is replaced by air pushed toward the city center from the edges. In this way, the urban heat island can produce light wind speeds and direction frequencies significantly different than those at a rural meteorological station.

In more complex terrain, both wind speed and direction may be significantly different from those at the distant recording site. In these cases, building site wind conditions should not be estimated from airport data. Options are either to establish an on-site wind recording station or to commission a detailed wind tunnel correlation study between the building site and long-term meteorological station wind observations.

WIND EFFECTS ON SYSTEM OPERATION

A building with only upwind openings is under a positive pressure (Figure 11A). Building pressures are negative when there are only downwind openings (Figure 11B). A building with internal partitions and openings (Figure 11C) is under various pressures, depending on the relative sizes of openings and wind direction. With larger openings on the upwind face, the building interior tends toward positive pressure; the reverse is also true (see Figures 4 to 9, and Chapter 16).

With few exceptions, building intakes and exhausts cannot be located or oriented such that a prevailing wind ensures ventilation

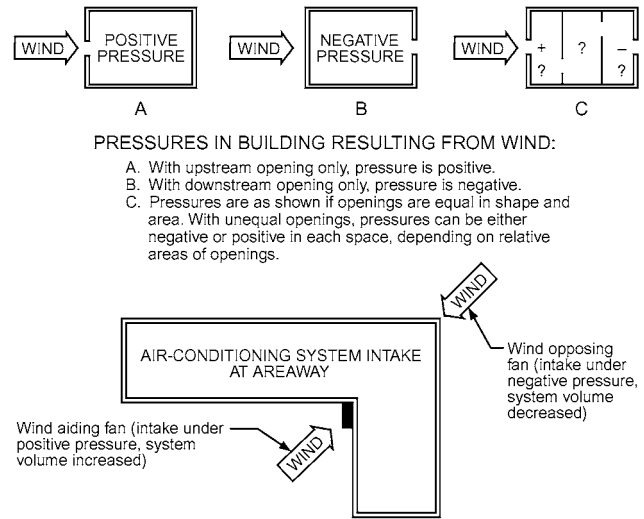

Fig. 11 Sensitivity of System Volume to Locations of Building Openings, Intakes, and Exhausts

and air-conditioning system operation. Wind can assist or hinder inlet and exhaust fans, depending on their positions on the building, but even in locations with a predominant wind direction, the ventilating system must perform adequately for all other directions. To avoid variable system flow rates, use Figures 4, 5, and 8 as a guide to placing inlets and exhausts in locations where surface pressure coefficients do not vary greatly with wind direction.

Airflow through a wall opening results from differential pressures, which may exceed 0.5 in. of water during high winds. Supply and exhaust systems, openings, dampers, louvers, doors, and windows make building flow conditions too complex for direct calculation. Iterative calculations are required because of the nonlinear dependence of volume flow rate on the differential pressure across an opening. Several multizone airflow models are available for these iterative calculations (Feustel and Dieris 1992; Walton and Dols 2005). Opening and closing of doors and windows by building occupants add further complications. In determining $C_{p(in-out)}$ from Equation (5), wind direction is more important than the position of an opening on a wall, as shown in Figures 4 and 5. Refer to Chapter 16 for details on wind effects on building ventilation, including natural and mechanical systems.

Cooling towers and similar equipment should be oriented to take advantage of prevailing wind directions, if possible, based on careful study of meteorological data and flow patterns on the building for the area and time of year.

Natural and Mechanical Ventilation

With natural ventilation, wind may augment, impede, or sometimes reverse the airflow through a building. For flat roof areas with large along-wind sides, wind can reattach to the roof downwind of the leading edge (see Figure 2). For peaked roofs, the upwind slope may be positively pressurized while the downwind slope may be negatively pressurized, as shown in Figure 8. Thus, any natural ventilation openings could see either a positive or negative pressure, dependent on wind speed and direction. Positive pressure existing where negative pressures were expected could reverse expected natural ventilation. These reversals can be avoided by using stacks, continuous roof ventilators, or other exhaust devices in which flow is augmented by wind.

Mechanical ventilation is also affected by wind conditions. A low-pressure wall exhaust fan (0.05 to 0.1 in. of water) can suffer drastic reduction in capacity. Flow can be reduced or reversed by wind pressure on upwind walls, or increased substantially when

subjected to negative pressure on the downwind wall. Side walls may be subjected to either positive or negative pressure, depending on wind direction. Clarke (1967), measuring medium-pressure air-conditioning systems (1 to 1.5 in. of water), found flow rate changes of 25% for wind blowing into intakes on an L-shaped building compared to wind blowing away from intakes. Such changes in flow rate can cause noise at supply outlets and drafts in the space served.

For mechanical systems, wind can be thought of as an additional pressure source in series with a system fan, either assisting or opposing it (Houlihan 1965). Where system stability is essential, supply and exhaust systems must be designed for high pressures (about 3 to 4 in. of water) or use devices to actively minimize unacceptable variations in flow rate. To conserve energy, the selected system pressure should be the minimum consistent with system needs.

Quantitative estimates of wind effects on a mechanical ventilation system can be made by using the pressure coefficients in Figures 4 to 9 to calculate wind pressure on air intakes and exhausts. A simple worst-case estimate is to assume a system with 100% makeup air supplied by a single intake and exhausted from a single outlet. The building is treated as a single zone, with an exhaust-only fan as shown in Figure 12. This overestimates the effect of wind on system volume flow.

Combining Equations (2) and (3), surface wind pressures at air intake and exhaust locations are

$$p_{s \text{ intake}} = C_{p \text{ intake}} \frac{\rho_a U_h^2}{2g_c} \quad (6)$$

$$p_{s \text{ exhaust}} = C_{p \text{ exhaust}} \frac{\rho_a U_h^2}{2g_c} \quad (7)$$

For the single-zone building shown in Figure 12, a worst-case estimate of wind effect neglects any flow resistance in the intake grill and duct, making interior building pressure p_{interior} equal to outdoor wind pressure on the intake ($p_{\text{interior}} = p_{s \text{ intake}}$). Then, with all system flow resistance assigned to the exhaust duct in Figure 12, and a pressure rise Δp_{fan} across the fan, pressure drop from outdoor intake to outdoor exhaust yields

$$(p_{s \text{ intake}} - p_{s \text{ exhaust}}) + \Delta p_{\text{fan}} = F_{\text{sys}} \frac{\rho Q^2}{A_L^2 g_c} \quad (8)$$

where F_{sys} is system flow resistance, A_L is flow leakage area, and Q is system volume flow rate. This result shows that, for the worst-case estimate, the wind-induced pressure difference simply adds to

Fig. 12 Intake and Exhaust Pressures on Exhaust Fan in Single-Zone Building

or subtracts from the fan pressure rise. With inlet and exhaust pressures from Equations (6) and (7), the effective fan pressure rise $\Delta p_{\text{fan eff}}$ is

$$\Delta p_{\text{fan eff}} = \Delta p_{\text{fan}} + \Delta p_{\text{wind}} \quad (9)$$

where

$$\Delta p_{\text{wind}} = (C_{p \text{ intake}} - C_{p \text{ exhaust}}) \frac{\rho_a U_h^2}{2g_c} \quad (10)$$

The fan is wind-assisted when $C_{p \text{ intake}} > C_{p \text{ exhaust}}$ and wind-opposed when the wind direction changes, causing $C_{p \text{ intake}} < C_{p \text{ exhaust}}$. The effect of wind-assisted and wind-opposed pressure differences is illustrated in Figure 13.

Example 3. Make a worst-case estimate for the effect of wind on the supply fan for a low-rise building with height $H = 50$ ft, located in a city suburb. Use the hourly average wind speed that will be exceeded only 1% of the time and assume an annual hourly average speed of $U_{\text{annual}} = 8$ mph measured on a meteorological tower at height $H_{\text{met}} = 33$ ft at a nearby airport. Outdoor air density is $\rho_a = 0.075 \text{ lb}_m/\text{ft}^3$.

Solution: From Table 2, the wind speed exceeded only 1% of the hours each year is a factor of 2.5 ± 0.4 higher than the annual average of 8 mph, so the 1% maximum speed at the airport meteorological station is

$$U_{\text{met}} = 2.5 \times 8 = 20 \text{ mph}$$

From Example 1, building wind speed U_H is 18.2 mph.

A worst-case estimate of wind effect must assume intake and exhaust locations on the building that produce the largest difference ($C_{p \text{ intake}} - C_{p \text{ exhaust}}$) in Equations (9) and (10). From Figure 5, the largest difference occurs for the intake on the upwind wall AB and the exhaust on the downwind wall CD, with a wind angle $\theta_{AB} = 0^\circ$. For this worst case, $C_{p \text{ intake}} = +0.8$ on the upwind wall and $C_{p \text{ exhaust}} = -0.43$ on the downwind wall. Using these coefficients in Equations (9) and (10) to evaluate effective fan pressure $\Delta p_{\text{fan eff}}$,

$$\begin{aligned} \Delta p_{\text{fan eff}} &= \Delta p_{\text{fan}} + [0.8 - (-0.43)] \frac{0.075(23.2)^2}{2(32.2)} \\ &= \Delta p_{\text{fan}} + 0.77 \text{ lb}_f/\text{ft}^2 \end{aligned}$$

This wind-assisted hourly averaged pressure is exceeded only 1% of the time (88 hours per year). When wind direction reverses, the outlet will be on the upwind wall and the inlet on the downwind wall, producing wind-opposed flow, changing the sign from +0.15

Fig. 13 Effect of Wind-Assisted and Wind-Opposed Flow

to -0.15 in. of water. The importance of these pressures depends on their size relative to the fan pressure rise Δp_{fan} , as shown in Figure 13.

Minimizing Wind Effect on System Volume

Wind effect can be reduced by careful selection of inlet and exhaust locations. Because wall surfaces are subject to a wide variety of positive and negative pressures, wall openings should be avoided when possible. When they are required, wall openings should be away from corners formed by building wings (see Figure 11). Mechanical ventilation systems should operate at a pressure high enough to minimize wind effect. Low-pressure systems and propeller exhaust fans should not be used with wall openings unless their ventilation rates are small or they are used in noncritical services (e.g., storage areas).

Although roof air intakes in flow recirculation zones best minimize wind effect on system flow rates, current and future air quality in these zones must be considered. These locations should be avoided if a contamination source exists or may be added in the future. The best area is near the middle of the roof, because the negative pressure there is small and least affected by changes in wind direction (see Figure 8). Avoid edges of the roof and walls, where large pressure fluctuations occur. Either vertical or horizontal (mushroom) openings can be used. On roofs with large areas, where intake may be outside the roof recirculation zone, mushroom or 180° gooseneck designs minimize impact pressure from wind flow. Vertical louvered openings or 135° goosenecks are undesirable for this purpose or for rain protection.

Heated air or contaminants should be exhausted vertically through stacks, above the roof recirculation zone. Horizontal, louvered (45° down), and 135° gooseneck discharges are undesirable, even for heat removal systems, because of their sensitivity to wind effects. A 180° gooseneck for hot-air systems may be undesirable because of air impingement on tar and felt roofs. Vertically discharging stacks in a recirculation region (except near a wall) have the advantage of being subjected only to negative pressure created by wind flow over the tip of the stack. See Chapter 44 of the 2007 *ASHRAE Handbook—HVAC Applications* for information on stack design.

Chemical Hood Operation

Wind effects can interfere with safe chemical hood operation. Supply volume variations can cause both disturbances at hood faces and a lack of adequate hood makeup air. Volume surges, caused by fluctuating wind pressures acting on the exhaust system, can cause momentary inadequate hood exhaust. If highly toxic contaminants are involved, surging is unacceptable. The system should be designed to eliminate this condition. On low-pressure exhaust systems, it is impossible to test the hoods under wind-induced, surging conditions. These systems should be tested during calm conditions for safe flow into the hood faces, and rechecked by smoke tests during high wind conditions. For more information on chemical hoods, see Chapter 14 of the 2007 *ASHRAE Handbook—HVAC Applications*. For more information on stack and intake design, see Chapter 44 of that volume.

BUILDING PRESSURE BALANCE AND INTERNAL FLOW CONTROL

Proper building pressure balance avoids flow conditions that make doors hard to open and cause drafts. In some cases (e.g., office buildings), pressure balance may be used to prevent confinement of contaminants to specific areas. In other cases (e.g., laboratories), the correct internal airflow is towards the contaminated area.

Pressure Balance

Although supply and exhaust systems in an internal area may be in nominal balance, wind can upset this balance, not only because of

its effects on fan capacity but also by superimposing infiltrated or exfiltrated air (or both) on the area. These effects can make it impossible to control environmental conditions. Where building balance and minimum infiltration are important, consider the following:

- Design HVAC system with pressure adequate to minimize wind effects
- Include controls to regulate flow rate, pressure, or both
- Separate supply and exhaust systems to serve each building area requiring control or balance
- Use revolving or other self-closing doors or double-door air locks to noncontrolled adjacent areas, particularly outside doors
- Seal windows and other leakage sources
- Close natural ventilation openings

Internal Flow Control

Airflow direction is maintained by controlling pressure differentials between spaces. In a laboratory building, for example, peripheral rooms such as offices and conference rooms are kept at positive pressure, and laboratories at negative pressure, both with reference to corridor pressure. Pressure differentials between spaces are normally obtained by balancing supply system airflows in the spaces in conjunction with exhaust systems in the laboratories. Differential pressure instrumentation is normally used to control the airflow.

The pressure differential for a room adjacent to a corridor can be controlled using the corridor pressure as the reference. Outdoor pressure cannot usually control pressure differentials within internal spaces, even during periods of relatively constant wind velocity (wind-induced pressure). A single pressure sensor can measure the outside pressure at one point only and may not be representative of pressures elsewhere.

Airflow (or pressure) in corridors is sometimes controlled by an outdoor reference probe that senses static pressure at doorways and air intakes. The differential pressure measured between the corridor and the outside may then signal a controller to increase or decrease airflow to (or pressure in) the corridor. Unfortunately, it is difficult to locate an external probe where it will sense the proper external static pressure. High wind velocity and resulting pressure changes around entrances can cause great variations in pressure.

To measure ambient static pressure, the probe should be located where airflow streamlines are not affected by the building or nearby buildings. One possibility is at a height of $1.5R$, as shown in Figure 1. However, this is usually not feasible. If an internal space is to be pressurized relative to ambient conditions, the pressure must be known on each exterior surface in contact with the space. For example, a room at the northeast corner of the building should be pressurized with respect to pressure on both the north and east building faces, and possibly the roof. In some cases, multiple probes on a single building face may be required. Figures 4 to 8 may be used as guides in locating external pressure probes. System volume and pressure control is described in Chapter 46 of the 2007 *ASHRAE Handbook—HVAC Applications*.

PHYSICAL AND COMPUTATIONAL MODELING

For many routine design applications, flow patterns and wind pressures can be estimated using the data and equations presented in the previous sections. Exhaust dilution for simple building geometries in homogeneous terrain environments (e.g., no larger buildings or terrain features nearby) can be estimated using the data and equations presented in the previous sections and in Chapter 44 of the 2007 *ASHRAE Handbook—HVAC Applications*. However, in critical applications, such as where health and safety are of concern, more accurate estimates may be required.

Computational Modeling

Computational fluid dynamics (CFD) models attempt to resolve airflow around buildings by solving the Navier-Stokes equations at

finite grid locations. CFD models are currently used to model internal flows (see Chapter 13), but are insufficient to accurately model atmospheric turbulence. According to Stathopoulos (2000, 2002), there is great potential for computational wind engineering (CWE), but the numerical wind tunnel “is still virtual rather than real.” According to Murakami (2000), CWE has become a more popular tool, but results usually include numerical errors and prediction inaccuracies. Murakami also notes that, although issues remaining for improving CWE are not many, they are very difficult.

Different methods for predicting turbulent flow around buildings are described and compared in the following paragraphs.

Direct numerical simulation (DNS) directly resolves all the spatial and temporal scales in the flow based on the exact Navier-Stokes equations. This requires very extensive computational resources (runs lasting from several hours to days, depending on computer characteristics, power, and capacity) and can at present only be applied for flow in simple geometries and at low Reynolds numbers. For the complex, high-Re-number flows in wind engineering, application of DNS will not be possible in the foreseeable future.

Large eddy simulation (LES) is a simplified method in which the spatially filtered Navier-Stokes equations are solved. Turbulent structures larger than the filter (sometimes taken equal to the grid size) are explicitly solved, while those smaller than the filter are modeled (i.e., approximated) by a subfilter model. Information on filtering and subfilter models can be found in Ferziger and Peric (2002), Geurts (2003), and Meyers et al. (2008).

In **Reynolds-averaged Navier-Stokes (RANS) simulation**, equations are obtained by averaging the Navier-Stokes equations (time-averaging if the flow is statistically steady or ensemble-averaging for time-dependent flows). With RANS, only the mean flow is solved, whereas all scales of turbulence must be modeled. Averaging generates additional unknowns for which turbulence models are required. Many turbulence models are available, but no single turbulence model is universally accepted as being the best for all types of applications.

In addition, hybrid RANS/LES approaches are available, in which **unsteady RANS (URANS)** is used near the wall, and LES in the rest of the flow field. This avoids the excessively high near-wall grid resolution required for application of LES near walls in high-Reynolds-number flow problems. An example of a hybrid RANS/LES approach is **detached eddy simulation (DES)**, as proposed by Spalart et al. (1997).

The statistically steady RANS method is the most widely applied and validated in CWE. It has been used for a wide range of building applications, including estimating pressure coefficients (Meroney et al. 2002; Murakami et al. 1992; Oliveira and Younis 2000; Richards and Hoxey 1992; Stathopoulos 1997; Stathopoulos and Zhou 1993); wind-driven rain (Blocken and Carmeliet 2002, 2004; Choi 1993, 1994; Tang and Davidson 2004); pollutant dispersion (Cowan et al. 1997; Dawson et al. 1991; Leidl et al. 1997; Li and Stathopoulos 1997; Meroney 2004; Meroney et al. 1999); pedestrian wind conditions (Blocken et al. 2008; Richards et al. 2002; Stathopoulos and Baskaran 1996; Yoshie et al. 2007); snow drift (Sundsbo 1998; This 2000); and cooling tower drift (Meroney 2006, 2008). Although many past applications of RANS have been limited to isolated buildings or relatively simple building arrangements, large and sometimes very large discrepancies have been found in comparisons with wind tunnel and full-scale measurements. These are at least partly attributed to turbulence model limitations and to the statistically steady solution of flows that exhibit pronounced transient features, such as intermittent separation, recirculation zones, and vortex shedding. In addition, a wide range of other computational aspects can contribute to uncertainties and errors, divided by COST (2007) into two broad categories: physical and numerical. Physical modeling errors and uncertainties result from assumptions and approximations made in the mathematical description of the physical process. Examples are

simplifications of the actual physical complexity (e.g., using RANS instead of DNS) and uncertainties and/or simplifications of the geometric and physical boundary conditions. Numerical errors and uncertainties are the result of the numerical solution of the mathematical model. Examples are computer programming errors, computer round-off errors, spatial and temporal discretization errors, and iterative convergence errors.

LES is a time-dependent approach in which more of the turbulence is resolved. It therefore has a larger potential to provide accurate results than statistically steady RANS simulations (Murakami et al. 1992; Tominaga et al. 1997). LES also provides more information about the flow, such as instantaneous and peak wind speeds, pressures, and pollutant concentrations. However, it requires considerably higher CPU times and memory than RANS. It also requires time- and space-resolved data as boundary conditions to properly simulate the inflow. Such experimental data are rarely available in practice (COST 2007). LES is also considered to require more experience for users to apply effectively than does RANS. These drawbacks imply that the practical application of CWE will continue to be based on statistically steady RANS for a considerable while.

Guidelines for using CFD have been developed and assembled to help users avoid, reduce, and estimate errors and uncertainties in applying CFD. ERCOFTAC (2000) provides extensive guidelines for industrial CFD applications, many of which are also applicable to CWE. COST (2007) assembled a comprehensive best-practice guideline document for CFD simulation of flows in the urban environment. Guidelines for application of CFD to pedestrian wind conditions around buildings and for predicting wind loads on buildings have been developed by the Architectural Institute of Japan and reported by Mochida et al. (2002), Tamura et al. (2008), Tominaga et al. (2008), and Yoshie et al. (2007). Other efforts have focused on specific problems, such as those encountered in simulating equilibrium atmospheric boundary layers in computational domains [e.g., Blocken et al. (2007a, 2007b); Hargreaves and Wright (2007); Richards and Hoxey (1993); Yang et al. (2008)]. Most of these guidelines apply to statistically steady RANS simulations.

Independent of whether RANS or LES is employed, evaluating the accuracy of CFD results by comparing them with wind tunnel or field experiments is very important because turbulence models are based on assumptions; no turbulence model is universally valid for all applications. Physical modeling therefore remains an indispensable tool in wind engineering.

Physical Modeling

Measurements on small-scale models in wind tunnels or water channels can provide information for design before construction. These measurements can also be used as an economical method of performance evaluation for existing facilities. Full-scale testing is not generally useful in the initial design phase because of the time and expense required to obtain meaningful information, but it is useful for verifying data derived from physical modeling and for planning remedial changes to improve existing facilities (Cochran 2006).

Detailed accounts of physical modeling, field measurements and applications, and engineering problems resulting from atmospheric flow around buildings are available in international journals, proceedings of conferences, and research reports on wind engineering (see the Bibliography).

The wind tunnel is the main tool used to assess and understand airflow around buildings. Water channels or tanks can also be used, but are more difficult to implement and give only qualitative results for some cases. Models of buildings, complexes, and the local surrounding topography are constructed and tested in a simulated turbulent atmospheric boundary layer. Airflow, wind pressures, snow loads, structural response, or pollutant concentrations can then be measured directly by properly scaling wind, building geometry, and

exhaust flow characteristics. Daghiesh (1975) and Petersen (1987a) found generally good agreement between the results of wind tunnel simulations and corresponding full-scale data. Cochran (1992) and Cochran and Cermak (1992) found good agreement between model- and full-scale measurements of low-rise architectural aerodynamics and cladding pressures, respectively. Stathopoulos et al. (1999, 2002, 2004) obtained good agreement between model- and full-scale measurements of the dispersion of gaseous pollutants from rooftop stacks on two different buildings in an urban environment.

Similarity Requirements

Physical modeling is most appropriate for applications involving small-scale atmospheric motions, such as recirculation of exhaust downwind of a laboratory, wind loads on structures, wind speeds around building clusters, snow loads on roofs, and airflow over hills or other terrain features. Winds associated with tornadoes, thunderstorms, and large-scale atmospheric motion cannot currently be physically modeled accurately.

Snyder (1981) gives guidelines for fluid modeling of atmospheric diffusion. This report contains explicit directions and should be used whenever designing wind tunnel studies to assess concentration levels of air pollutants. ASCE *Standard 7*, ASCE *Manual of Practice 67* (ASCE 1999), and AWES *Quality Assurance Manual* (AWES 2001) also provide guidance when wind tunnels are used for evaluating wind effects on structures.

A complete and exact simulation of airflow over buildings and the resulting concentration or pressure distributions cannot be achieved in a physical model. However, this is not a serious limitation. Cermak (1971, 1975, 1976a, 1976b), Petersen (1987a, 1987b), and Snyder (1981) found that transport and dispersion of laboratory exhaust can be modeled accurately if the following criteria are met in the model and full scale:

1. Match exhaust velocity to wind speed ratios, V_e/U_H .
2. Match exhaust to ambient air density ratios, ρ_e/ρ_a .
3. Match exhaust Froude numbers. $Fr^2 = \rho_a V_e^2 / [(\rho_e - \rho_a)gd]$, where d is effective exhaust stack diameter.
4. Ensure fully turbulent stack gas flow by ensuring stack flow Reynolds number ($Re_s = V_e d/\nu$) is greater than 2000 [where ν is the kinematic viscosity of ambient (outdoor) air], or by placing an obstruction inside the stack to enhance turbulence.
5. Ensure fully turbulent wind flow.
6. Scale all dimensions and roughness by a common factor.
7. Match atmospheric stability by the bulk Richardson number (Cermak 1975). For most applications related to airflow around buildings, neutral stratification is assumed, and no Richardson number matching is required.
8. Match mean velocity and turbulence distributions in the wind.
9. Ensure building wind Reynolds number ($Re_b = U_H R/\nu$) is greater than 11,000 for sharp-edged structures, or greater than 90,000 for round-edged structures.
10. Ensure less than 5% blockage of wind tunnel cross section.

For wind speeds, flow patterns, or pressure distributions around buildings, only conditions 5 to 10 are necessary. Usually, each wind tunnel study requires a detailed assessment to determine the appropriate parameters to match in the model and full scale.

In wind tunnel simulations of exhaust gas recirculation, buoyancy of the exhaust gas (condition 3) is often not modeled. This allows using a high wind tunnel speed or a smaller model to achieve high enough Reynolds numbers (conditions 4, 5, and 9). Neglecting buoyancy is justified if the density of building exhaust air is within 10% of the ambient (outdoor) air. Also, critical minimum dilution D_{crit} occurs generally at wind speeds high enough to produce a well-mixed, neutrally stable atmosphere, allowing stability matching (condition 7) to be neglected (see Chapter 44 of the 2007 *ASHRAE Handbook—HVAC Applications* for discussion of D_{crit}). However, in some cases and depending on emission sources, calm conditions

may produce critical dilution. Nevertheless, omission of conditions 3 and 7 simplifies the test procedure considerably, reducing both testing time and cost.

Buoyancy should be properly simulated for high-temperature exhausts such as boilers and diesel generators. Equality of model and prototype Froude numbers (condition 3) requires tunnel speeds of less than 100 fpm for testing. However, greater tunnel speeds may be needed to meet the minimum building Reynolds number requirement (condition 4).

Wind Simulation Facilities

Boundary layer wind tunnels are required for conducting most wind studies. The wind tunnel test section should be long enough to establish, upwind of the model building, a deep boundary layer that slowly changes with downwind distance.

Other important wind tunnel characteristics include width and height of the test section, range of wind speeds, roof adjustability, and temperature control. Larger models can be used in tunnels that are wider and taller, which, in turn, give better measurement resolution. Model blockage effects can be minimized by an adjustable roof height. Temperature control of the tunnel surface and airflow is required when atmospheric conditions other than neutral stability are to be simulated. Boundary layer characteristics appropriate for the site are established by using roughness elements on the tunnel floor that produce mean velocity, turbulence intensity profiles, and spectra characteristic of full scale.

Water can also be used for the modeling fluid if an appropriate flow facility is available. Flow facilities may be in the form of a tunnel, tank, or open channel. Water tanks with a free surface ranging in size up to that of a wind tunnel test section have been used by towing a model (upside down) through the nonflowing fluid. Stable stratification can be obtained by adding a salt solution. This technique does not allow development of a boundary layer and therefore yields only approximate, qualitative information on flow around buildings. Water channels can be designed to develop thick turbulent boundary layers similar to those developed in the wind tunnel. One advantage of such a flow system is ease of flow visualization, but this is offset by a greater difficulty in developing the correct turbulence structure and the measurement of flow variables and concentrations.

Designing Model Test Programs

The first step in planning a test program is selecting the model length scale. This choice depends on cross-sectional dimensions of the test section, dimensions of the buildings to be modeled, and/or topographic features and thickness of the simulated atmospheric boundary layer. Typical geometric scales range from about 120:1 to 1000:1.

Because a large model is desirable to meet minimum Reynolds and Froude number requirements, a wide test section is advantageous. In general, the model at any section should be small compared to the test section area so that blockage is less than 5% (Melbourne 1982).

The test program must include specifications of the meteorological variables to be considered (e.g., wind direction, wind speed, thermal stability). Data taken at the nearest meteorological station should be reviewed to obtain a realistic assessment of wind climate for a particular site. Ordinarily, local winds around a building, pressures, and/or concentrations are measured for 16 wind directions (e.g., 22.5° intervals). This is easily accomplished by mounting the building model and its nearby surroundings on a turntable. More than 16 wind directions are required for highly toxic exhausts or for finding peak fluctuating pressures on a building. If only local wind information and pressures are of interest, testing at one wind speed with neutral stability is sufficient.

SYMBOLS

- a = exponent in power law wind speed profile for local building terrain, Equation (4) and Table 1, dimensionless
 A_L = flow leakage area, Equation (8), ft²
 a_{met} = exponent a for the meteorological station, Equation (4) and Table 1, dimensionless
 B_L = larger of two upwind building face dimensions H and W , Equation (1), ft
 B_s = smaller of two upwind building face dimensions H and W , Equation (1), ft
 C_p = local wind pressure coefficient for building surface, Equation (3), dimensionless
 $C_{p\ in}$ = internal wind-induced pressure coefficient, Equation (5), dimensionless
 $C_{p\ (in-out)}$ = difference between outdoor and indoor pressure coefficients, Equation (5), dimensionless
 C_s = surface-averaged pressure coefficient, Figure 6, dimensionless
 d = effective stack diameter, ft
 D_{crit} = critical dilution factor at roof level for uncapped vertical exhaust at critical wind speed (see Chapter 44 of the 2007 ASHRAE Handbook—HVAC Applications), dimensionless
 Fr = Froude number, dimensionless
 F_{sys} = system flow resistance, Equation (8), dimensionless
 g = acceleration of gravity, 32.2 ft/s²
 g_c = gravitational proportionality constant, Equations (2), (6), (7), (10), 32.2 ft·lb_m/lb_f·s²
 H = wall height above ground on upwind building face, Equation (4) and Figure 1, ft
 H_c = maximum height above roof level of upwind roof edge flow recirculation zone, Figures 1 and 3, ft
 H_{met} = height of anemometer at meteorological station, Equation (4), ft
 h_s = exhaust stack height (typically above roof unless otherwise specified, ft (see Figure 3, and Chapter 44 in the 2007 ASHRAE Handbook—HVAC Applications)
 L = length of building in wind direction, Figures 1 and 2, ft
 L_c = length of upwind roof edge recirculation zone, Figure 3, ft
 L_r = length of flow recirculation zone behind rooftop obstacle or building, Figures 1 and 3, ft
 p_s = wind pressure difference between exterior building surface and local ambient (outdoor) atmospheric pressure at same elevation in undisturbed approach wind, Equation (3), lb_f/ft²
 p_v = wind velocity pressure at roof level, Equation (2), lb_f/ft²
 Q = volumetric flow rate, Equation (8), cfm
 R = scaling length for roof flow patterns, Equation (1), ft
 Re_b = building Reynolds number, dimensionless
 Re_s = stack flow Reynolds number, dimensionless
 S = stretched-string distance; shortest distance from exhaust to intake over obstacles and along building surface, ft (see Figure 3, and Chapter 44 in the 2007 ASHRAE Handbook—HVAC Applications)
 U_{annual} = annual average of hourly wind speeds U_{met} , Table 2, mph
 U_H = mean wind speed at height H of upwind wall in undisturbed flow approaching building, Equation (2) and Figures 1, 2, and 3, mph
 U_{met} = meteorological station hourly wind speed, measured at height H_{met} above ground in smooth terrain, Equation (4) and Table 2, mph
 V_e = exhaust face velocity, mph
 W = width of upwind building face, Figure 2, ft
- Greek**
- δ = fully developed atmospheric boundary layer thickness, Equation (4) and Table 1, ft
 δ_{met} = atmospheric boundary layer thickness at meteorological station, Equation (4) and Table 1, ft
 Δp_{fan} = pressure rise across fan, Equation (8), psi
 $\Delta p_{fan\ eff}$ = effective pressure rise across fan, Equation (9), psi
 Δp_{wind} = wind-induced pressure, Equations (9) and (10), psi
 θ = angle between perpendicular line from upwind building face and wind direction, Figures 4 to 7, degrees
 ν = kinematic viscosity of ambient (outdoor) air, ft²/s
 ρ_a = ambient (outdoor) air density, Equation (2), lb_m/ft³
 ρ_e = density of exhaust gas mixture, lb_m/ft³

PROPER design of space heating, cooling, and air conditioning requires detailed knowledge of the building envelope’s overall heat, air, and moisture control performance. This chapter provides guidance in the analysis and design of building envelope assemblies for good heat, air, and moisture control performance. Guidance for designing mechanical systems is found in other chapters of the ASHRAE Handbook series. This chapter discusses the fundamentals of combined heat, air, and moisture movement as it relates to envelope assemblies.

Because heat, air, and moisture transfer are coupled and closely interact with each other, they should not be treated separately. In fact, improving a building envelope’s energy performance may cause moisture-related problems. Evaporation of water or removal of moisture by any other means are processes that may require considerable energy that is not always available. Only a sophisticated moisture control strategy can ensure hygienic conditions and adequate durability for modern, energy-efficient building assemblies. Effective moisture control design must deal with all hygrothermal loads (heat and humidity) acting on the building envelope.

TERMINOLOGY AND SYMBOLS

The following heat, air, and moisture definitions and symbols are commonly used.

A **building envelope** or **building enclosure** provides physical separation between the indoor and outdoor environments. A **building assembly** is any part of the building enclosure, such as wall assembly, window assembly, or roof assembly, that has boundary conditions at the interior and the exterior of the building. A **building component** is any element or material within a building assembly.

Heat

Specific heat capacity c is the change in heat (energy) of unit mass of material for unit change of temperature in $\text{Btu}/\text{lb}\cdot^{\circ}\text{F}$.

Volumetric heat capacity ρc is the change in heat stored in unit volume of material for unit change of temperature, in $\text{Btu}/\text{ft}^3\cdot^{\circ}\text{F}$.

The vector **heat flux** q is the time rate of heat transfer through a unit area, in $\text{Btu}/\text{h}\cdot\text{ft}^2$.

Thermal conductivity k [also often the Greek letter λ (lambda)] is the steady-state heat flux through a unit thickness of a homogeneous material in a direction perpendicular to the isothermal planes, induced by a unit temperature difference. (ASTM *Standard* C168 defines homogeneity.) Units are $\text{Btu}\cdot\text{in}/\text{h}\cdot\text{ft}^2\cdot^{\circ}\text{F}$ (preferred) or $\text{Btu}/\text{h}\cdot\text{ft}\cdot^{\circ}\text{F}$. Thermal conductivity must be evaluated for a specific mean temperature, thickness, age, and moisture content. For porous

materials, heat flows by a combination of conduction, convection, radiation, and latent heat exchange and may depend on orientation, direction, or both. The measured property of such materials is called **apparent thermal conductivity**. The specific test conditions (i.e., sample thickness, orientation, environment, environmental pressure, surface temperature, mean temperature, temperature difference, and moisture distribution) should be reported with the values. The symbol k_{app} is used to denote the lack of pure conduction or to indicate that all values reported are apparent. Materials with a low apparent thermal conductivity are called *insulation* materials (see Chapter 26 for more detail).

Thermal resistivity R_u is the reciprocal of thermal conductivity. Units are $\text{h}\cdot\text{ft}^2\cdot^{\circ}\text{F}/\text{Btu}\cdot\text{in}$.

Thermal conductance C is the heat flux through a flat body induced by a unit temperature difference between the surfaces of that body. Units are $\text{Btu}/\text{h}\cdot\text{ft}^2\cdot^{\circ}\text{F}$. When the two defined surfaces have unequal areas, as with heat flux through materials of nonuniform thickness, an appropriate mean area and mean thickness must be given. Thermal conductance formulas involving materials that are not uniform slabs must contain shape factors to account for the area variation involved. When heat flux occurs by conduction alone, the thermal conductance of a layer may be obtained by dividing the material’s thermal conductivity by its thickness. When several modes of heat transfer are involved, the **apparent thermal conductance** may be obtained by dividing the material’s apparent thermal conductivity by its thickness. When air circulates within or passes through insulation, as may happen in low-density fibrous materials, the apparent thermal conductance is affected. Thermal conductances and resistances of common building and insulation materials are listed in Chapter 26.

Thermal resistance R is the mean temperature difference between two defined surfaces of material or construction under steady-state conditions that induces a unit heat flux, in $\text{ft}^2\cdot\text{h}\cdot^{\circ}\text{F}/\text{Btu}$.

Heat transfer film coefficient h_i or h_o is heat transferred by convection and radiation between an inside or outside surface and the surrounding environment per unit time and unit area, induced by a unit temperature difference between the surface and reference temperature in the surrounding environment. Units are $\text{Btu}/\text{h}\cdot\text{ft}^2\cdot^{\circ}\text{F}$.

Surface film resistance R_i or R_o is the reciprocal of the inside or outside surface heat transfer film coefficient, in $\text{ft}^2\cdot\text{h}\cdot^{\circ}\text{F}/\text{Btu}$. For convection to occur, the surrounding space must be filled with air or another fluid. If the space is evacuated, heat flow occurs by radiation only.

Thermal transmittance U is the heat flux under steady-state conditions from the environment on the one side of a body to the environment on the other side, per unit temperature difference between the two environments, in $\text{Btu}/\text{h}\cdot\text{ft}^2\cdot^{\circ}\text{F}$. Thermal transmittance is sometimes called the **overall coefficient of heat transfer** or

The preparation of this chapter is assigned to TC 4.4, Building Materials and Building Envelope Performance.

U-factor. Thermal transmittance includes surface film conductance.

Thermal emittance ϵ is the ratio of radiant flux emitted by a surface to that emitted by a black surface at the same temperature.

Effective emittance of an air space E is the combined effect of emittances from the boundary surfaces of an air space, where the boundaries are parallel and of a dimension much larger than the distance between them. Chapter 26 lists values of E for various air spaces.

Air

Air transfer M_a is airflow induced by an air pressure difference, caused by wind, stack effect, or mechanical systems, in lb_m/s .

Air flux m_a , a vector, is the time rate of air transfer through a unit area, in $\text{lb}/\text{ft}^2 \cdot \text{h}$.

Air permeability k_a is the air flux through a unit thickness of homogeneous material in a direction perpendicular to the isobaric planes, induced by a unit air pressure difference. Units are in $\text{lb}/\text{ft} \cdot \text{h} \cdot \text{in. Hg}$ or $\text{lb}/\text{ft} \cdot \text{s} \cdot \text{in. Hg}$.

Air permeance K_a is the time rate of air transfer through a unit surface of a porous membrane or layer induced by a unit air pressure difference over that layer. Units are $\text{lb}/\text{ft} \cdot \text{h} \cdot \text{in. Hg}$ or $\text{lb}/\text{h} \cdot \text{in. Hg}$.

Moisture

Moisture content w is the amount of moisture per unit volume of porous material, in lb/ft^3 .

Moisture ratio X (in weight) or Ψ (in volume) is the amount of moisture per unit weight of dry porous material or the volume of moisture per unit volume of dry material, in percent.

Specific moisture content is the ratio between a change in moisture content and the corresponding change in driving potential.

Specific moisture ratio is the ratio between a change in moisture ratio and the corresponding change in driving potential.

Water vapor flux m_v , is the time rate of water vapor transfer through a unit area, in $\text{lb}/\text{ft}^2 \cdot \text{h}$.

Water vapor permeance M is the water vapor flux by diffusion through a unit area of a flat layer, induced by a unit partial water vapor pressure difference across that layer, in $\text{lb}/\text{ft}^2 \cdot \text{h} \cdot \text{in. Hg}$.

Water vapor permeability μ_p is the water vapor flux through a unit thickness of homogeneous material in a direction perpendicular to the isobaric planes, induced by a unit partial water vapor pressure difference, under specified temperature and humidity. Units are $\text{lb}/\text{ft} \cdot \text{h} \cdot \text{in. Hg}$. When permeability varies with psychrometric conditions, the specific permeability defines the property at a specific condition.

Water vapor resistance Z is the reciprocal of water vapor permeance, in $\text{ft}^2 \cdot \text{h} \cdot \text{in. Hg}/\text{kg}$.

Moisture transfer M_m is the moisture flow induced by a difference in suction or in relative humidity, in lb/h .

Moisture flux m_m , a vector, is the time rate of moisture transfer through a unit area, in $\text{lb}/\text{ft}^2 \cdot \text{h}$.

Moisture permeability k_m is the moisture flux through a unit thickness of a homogeneous material in a direction perpendicular to the isosuction planes, induced by a unit difference in suction. Units are $\text{lb}/\text{ft} \cdot \text{h} \cdot \text{in. Hg}$ (suction).

Moisture diffusivity D_m is the ratio between the moisture permeability and the volumetric moisture capacity, in ft^2/h .

ENVIRONMENTAL HYGTHERMAL LOADS

The main function of the building enclosure is separation of indoor spaces from the outdoor climate. This section describes the hygrothermal loads acting on the building envelope. The purpose of these load descriptions is to predict their influence on the hygrothermal behavior of building assemblies, as a basis for design recommendations and moisture control measures (Künzel and Karagiozis

2004). Load estimations for sizing mechanical systems can be found in Chapters 17 and 18.

In Figure 1, the hygrothermal loads relevant for building envelope design are represented schematically for an external wall. Generally, they show diurnal and seasonal variations at the exterior surface and mainly seasonal variations at the interior surface. During daytime, the exterior wall surface heats by solar radiation, leading to evaporation of moisture from the surface layer. Around sunset, when solar radiation decreases, long-wave (infrared) emission may lead to overcooling (cooling below ambient air temperature) of the façade, and exterior surface condensation may occur. The exterior surface is also exposed to moisture from wind-driven precipitation.

Usually, several load cycles overlap (e.g., summer/winter, day/night, rain/sun). Therefore, a precise analysis of the expected hygrothermal loads should be done before starting to design any building envelope component. However, the magnitude of the loads is not always independent of building geometry and the component's properties. Analysis of the transient hygrothermal loads is generally based on hourly meteorological data. However, the determination of local conditions at the envelope's surface is rather complicated and requires specific experience. In some cases, computer simulations are necessary to assess the microclimate acting on differently oriented or inclined building assemblies.

Ambient Temperature and Humidity

Ambient temperature and humidity with respect to (res.) partial vapor pressure are the boundary conditions always affecting both sides of the building envelope. The climate-dependent exterior conditions may show large diurnal and seasonal variations. Therefore, hourly data are required for most building simulations. ASHRAE provides such meteorological data sets, including temperature and relative humidity, for many locations worldwide (see Chapter 14). These data sets usually represent average meteorological years based on long-term observations at specific locations. However, data of more extreme climate conditions may be important to assess the risks of moisture damage. Therefore, Sanders (1996) proposed using data of the coldest or warmest year in 10 years for hygrothermal analysis instead of data from an average year. However, the temperature at the building site may differ from the meteorological reference data when the site's altitude differs from that of the station recording the data. On average, there is a temperature shift of $\pm 1^\circ\text{F}$ for every ± 350 ft. The microclimate around the building may result

Fig. 1 Hygrothermal Loads and Alternating Diurnal or Seasonal Directions Acting on Building Envelope

Fig. 2 Solar Vapor Drive and Interstitial Condensation

in an additional temperature shift that depends on the season. For example, the proximity of a lake can moderate seasonal temperature variations, with higher temperatures in winter and lower temperatures in summer compared to sites without water nearby. A low-lying site experiences lower temperatures in winter, whereas city temperatures are higher year round (METEOTEST 2007).

Indoor climate conditions depend on the purpose and occupation of the building. For most commercial constructions, temperature and humidity are controlled by HVAC systems with usually well-defined set points. Indoor conditions in residential buildings are influenced by the outdoor climate and by occupant behavior. The moisture release in an average household is highly variable. According to Sanders (1996), it may range from 6 to 40 lb per day, with an average of approximately 16 lb per day. This moisture must be removed by ventilation or air conditioning. The resulting relative humidity may be determined by hygrothermal whole-building simulation or by simple estimation methods using information on moisture production, air change rates, and climate-dependent HVAC operation (Ten-Wolde and Walker 2001). The presence of spa or swimming pools may increase the load substantially. Information on typical indoor climate conditions of special-purpose constructions like spas, ice rinks, or agricultural buildings and production plants may be found in the 2007 *ASHRAE Handbook—HVAC Applications*.

Solar Radiation

Incident solar radiation is the major thermal load at the building envelope's exterior. For mainly direct solar radiation, the resultant heat source depends on the angle between the sun and the normal of the exposed surface and on its color (short-wave absorptivity). For calculation of incident solar heat flux and spectra, see Chapter 15.

Regarding moisture control, solar radiation is usually considered beneficial unless an envelope component is completely shaded. However, in some cases solar radiation combined with water from precipitation or other sources (e.g., construction moisture) can lead to severe moisture problems. For example, as shown in Figure 2, if the water-absorbing exterior layer of an assembly (e.g., brick veneer, a typical example of “reservoir” cladding) has been wetted by wind-driven rain, heat from solar radiation may drive some of the evaporating water inwards. The resulting high vapor pressure in the cladding causes vapor diffusion toward the ambient air as well as toward the interior of the building assembly, leading to condensation on material layers within the assemblies such as sheathing boards or vapor retarders. Adapting the permeance of vapor retarders and weather-resistive barriers (WRB) to the potential loads may improve the situation. ASHRAE Research Project RP-1091 (Burnett et al. 2004) showed that cladding ventilation is also an effective remedy within specified exterior air humidity limits.

Exterior Condensation

Long-Wave Radiant Effects. Long-wave radiation exchange of the envelope surface with the cold layers of the lower atmosphere is a major heat transfer process. At night or with the sun at a low angle, it results in a net heat flux to the sky (i.e., heat energy sink) (see Chapter 15). Depending on the building assembly's thermal properties, this may lead to a drop in the envelope's surface temperature below the ambient air temperature (overcooling). If the surface temperature reaches the air's dew point, condensation will occur on the exterior surface of the building assembly. Massive structures with a high thermal inertia do not usually lose enough heat to the nighttime radiation sink to bring the surface temperature below the dew point for a significant period of time. However, many modern building assemblies, such as lightweight roofs or exterior insulation finish systems (EIFS), have little thermal inertia in their exterior surface layers and are therefore subject to considerable amounts of exterior condensation (Künzel 2007).

Interior Temperature Differential. Exterior condensation can also occur on poorly insulated assemblies in cooling climates because of the operation of air-conditioning systems. Repeated exterior condensation or long-lasting, high relative humidity often provides the basis for soiling or microbial growth (fungi or algae), which may not be acceptable even though the durability of the assembly is unlikely to be affected.

Effect on Other Layers. Under exterior condensation conditions, ventilated assemblies may also experience condensation within the ventilated air layer. This phenomenon has been discovered by investigating pitched roofs with cathedral ceiling insulation (Hens 1992; Janssens 1998; Künzel and Grosskinski 1989). However, damage cases because of condensation in the ventilation plane are rare, except in metal roofs (Zheng et al. 2004). Occasionally, soiling because of condensate runoff has been reported.

Wind-Driven Rain

The load from rain, especially wind-driven rain, is the main reason for moisture-related building failure. Because the requirements of sometimes costly rain-protection measures depend on the local climate, some countries have introduced regional driving-rain classifications. Generally, coastal regions and those on the windward side of mountains receive the highest precipitation load. Areas of low rainfall do not have the potential for severe wind-driven rain.

Regional precipitation and wind loads are significant factors in determining local wind-driven rain load, but local exposure conditions are of equal importance. A building in the open field receives a higher load than one sheltered by a forest or other buildings. A quantification of exposure conditions for walls depending on landscape, neighborhood, and building size and geometry can be found in the British *Standard* BS 8104 and in the European *ISO/DIN Standard* 15927-3:2006. The average wind-driven rain load R_D in the open ground was investigated by Lacy (1965). It may be estimated from normal rain R_N and the wind velocity component v parallel to the considered orientation, as shown in the following equation:

$$R_D = fvR_N \quad (1)$$

where

R_D = wind-driven rain intensity, lb/ft²·h

f = empirical factor = approximately 0.06 s/ft

v = mean wind velocity, ft/s (or mph)

R_N = rain intensity on a horizontal surface in the open field, lb/ft²·h

Figure 3 shows a typical plot (a “rain rose”) of results from Equation (1) plotted in polar coordinates indicating the amount of wind-driven rain in mass per unit area hitting an unobstructed and isolated vertical surface in the open ground.

The driving rain load close to a façade is considerably less than in the open ground (as shown in Figure 4), and it becomes irregular. Tops and edges of walls generally receive the highest amount of

driving rain deposition. This is caused by the airflow pattern around a building (see Chapter 24 for more information). At the windward side, high pressure gradients coincide with large changes in air velocity. The building acts as an obstacle for the wind, slowing down the airflow and subsequently reducing the wind-driven rain load near the façade. Gravity and the momentum of the rain droplets prevent them from following the airflow around the building, causing them to strike the façade mainly at the edges of the flow obstacle (Straube and Burnett 2000).

However, the irregular driving rain deposition is often evened out by water running off the hard-hit areas, especially when the façade surface has low water absorptivity or the wind-driven rain load is high enough to saturate the most exposed surface layers.

Roof overhangs can reduce the driving rain load on low-rise buildings. Slightly inclined wall sections or protruding façade elements may receive a considerable amount of splash water from façade areas above them, in addition to the direct driving rain deposition. This is often a problem for buildings with walls slightly out of vertical (Hens 2008).

Construction Moisture

Building damage as a result of migrating construction moisture has become more frequent because tight construction schedules leave little time for building materials to dry. Although often disregarded, construction moisture is either delivered with the building products or absorbed by the materials during storage or construction. Cast-in-place concrete, autoclaved aerated concrete (AAC), calcium silicate brick (CSB) and “green” wood are examples of materials that contain significant moisture when delivered. Stucco, mortar, clay brick, and concrete blocks are examples of materials that are either mixed or brought into contact with water at the construction site. All other porous building materials may take up considerable amounts of precipitation or groundwater when left unprotected during storage or construction before the enclosure of the building.

A single-family house made of AAC may initially contain up to 15 tons of water in its walls. Care must be taken to safely remove that water, either by additional ventilation during the first years of

operation or by using construction dryers before putting the building into service. Even “dry” materials have an initial water content of approximately the **equilibrium moisture content at 80% rh (EMC₈₀)**. When significant construction moisture is encountered, EMC₈₀ can be exceeded by a factor of two or more.

Ground- and Surface Water

A high groundwater table or surface water running toward the building and filling the loosefill triangle around the basement represent important moisture loads to the lower parts of the building envelope. These loads should be met by grading the ground away from the building, perimeter drainage, and waterproofing the basement and foundation. Instead of waterproofing by bituminous membranes or coatings, water-impermeable structural elements may be used in building practice (e.g., reinforced concrete, which may, however, be vapor permeable). The resulting vapor flux also presents a load that must be accounted for (e.g., by basement ventilation). Moisture loads in the ground may impair the performance of exterior basement insulation applied on the outside of the waterproofing layer. Therefore, special care must be taken to protect insulation from moisture accumulation unless the insulation material is itself impermeable to water and vapor (e.g., foam glass).

Wicking of ground- or surface water into porous walls by capillary action is called **rising damp**. This phenomenon may be a sign of poor drainage or waterproofing of the building’s basement or foundation. However, other phenomena show moisture patterns similar to rising damp. If the wall is contaminated with salts, which may be the case in historic buildings, there might also be an elevated moisture content in the wall caused by a hygroscopicity increase resulting from water uptake by the salt crystals. Another reason for the appearance of rising damp may actually be surface condensation in unheated buildings during summer.

Air Pressure Differentials

Wind and stack effects caused by differences between indoor and outdoor temperature result in air pressure differentials over the building envelope. In contrast to wind, stack effect is a permanent load that may not be neglected. Worse, stack pressure may act in the same direction as vapor pressure: from inside to outside during the heating season, and in the opposite direction during the cooling season. Therefore, airflow through cracks, imperfect joints, or air-permeable assembly layers may cause interstitial condensation in a manner similar to vapor diffusion. However, condensation caused by stack-induced airflow is likely to be more intense and concentrated around leaks in the building envelope. This can become a problem at the top of a building, which may be especially vulnerable because of leaks at the parapets. To avoid moisture damage, airflow through and within the building envelope should be prevented by a continuous air barrier. Because it is difficult to guarantee total airtightness of the building envelope, the hygrothermal effect of airflow can be quite important, especially when high pressure differentials are expected (e.g., in multistory or mechanically pressurized buildings). For the practical determination of pressure differentials and airflow, see Chapter 16. Air pressures across the envelope may also drive liquid water inward or outward.

HEAT TRANSFER

Heat flow through the building envelope is mainly associated with the energy performance of buildings. However, other aspects of heat transfer are equally important. Interior surface temperature serves not only as an indicator for hygienic conditions in the building (e.g., conditions preventing surface condensation or mold growth), it can also be a major factor for thermal comfort. Temperature peaks and fluctuations within the building envelope or on its surfaces may also affect the envelope’s durability. At low temperature, building materials tend to become less elastic and sometimes brittle, making

Fig. 3 Typical Wind-Driven Rain Rose for Open Ground

Fig. 4 Measured Reduction in Catch Ratio Close to Façade of One-Story Building at Height of 6 ft

them vulnerable to strain or mechanical impact. At high temperature, some materials degrade because of chemical reactions or irreversible deformation. Deformation and local mechanical failure can also occur under the influence of steep temperature gradients or transients. Whereas some of these aspects can be assessed by steady state calculations (e.g., heating energy losses), others require transient simulations for accurate evaluation.

As explained in Chapter 4, heat transfer by apparent conduction in a solid is governed by Fourier's law:

$$q = -k \text{grad}(t)$$

$$q = -\left(k_x \frac{dt}{dx} + k_y \frac{dt}{dy} + k_z \frac{dt}{dz}\right) \quad (2)$$

where

- q = heat flux, Btu/h·ft²
- t = temperature, °F
- k_x, k_y, k_z = apparent thermal conductivity in direction of $x, y,$ and z axes, Btu/h·ft·°F
- $\text{grad}(t)$ = gradient of temperature (change in temperature per unit length, perpendicular to isothermal surfaces in solid), °F/ft
- dt/dx = gradient of temperature along x axis, °F/ft
- dt/dy = gradient of temperature along y axis, °F/ft
- dt/dz = gradient of temperature along z axis, °F/ft

The thermal conductivity k of the material may be directionally dependent. In fact, many building materials show considerable anisotropy. Examples are wood and wood-based materials, mineral fiber insulation, and perforated bricks. Therefore, $k_x, k_y,$ and k_z are generally not equal.

Substituting Equation (2) into the relationship for conservation of energy yields

$$\frac{\partial h}{\partial t} \times \frac{\partial t}{\partial \tau} = \text{div}[k \text{grad}(t)] + S$$

$$= \frac{\partial}{\partial x} \left(k_x \frac{\partial t}{\partial x} \right) + \frac{\partial}{\partial y} \left(k_y \frac{\partial t}{\partial y} \right) + \frac{\partial}{\partial z} \left(k_z \frac{\partial t}{\partial z} \right) + S \quad (3)$$

where

- h = enthalpy per unit volume, Btu/ft³
- S = heat sources and sinks (e.g., caused by latent heat of evaporation/condensation in presence of moisture or chemical reactions such as in concrete hydration), Btu/h·ft³

with

$$\frac{\partial h}{\partial \tau} = \rho_s c_s + w c_w \quad (4)$$

where

- ρ_s = density of solid (dry material), lb/ft³
- c_s = specific heat capacity of dry solid, Btu/lb·°F
- c_w = specific heat capacity of liquid water, Btu/lb·°F
- w = moisture content, lb/ft³

STEADY-STATE THERMAL RESPONSE

In steady state without sources or sinks, Equation (3) reduces to

$$\frac{\partial}{\partial x} \left(k_x \frac{\partial t}{\partial x} \right) + \frac{\partial}{\partial y} \left(k_y \frac{\partial t}{\partial y} \right) + \frac{\partial}{\partial z} \left(k_z \frac{\partial t}{\partial z} \right) = 0 \quad (5)$$

If the steady-state heat flux is only in one direction (e.g., perpendicular to the building envelope), Equation (2) can be rewritten for each material layer within the building envelope as

$$q = -k_m \frac{\Delta t}{\Delta x} = -C \Delta t = -\frac{1}{R} \Delta t \quad (6)$$

where

- Δt = temperature difference between two interfaces of one material layer, °F
- Δx = layer thickness, ft
- k_m = mean thermal conductivity of material layer with thickness Δx , Btu/h·ft²·°F
- C = thermal conductance of layer with thickness Δx , Btu/h·ft²·°F
- R = thermal resistance of layer with thickness Δx , h·ft²·°F/Btu

Under steady-state conditions, the one-dimensional heat flux is the same through all material layers, but their individual thermal conductance or resistance is usually different.

Thermal Resistance of a Flat Assembly

A single layer's thermal resistance to heat flow is given by the ratio of its thickness to its apparent thermal conductivity. Accordingly, the surface-to-surface thermal resistance of a flat building assembly composed of parallel layers (e.g., a ceiling, floor, or wall), or a curved component if the curvature is small, consists of the sum of the resistances (R -values) of all layers in series:

$$R_s = R_1 + R_2 + R_3 + R_4 + \dots + R_n \quad (7)$$

where

- R_1, R_2, \dots, R_n = resistances of individual layers, h·ft²·°F/Btu
- R_s = resistance of building assembly surface to surface (system resistance), h·ft²·°F/Btu

For building components with nonuniform or irregular sections, such as hollow clay and concrete blocks, use the R -value of the unit as manufactured. To obtain the overall resistance (air to air), the surface film resistances R_i and R_o must be added to R .

The surface film resistance and its reciprocal, the heat transfer film coefficient, specify the heat transfer to or from a surface by the combined effect of convection and conduction. Although these contributions are affected by surface roughness and temperature difference between the air and surface, the largest influence is that of air movement, turbulence, and velocity close to the surface. Because air movement at the envelope surface depends on wind speed and direction, as well as flow patterns around the building, which are usually unknown, average film coefficients for interior and exterior heat transfer are normally used. Correlations such as that of Schwarz (1971) link the convective film coefficient to wind speed recorded at a height of 30 ft and to orientation of the surface (windward or leeward side). However, because the surface-to-surface thermal resistance of a wall is usually high compared with the surface film resistances, an exact value is of minor importance for most applications.

Heat is also transported between the envelope's surface and the environment by thermal radiation. Because air is rather permeable to long-wave radiation, the radiative heat exchange takes place between the surface and objects in the environment, not the surrounding air. Heat transfer by radiation between two surfaces is controlled by the character of the surfaces (emittance and reflectance), the temperature difference between them, and the angle factor through which they see each other. Indoors, the external wall surface exchanges radiation with partition walls, floor, and ceiling, furniture, and other external walls. In winter, most of the other surfaces have a higher temperature than the external wall surface; therefore, there is a net heat flux to the external wall by radiative exchange. Outdoors, the external wall surface sees the ground, neighboring buildings, and the sky. Without the sun, thermal radiation from the sky is normally low compared to the radiation from the wall. This means the wall is losing energy to the sky. Especially during clear nights, the temperature of the exterior surface of the external wall may drop below the ambient air temperature. In this case, convective and radiative heat transfer at the surface are opposed to each other.

Combined Convective and Radiative Surface Transfer

For simplicity, convective and radiative surface transfer coefficients are often combined, leading to the **apparent transfer coefficient h** :

$$q = h(t_{en} - t_s) \quad (8)$$

with

$$h = h_c + h_r \quad (9)$$

where

- q = total surface heat transfer, Btu/h·ft²
- h = apparent surface transfer coefficient, Btu/h·ft²·°F
- h_r = surface transfer coefficient to account for long-wave radiation exchange, Btu/h·ft²·°F
- h_c = convective surface transfer coefficient (also called surface film coefficient), Btu/h·ft²·°F
- t_{en} = environmental temperature, °F
- t_s = surface temperature, °F

For indoor surface heat transfer, this approach is acceptable when only the heat transport through the building envelope is considered. Environmental temperature t_{en} includes the temperature of surfaces within the field of view of the considered envelope assembly. When all these surfaces are of partition walls and floors that have the same temperature as the indoor air, t_{en} may be replaced by the indoor air temperature.

This approach becomes questionable when heat transfer at the outdoor surface is concerned. Because radiation to the sky can lead to surface temperatures below ambient air temperature, Equation (8) underestimates the real heat flux when environmental temperature is replaced by outdoor air temperature. Therefore, t_{en} must include all short- and long-wave radiation contributions perpendicular to the assembly's exterior surface. However, t_{en} cannot be used for moisture transfer calculations. Therefore, a more convenient way may be to treat the heat transfer by convection and the radiation exchange separately. In this case, h_r in Equation (9) becomes zero and t_{en} is equal to the outdoor air temperature. The heat exchange by radiation is then calculated by balancing the solar and environmental radiation onto the assembly's exterior surface with the long-wave emission from it.

Steady-state calculation of thermal transport through the building envelope is generally done using surface resistances based on combined surface transfer coefficients, with R being the inverse of h . Because of greater air movement outdoors, the mean thermal resistance at the exterior surface is lower than at the interior surface. Typical ranges for the apparent exterior and interior surface transfer coefficient with surface infrared reflectance ≤ 0.1 (nonmetallic) are

$$R_o = 0.17 \text{ to } 0.34 \text{ h} \cdot \text{ft}^2 \cdot \text{°F}/\text{Btu}$$

$$R_i = 0.68 \text{ to } 1.13 \text{ h} \cdot \text{ft}^2 \cdot \text{°F}/\text{Btu}$$

To calculate thermal transmittance U , the lower values of R should be used. To calculate interior surface film temperature for risk assessment of surface condensation or mold growth, the higher interior and lower exterior R values should be used.

Heat Flow Across an Air Space

Heat flow across an air space is affected by the nature of the boundary surfaces, orientation of the air space, distance between boundary surfaces, and direction of heat flow. Air space thermal conductance, the reciprocal of the air space thermal resistance, is the sum of a radiation component, a conduction component, and a convection component. For computational purposes, spaces are considered airtight, with neither air leakage nor air washing along the boundary surfaces.

The radiation portion is affected by the temperature of the two boundary surfaces and by their respective surface properties. For surfaces that can be considered ideal gray, the surface properties are emittance, absorptance, and reflectance. Chapter 4 explains all three in depth. For an opaque surface, reflectance is equal to one minus the emittance, which varies with surface type and condition and radiation wavelength. The combined effect of the emittances of the two boundary surfaces is expressed by the effective emittance E of the air space. Table 2 in Chapter 26 lists typical emittance values for reflective surfaces and building materials, and the corresponding effective emittance for air spaces. More exact surface emittance values should be obtained by tests. The radiation component is not affected by the thickness of the air space, its orientation, direction of heat flow, or order of emittance (i.e., which surface is hot or cold).

In contrast, heat transfer by convection is affected markedly by the orientation of the air space, direction of heat flow, temperature difference across the space, and, in some cases, thickness of the space. It is also slightly affected by the mean temperatures of both surfaces. For air spaces in building components, radiation and convection components both contribute to the total heat flow. An example of the magnitudes of heat flow by radiation and convection/conduction across a vertical or horizontal airspace (up and down) is given in Figure 5.

Table 3 in Chapter 26 lists typical thermal resistance values of sealed air spaces of uniform thickness with moderately smooth, plane, parallel surfaces. These data are based on experimental measurements (Robinson et al. 1954). Resistance values for systems with air spaces can be estimated from these results if emittance values are corrected for field conditions. However, for some common composite building insulation systems involving mass-type insulation with a reflective surface in conjunction with an air space, the resistance value may be appreciably lower than the estimated value, particularly if the air space is not sealed or of uniform thickness (Palffy 1980). For critical applications, a particular design's effectiveness should be confirmed by actual test data undertaken by using the ASTM hot-box method (ASTM Standard C1363). This test is especially necessary for constructions combining reflective and non-reflective thermal insulation.

Total Thermal Resistance of a Flat Building Assembly

Total thermal resistance to heat flow through a flat building component composed of parallel layers between the environments at both sides is given by

Fig. 5 Heat Flux by Thermal Radiation and Combined Convection and Conduction Across Vertical or Horizontal Air Layer

$$R_T = R_i + R_s + R_o \quad (10)$$

where

R_i = apparent thermal resistance of interior surface film, $\text{h} \cdot \text{ft}^2 \cdot ^\circ\text{F}/\text{Btu}$

R_o = apparent thermal resistance of exterior surface film, $\text{h} \cdot \text{ft}^2 \cdot ^\circ\text{F}/\text{Btu}$

R_s = resistance of building assembly surface to surface (system resistance), $\text{h} \cdot \text{ft}^2 \cdot ^\circ\text{F}/\text{Btu}$

Thermal Transmittance of a Flat Building Assembly

The thermal transmittance or U-factor of a flat building assembly is the reciprocal of R_T :

$$U = 1/R_T \quad (11)$$

Calculating thermal transmittance requires knowing the (1) apparent thermal resistance of all homogeneous layers, (2) thermal resistance of the nonhomogeneous layers, (3) surface film resistances at both sides of the construction, and (4) thermal resistances of air spaces in the construction. The steady-state heat flux Q_n across the building envelope assembly is then defined by

$$Q_n = A_n U_n (t_i - t_o) \quad (12)$$

where

t_i, t_o = indoor and outdoor reference temperatures, $^\circ\text{F}$

A_n = component area, ft^2

U_n = U-factor of component, $\text{Btu}/\text{h} \cdot \text{ft}^2 \cdot ^\circ\text{F}$

Interface Temperatures in a Flat Building Component

The temperature drop through any layer of an assembly is proportional to its resistance. Thus, the temperature drop Δt_j through R_j is

$$\Delta t_j = \frac{R_j (t_i - t_o)}{R_T} \quad (13)$$

The temperature in an interface j then becomes ($t_o < t_i$)

$$t_j = t_o + \frac{R_o^j}{R_T} (t_i - t_o) \quad (14)$$

where R_o^j is the sum of thermal resistances between inside and interface j in flat assembly, in $\text{h} \cdot \text{ft}^2 \cdot ^\circ\text{F}/\text{Btu}$.

If the apparent thermal conductivity of materials in a building component is highly temperature-dependent, the mean temperature must be known before assigning an appropriate thermal resistance. In such a case, use trial and error: first, select the R-values for the particular layers. Then calculate total resistance R_T with Equation (10) and the temperature at each interface using Equation (14). The mean temperature in each layer (arithmetic mean of its surface temperatures) can then be used to obtain second-generation R-values. The procedure is repeated until the R-values are correctly selected for the resulting mean temperatures. Generally, this is done in two or three trial calculations.

Series and Parallel Heat Flow Paths

In many building assemblies (e.g., wood-frame construction), components are arranged so that heat flows in parallel paths of different conductances. If no heat flows through lateral paths, the thermal transmittance through each path may be calculated. The average transmittance of the enclosure is then

$$U_{av} = aU_a + bU_b + \dots + nU_n \quad (15)$$

where a, b, \dots, n are the surface-weighted path fractions for a typical basic area composed of several different paths with transmittances U_a, U_b, \dots, U_n .

If heat can flow laterally with little resistance in any continuous layer, so that transverse isothermal planes result, the flat construction performs as a series combination of layers, of which one or more provide parallel paths. Total average resistance $R_{T(av)}$ in that case is the sum of the resistance of the layers between the isothermal planes, each layer being calculated and the results weighted by contributing surface area. For further information, see Chapter 27.

The U-factor, assuming parallel heat flow only, is usually lower than that assuming combined series-parallel heat flow. The actual U-factor lies between the two. Without test results, a best choice must be selected. Generally, if the construction contains a layer in which lateral conduction is somewhat high compared to heat flux through the wall, a value closer to the series-parallel calculation should be used. If, however, there is no layer of high lateral conductance, use a value closer to the parallel calculation. For assemblies with large differences in material conductivities (e.g., assemblies using metal structural elements), the zone method is recommended (see Chapter 27). An alternative is using linear and punctual thermal transmittances. These characterize the excess heat transfer per degree temperature difference caused by a linear or local thermal bridge.

Thermal Bridges and Whole-Assembly Thermal Transmittance

In many envelope constructions, heat flow develops two- or three-dimensionally (**thermal bridging**). Heat loss and gain through thermal bridges are higher than their share in total surface may suggest. In heating climates, the inside surface may also be colder than the surrounding surfaces. This makes thermal bridges likely places for dirt deposit and mold growth because of elevated moisture content of surfaces in equilibrium with higher relative humidity.

The hot-box method (ASTM *Standard* C1363) or a multidimensional computer model should be used to determine the overall thermal transmittance of a wall with thermal bridges. Computer models also give the temperatures and heat fluxes.

For flat-wall thermal bridging calculations, refer to the zone and modified zone methods described in Chapter 27. Two- and three-dimensional thermal bridging estimates require the use of appropriate computer modeling tools.

TRANSIENT THERMAL RESPONSE

Steady-state calculations are used to define the average heating energy demand in cold climates. However, in climates where daily temperature swings oscillate around a comfortable mean temperature, transient analysis is more appropriate. The thermal response of a building to daily swings in temperature and solar radiation depends on the properties of its opaque and transparent (fenestration) envelope components and on its operation. The effects on the mutual dependences of the different factors are rather complex and there is no simplified approach that can account for these interactions. Therefore, whole-building simulations complying with ANSI/ASHRAE *Standard* 140 are recommended.

AIRFLOW

Air transfer in and through building components develops when the air permeance of the component differs from zero. Driving forces are stack pressure, wind pressure, and pressure differences induced by the mechanical system; see Chapters 16 and 24 for more details. When performing air flux calculations through a building component, distinguish between open porous materials and the openings

that occur with layers, cavities, cracks, leaks, and intentionally installed vents. Air flux through an open porous material is given by

$$m_a = -k_a \text{grad}(P_a) \quad (16)$$

where

m_a = air flux, lb/(ft²·h)
 k_a = air permeability of open porous material, lb/ft·h·in. Hg
 $\text{grad}(P_a)$ = gradient in total air pressure (stack, wind, and mechanical systems), in. Hg/ft

For openings in layers, cavities, cracks, leaks, and intentionally installed vents, the air flux (fractionated layers) or air transfer equation (all other) is

$$m_a \text{ or } M_a = C(\Delta P_a)^n \quad (17)$$

where the flow coefficient C and flow exponent n are determined experimentally.

A single layer with low air permeability (an **airflow retarder**) minimizes air flux through an assembly. The main function of an airflow retarder is to minimize airflow through an assembly, so the retarder must be continuous and leak-free. It must also be strong enough to withstand the air pressure difference.

When a building component contains coupled discrete layers, cavities, cracks, leaks, and intentionally installed vents, airflow becomes three-dimensional. For such cases, Kronvall (1982) developed an equivalent hydraulic network methodology, which was adapted by Janssens (1998) to calculate airflow in lightweight sloped roofs.

Water Vapor Flow by Air Movement

Air not only transports heat but also the water vapor the air contains. The water vapor flux is represented by

$$m_v = W m_a \approx \frac{0.62}{P_a} m_a p \quad (18)$$

where

W = humidity ratio of moving air
 m_a = air flux, lb/ft²·h
 p = partial water vapor pressure in air, in. Hg
 P_a = atmospheric air pressure, in. Hg

Even small air fluxes can carry large amounts of water vapor when compared to vapor diffusion. However, potentially damaging airflow always takes place through cracks and leaky joints rather than through the entire area of a building component.

Heat Flux with Airflow

Air leakage through building components may increase ventilation in a building beyond that needed for comfort and indoor air quality (see Chapter 16). Air also carries heat that may degrade a building's thermal performance. Airflow changes the assumption at the basis of Equation (2) that no mass flow develops in the solid. The sensible heat flux q that moves together with the air is

$$q = c_a m_a t \quad (19)$$

where q is in Btu/h·ft² and c_a is the specific heat capacity of air, Btu/lb·°F.

MOISTURE TRANSFER

Moisture may enter a building envelope by various paths, including built-in moisture, water leaks, wind-driven rain, and foundation leaks. Water vapor activates sorption in the envelope materials, and water vapor flow in and through the envelope may cause condensation on both nonporous and wet, porous surfaces.

Visible and invisible degradation caused by moisture is an important factor limiting the useful life of a building. Invisible degradation includes the decrease of thermal resistance of building and insulating materials and the decrease in strength and stiffness of load-bearing materials. Visible degradation includes (1) mold on surfaces, (2) decay of wood-based materials, (3) spalling of masonry and concrete caused by freeze/thaw cycles, (4) hydration of plastic materials, (5) corrosion of metals, (6) damage from expansion of materials (e.g., buckling of wood floors), and (7) decline in appearance. In addition, high moisture levels can lead to odors and mold spores in indoor air.

MOISTURE STORAGE IN BUILDING MATERIALS

Many building materials are porous. The pores provide a large internal surface, which generally has an affinity for water molecules. In some materials, such as wood, moisture may also be adsorbed in the cell wall itself. The amount of water in these **hygroscopic** (water-attracting) materials is related to the relative humidity of surrounding air. When relative humidity rises, hygroscopic materials gain moisture (**adsorption**), and when relative humidity drops, they lose moisture (**desorption**). The relationship between relative humidity and moisture content at a particular temperature is represented in a graph called the **sorption isotherm** (Figure 6). Isotherms obtained by adsorption are not identical to isotherms obtained by desorption; this difference is called **hysteresis**. At high relative humidity, small pores become entirely filled with water by capillary condensation. The maximum moisture content should be reached at 100% rh, when all pores are water-filled, but experimentally this can only be achieved in a vacuum, by boiling the material or by keeping it in contact with water for an extremely long time. In practice, the maximum moisture content of a porous material is lower. That value is referred to as **free water saturation** w_f or sometimes **capillary moisture content**. Figure 6 shows a typical sorption curve, giving the equilibrium moisture content as a function of relative humidity. The equilibrium moisture content increases with relative humidity, especially above 80% rh. It decreases slightly with increasing temperature. Moisture contents above $w_{0.95}$ (the equilibrium water content at 95% rh) cannot be achieved solely by vapor adsorption, because this region is characterized by capillary (unbound) water.

Chapter 32 describes hygroscopic substances and their use as dehumidifying agents. Chapter 26 has data on the moisture content of various materials in equilibrium with the atmosphere at various relative humidity steps. Wood and many other hygroscopic materials change dimensions with variations in moisture content.

Porous materials also absorb liquid water when in contact with it. Liquid water may be present because of leaks, rain penetration, flooding, or surface condensation. Wetting may be so complete that the material reaches free water saturation when the largest pores are filled with water. Up to this point there is still a distinct equilibrium between the moisture content of the material and its environment. This becomes evident when different porous materials are brought in direct (capillary) contact with each other. In that case, there is capillary flow from one material to the other until all pores at a certain size are filled with water in both materials; all pores with sizes above this limit remain empty because smaller capillaries have a higher suction force than larger ones. This phenomenon is used to determine the moisture storage function above 95% rh, which represents the limit of vapor sorption tests in climatic chambers. Dalehaug et al. (2005), Krus (1996), and Roels et al. (2003) described using a pressure plate apparatus, in which water-saturated material samples are placed on a porous membrane permeable to water but impermeable to air. Then pressure is applied in different steps each time until capillary equilibrium is achieved. The equilibrium moisture content at each pressure step is determined by weighing the samples. The moisture storage function from zero pressure (free

Fig. 6 Sorption Isotherms for Porous Building Materials

water saturation at 100% rh) up to 2967 in. Hg, which corresponds to approximately 93% rh, is defined by plotting the equilibrium water content over the applied pressure (Figure 7), which is assumed to be equal to the suction pressure of the largest still-water-filled capillaries.

For a continuous moisture storage function from the dry state to 100% rh, the sorption isotherm and the resultant curve from the pressure plate test are combined, either by converting the suction pressure into relative humidity or vice versa, using Kelvin’s equation:

$$\phi = \exp\left(-\frac{s}{\rho_w R_D T}\right) \tag{20}$$

where

ϕ = relative humidity of air in pores

- s = suction pressure, in. Hg
- ρ_w = density of water, lb/ft³
- R_D = gas constant for water vapor, Btu/lb·°R
- T = absolute temperature, °R

The hatched zones in Figure 7 represent the overhygroscopic range where the converted results from the pressure plate tests are plotted to complete the sorption isotherm. This narrow range is less important if vapor diffusion is the dominant moisture transport mechanism, for which an approximative interpolation of the moisture storage function between the end of the sorption isotherm and the free water saturation suffices. However, if capillary water flow from one material to the other becomes dominant (e.g., water absorption by bricks from mortar or stucco), the influence of the pressure plate results on the outcome of the calculation may not be negligible (Krus 1996). In that case, the detailed suction curve (Figure 7, right) should be used for simulations.

MOISTURE FLOW MECHANISMS

Water vapor and liquid water migrate by a variety of transport mechanisms, including the following:

- Water vapor diffusion by partial water vapor pressure gradients
- Displacement of water vapor by air movement (see the section on Airflow)
- Surface diffusion and capillary suction of liquid water in porous building materials
- Liquid flow by gravity or water and air pressure gradients

In the past, moisture control strategies focused on water vapor diffusion. Displacement of water vapor by air movement was treated superficially, and liquid water transport provoked by wind-driven rain or soil moisture was overlooked almost completely. When present, however, these mechanisms can move far greater amounts of moisture than diffusion does. Therefore, air movement and liquid flow should have a higher priority in moisture control.

Liquid flow by gravity and by pressure gradients is not discussed here, but a short description of the other mechanisms follows. More comprehensive treatment of moisture transport and storage may be found in Hens (1996), Künzel (1995), and Pedersen (1990). For a discussion of water vapor in air, see Chapter 1.

Water Vapor Flow by Diffusion

Water vapor migrates by diffusion through air and building materials, normally in small quantities. Diffusion can be important in industrial applications, such as cold-storage facilities and built-in refrigerators, or in buildings where a high inside partial water vapor pressure is needed. Diffusion control also becomes more important with increasingly airtight construction.

The equation used to calculate water vapor flux by diffusion through materials is based on Fick's law for diffusion of a very dilute gas (water vapor) in a binary system (water vapor and dry air):

$$m_v = -\mu_p \text{grad}(p) \quad (21)$$

where

$\text{grad}(p)$ = gradient of partial water vapor pressure, in. Hg
 μ_p = water vapor permeability of porous material, gr/ft·h·in. Hg

According to Equation (21), water vapor flux by diffusion closely parallels Fourier's equation for heat flux by conduction. However, actual diffusion of water vapor through a material is far more complex than the equation suggests. For hygroscopic materials, water vapor permeability may be a function of relative humidity. Also temperature has an impact. The permeability may even vary spatially or by orientation because of variations or anisotropy in the material's porous system.

Test methods for measuring water vapor permeability are described in ASTM Standard E96. Water vapor flux through a material is determined gravimetrically while maintaining constant temperature and partial water vapor pressure differential across the specimen. Tests are usually done in a climatic chamber at controlled temperature (68 or 73°F) and 50% rh. The material samples are sealed to the top of a cup that contains either a desiccant (dry-cup) or water res. salt solution (wet-cup).

Permeability is usually expressed in grains/h·ft·in. Hg and permeance in grains/h·ft·in. Hg. Whereas *permeability* refers to the water vapor flux per unit thickness, *permeance* is used in reference to a material of a specific thickness. For example, a material that is 2 in. thick generally is assumed to have half the permeance of a 1 in. thick material, even though permeances of many materials often are not strictly proportional to thickness. In many cases, the property ignores the effect of cracks or holes in the surface. It is inappropriate to refer to permeability with regard to inhomogeneous or composite materials, such as structural insulated panels (SIPs) or film-faced insulation batts.

Methods have been developed that allow measurement of water vapor transport with temperature gradients across the specimen (Douglas et al. 1992; Galbraith et al. 1998; Krus 1996). These methods may give more accurate data on water vapor transfer through materials and will eventually allow better distinction between the various transport modes.

There are some plastic materials (e.g., polyamide [Künzel 1999]) where the vapor permeability rises substantially with ambient relative humidity because of slight changes in the pore structure: water molecules squeeze between polymer molecules and thereby create new passages through the material. This effect is called **solution diffusion**. Moisture transport by solution diffusion can be adequately described by Equation (21) using humidity-dependent vapor permeability functions determined by a dry-cup test and wet-cup-tests with several humidity steps.

Water Flow by Capillary Suction

Within small pores of an equivalent diameter less than 0.004 in., molecular attraction between the surface and the water molecules causes capillary suction (Figure 8), defined as

$$s = \frac{2\sigma \cos\theta}{r} \quad (22)$$

where

s = capillary suction, in. Hg
 σ = surface tension of water, lb_f/in.
 r = equivalent radius of capillary, in.
 θ = contact wetting angle, degrees

The contact wetting angle is the angle between the water meniscus and capillary surface. The smaller this angle, the larger the capillary suction. In hydrophilic (water-attracting) materials, the contact wetting angle is less than 90°; in hydrophobic (water-repelling) materials, it is between 90 and 180°.

Capillary water movement is governed by the gradient in capillary suction s :

$$m_l = -k_m \text{grad}(s) \quad (23)$$

where

m_l = liquid flux, lb/ft²·h
 k_m = water permeability, lb/ft·h·in. Hg

Fig. 8 Capillary Rise in Hydrophilic Materials

Alternatively, replace s with relative humidity [for conversion, see Equation (20)]:

$$m_l = -\delta_\phi \text{ grad}(\phi) \quad (24)$$

where δ_ϕ is the liquid transport coefficient related to the relative humidity as driving potential, in lb/ft·h.

Capillary suction is greater in smaller capillaries, so water moves from larger to smaller capillaries. In pores with constant equivalent radius, water moves toward zones with smaller contact wetting angles. Although surface tension is a decreasing function of temperature (the higher the temperature, the lower the surface tension) and water moves toward zones with lower temperature, that effect is small compared to the effect of equivalent pore diameter and contact angle.

Capillary suction increases linearly with the inverse of the radius [see Equation (22)], but the flow resistance increases proportionally to the fourth power of the inverse radius. Therefore, larger pores have a much greater liquid transport capacity than smaller pores. Because larger pores can only be filled with water when the smaller pores are already saturated, the liquid transport capacity is a function of moisture content. Thus, water permeability k_m and liquid transport coefficient δ_ϕ are also functions of water content. Determination of these functions is, however, quite difficult because it requires the measurement of suction res. relative humidity distributions during transient water absorption and drying tests (Plagge et al. 2007).

Whereas measuring suction requires experience and special preparation of material samples, determining one-dimensional moisture content distributions in porous building materials can be done accurately with state-of-the-art scanning technologies using nuclear magnetic resonance (NMR), or gamma ray or x-ray attenuation (Krus 1996; Kumaran 1991; van Besien et al. 2002). Transient water content profiles recorded during such scanning tests serve to determine the liquid diffusivity D_w of the examined material, which is defined by

$$m_l = -D_w \text{ grad}(w) \quad (25)$$

where

w = moisture content, lb/ft³

D_w = liquid diffusivity, ft²/h

For most hygroscopic building materials, D_w is a function of moisture content. The diffusivity of calcium silicate brick, a masonry block with hygrothermal behavior that has been investigated extensively, shows an almost exponential increase with water content. As shown in Figure 9, the straight line indicates an exponential increase because the ordinate has a logarithmic scale. This exponential dependence of D_w has been found for many porous materials. Therefore, an exponential approximation is often used when D_w is determined from simple water absorption tests (Kumaran 1999; Künzel 1995).

Although Equation (25), which resembles Fick's law for diffusion, would seem a natural choice for calculating liquid flow, its use is not recommended because water content is not a continuous potential in building envelopes consisting of different materials. Using Equation (23) or (24) is recommended because relative humidity ϕ and capillary suction s are considered to be continuous potentials (no jumps at material interfaces). Where diffusivity functions are available, the liquid transport coefficient δ_ϕ in Equation (24) can be determined by

$$\delta_\phi = D_w \frac{dw}{d\phi} \quad (26)$$

where $dw/d\phi$ is the slope of sorption isotherm res. moisture retention curve, in lb/ft³.

Liquid Flow at Low Moisture Content

The explanation of liquid flow at low moisture content is still a matter of controversy. Some researchers assume it is surface diffusion (e.g., Krus 1996), whereas others believe liquid flow only fully starts beyond critical moisture content (Carmeliet et al. 1999; Kumaran et al. 2003; Vos and Coelman 1967). Liquid flow begins within the hygroscopic range, and is often mistaken for a part of vapor diffusion. In porous materials with a fixed pore structure, the apparent increase in vapor permeability during a wet-cup test may be partly due to liquid transport phenomena, and partly to shorter diffusion paths among water islands in the porous system formed by capillary condensation. Surface diffusion is defined as molecular movement of water adsorbed at the pore walls of the material. The driving potential is the mobility of the molecules, which depends on relative humidity in the pores (i.e., the adsorbed water migrates from zones of high to low relative humidity). Liquid flow, if present at low moisture content, can be described by Equations (23) or (24), as for capillary flow.

Under isothermal conditions, it is impossible to differentiate between vapor and liquid flow at low moisture content. However, in the presence of a temperature gradient, both transport processes may oppose each other in a pore; the fluxes may go in opposite directions (Künzel 1995). This can be explained by looking at the physical processes in a single capillary going through a wall, as shown in Figure 10. In winter, the indoor vapor pressure is usually higher than outdoors while the indoor humidity is lower than outdoor relative humidity. Therefore, the partial vapor pressure gradient is opposed to the relative humidity gradient over the cross section of a exterior wall. Looking at one capillary in that wall under very dry conditions (Figure 10), the only moisture transport mechanism is vapor diffusion and the total flux is directed towards the exterior. If the average humidity in the wall rises to 50 to 80% rh, liquid water begins to move in the opposite direction either by surface diffusion or by capillary suction in the nanopores. Under these conditions, the total moisture flux may go to zero if both fluxes are of the same magnitude (Krus 1996). When conditions are very wet (e.g., from wind-driven rain), most of the capillary pores are filled with water, and the dominant transport mechanism is flow by capillary suction.

Fig. 9 Moisture-Dependent Diffusivity of Calcium Silicate Brick (CSB) Determined from NMR Scans During Water Absorption Tests (Krus 1996)

Fig. 10 Moisture Fluxes by Vapor Diffusion and Liquid Flow in Single Capillary of Exterior Wall under Winter Conditions

Transient Moisture Flow

It is difficult to experimentally distinguish between liquid flow by suction and water vapor flow by diffusion in porous, hygroscopic materials. Because these materials have a very complex porous system and each surface is transversely by liquid-filled pore fractions and vapor-filled pore fractions, vapor and liquid flow are often treated as parallel processes. This allows expression of moisture flow as the summation of the two transport equations, one using water vapor pressure to drive water vapor flow by diffusion, and the other using either capillary suction or relative humidity ϕ to drive liquid moisture flow. The conservation equation in that case can be written as

$$\frac{\partial w}{\partial t} = -\text{div}(m_w + m_v) + S_w \quad (27)$$

where

- w = moisture content of building material, lb/ft³
- m_v = water vapor flux, lb/ft²·h
- m_w = liquid water flux, lb/ft²·h
- S_w = moisture source or sink, lb/ft³·h
- div = divergence (resulting inflow or outflow per unit volume of solid), ft⁻¹

Vapor and liquid fluxes are given by Equations (21), (23), and (24), which may be rewritten in terms of only two driving forces, capillary suction pressure s and partial vapor pressure p :

$$\frac{\partial w}{\partial t} \times \frac{\partial s}{\partial t} = \text{div} \left[k_m \text{grad}(s) + \mu_p \text{grad}(p) \right] + S_w \quad (28)$$

where

- s = capillary suction pressure, in. Hg
- p = partial vapor pressure, in. Hg
- μ_p = vapor permeability (related to partial vapor pressure), lb/ft·h·in. Hg
- k_m = water permeability (related to partial suction pressure), lb/ft·h·in. Hg
- S_w = moisture source or sink, lb/ft³·h

Alternatively, suction pressure s in Equation (28) can be replaced by relative humidity as the sole variable, with the saturation pressure p_{sat} only a function of temperature:

$$\frac{\partial w}{\partial \phi} \times \frac{\partial \phi}{\partial \tau} = \text{div} \left[\delta_\phi \text{grad}(\phi) + \mu_p \text{grad}(\phi p_{sat}) \right] + S_w \quad (29)$$

where

- ϕ = relative humidity, %
- p_{sat} = saturation vapor pressure, in. Hg
- μ_p = vapor permeability (related to partial vapor pressure), lb/ft·h·in. Hg
- δ_ϕ = liquid transport coefficient (related to relative humidity), lb/ft·h

Because of the strong temperature dependence of vapor pressure res. saturation vapor pressure, Equation (28) res. (29) must be coupled with Equation (3) to describe nonisothermal moisture flow. Under isothermal conditions, Equation (28) res. (29) could be solved independently. However, pure isothermal conditions hardly ever exist in reality because as soon as water evaporates or condenses, the latent heat effect leads to temperature differences. Other potentials may be used if material properties appropriate to those potentials are available.

COMBINED HEAT, AIR, AND MOISTURE TRANSFER

The consequences of combined heat, air, and moisture transfer can be detrimental to a building's thermal performance, occupant comfort, and indoor air quality. Air in- and exfiltration short-circuit the U-factor as a designed wall performance. Wind washing, inside air washing, and stack-induced air movement may increment the U-factor by a factor of 2.5 or more. High moisture levels in building materials may also have a negative effect on the thermal performance of the building envelope. Therefore, it is advisable to analyze the combined heat, air, and moisture transfer through building assemblies. However, some of these transport phenomena, especially those involving airflow, are three-dimensional in nature and difficult to predict because they only occur through accidental gaps, cracks, or imperfect joints. Research that attempts to describe these effects is ongoing, but at present, practitioners can only use simplified tools or hygrothermal models that do not yet cover all airflow aspects.

SIMPLIFIED HYGROTHERMAL DESIGN CALCULATIONS AND ANALYSES

SURFACE HUMIDITY AND CONDENSATION

Surface condensation occurs when water vapor contacts a non-porous surface that has a temperature lower than the dew point of the surrounding air. Insulation should therefore be thick enough to ensure that the surface temperature on the warm side of an insulated assembly always exceeds the dew-point temperature there. However, even without reaching the dew point, relative humidity at the surface may become so high that, given enough time, mold growth occurs. According to Hens (1990), a design rule is that surface relative humidity should not exceed 80% on a monthly mean basis.

The temperature ratio f_{h_i} is useful for calculating the surface temperature:

$$f_{h_i} = \frac{t_s - t_o}{t_i - t_o} \quad (30)$$

where

- t_s = surface temperature on warm side, °F
- t_o = ambient temperature on cold side, °F
- t_i = ambient temperature on warm side, °F

The minimum temperature ratio to avoid surface condensation is

$$f_{h_i, \min} = \frac{t_{d,i} - t_o}{t_i - t_o} \quad (31)$$

where $t_{d,i}$ is the dew point of ambient air on the warm side, °F.

The minimum insulation thickness to avoid surface condensation on a flat element can be calculated from

$$L_{\min} = k \left[\frac{f_{h_i, \min}}{h_i(1 - f_{h_i, \min})} - R_{\text{add}} \right] \quad (32)$$

where R_{add} is the thermal resistance between the surface on the warm side and the cold ambient for the wall without thermal insulation, ft²·h·°F/Btu.

The condensation resistance of glazing is often estimated from outdoor and indoor design temperature, U-factor of the window assembly, and air film resistance. A window assembly may have different U-factors at the glass, frame, and the edge where the glass meets the frame; condensation resistance must be calculated at each of these locations. A procedure for these calculations can be found in NFRC (2004). The likelihood of window condensation depends strongly on the indoor air film resistance. This resistance may be reduced by washing the window with supply air. It may be increased with the use of window treatments such as blinds or curtains. Condensation on glazing is not inherently damaging, unless water is allowed to run onto painted or other surfaces that can be damaged by water.

INTERSTITIAL CONDENSATION AND DRYING

Dew-Point Methods

The best-known simple steady-state design tools for evaluating interstitial condensation and drying within exterior envelopes (walls, roofs, and ceilings) are the dew-point method and the Glaser method (which uses the same underlying principles as the dew-point method, but uses graphic rather than computational methods). These methods assume that steady-state conduction governs heat flow and steady-state diffusion governs water vapor flow. Both analyses compare partial water vapor pressures within the envelope, as calculated by steady-state water vapor diffusion, with saturation water vapor pressures, which are based on calculated steady-state temperatures within the envelope.

The condition where the calculated partial water vapor pressure is greater than saturation has been called **condensation**. Strictly speaking, condensation is the change in phase from vapor to liquid, as occurs on glass, metal, etc. For porous and hygroscopic building materials (e.g., wood, gypsum, masonry materials), vapor may be adsorbed or absorbed and never form the droplets usually associated with true condensation. Nevertheless, the term *condensation* is used for this method to indicate vapor pressure in excess of saturation vapor pressure, although this could be misleading about actual water conditions on porous and hygroscopic surfaces. This is one of the unfortunate simplifications inherent in a steady-state analytic tool.

Steady-state heat conduction and vapor diffusion impose severe limitations on applicability and interpretation. The greatest one is that the main focus is on preventing sustained interstitial condensation, as indicated by vapor pressures beyond saturation vapor pressures. Many building failures (e.g., mold, buckling of siding, paint failure) are not necessarily related to interstitial condensation; conversely, limited interstitial condensation can often be tolerated, depending on the materials involved, temperature conditions, and speed at which the material dries out. (Drying can only be approximated because both the dew-point and Glaser methods neglect moisture storage and capillary flow.) Because all moisture transfer mechanisms except water vapor diffusion are excluded, results should be considered as approximations and should be used with extreme care. Their validity and usefulness depend on judicious selection of boundary conditions, initial conditions, and material

properties. Specifically, the methods should be used to estimate monthly or seasonal mean conditions only, rather than daily or weekly means. Furthermore, water vapor permeances may vary with relative humidity, and rain, flashing imperfections, leaky or poorly formed joints, rain exposure, airflow, and sunshine can have overriding effects. The dew-point and Glaser methods, however, are still used by design professionals and actually form the basis for most codes dealing with moisture control and vapor retarders.

For those who want to use this simple tool despite its shortcomings, a description of the dew-point method is presented in this chapter, with two application examples in Chapter 27. A comprehensive description of the dew-point and Glaser methods can be found in TenWolde (1994).

The dew-point method uses the equations for steady-state heat conduction and diffusion in a flat component, with the vapor flux in a layer written as

$$-m_v = \mu_p \frac{\Delta p}{d} = \frac{\Delta p}{Z} \quad (33)$$

where

- m_v = water vapor flux through layer of material, gr/h·ft²
- Δp = partial water vapor pressure difference across layer, in. Hg
- μ_p = water vapor permeability of material, gr/ft·h·in. Hg
- d = thickness of layer, ft
- Z = water vapor resistance, in. Hg·ft²·h/gr

Over time, upgrades have been added to the dew-point method: (1) the concept of critical moisture content allows accounting for moisture build-up and upgraded calculation of drying, and (2) carried vapor flow has been included, underlining the importance of airtightness to avoid moisture deposition by condensation in building assemblies (Hens 2007; Vos and Coleman 1967).

TRANSIENT COMPUTATIONAL ANALYSIS

Computer models can analyze and predict the heat, air, and moisture response of building components. These transient models can predict the varying hygrothermal situations in building components for different design configurations under various conditions and climates, and their capabilities are continually improved. Hens (1996) reviewed the state of the art of heat, air, and moisture transport modeling for buildings and identified 37 different models, most of which were research tools that are not readily available and may have been too complex for use by practitioners. Some, however, were available either commercially, free of charge, or through a consultant. Also, Trechsel (2001) provides an update on existing tools and approaches.

For many applications and for design guide development, the actual behavior of an assembly under transient climatic conditions must be simulated, to account for short-term processes such as driving rain absorption, summer condensation, and phase changes. Understanding the application limits of a model is an important part of that process.

The features of a complete moisture analysis model include transient heat, air, and moisture transport formulation, incorporating the physics of contact conditions between layers and materials. Interfaces may be bridgeable for vapor diffusion, airflow, and gravity or pressure liquid flow only. They may be ideally capillary (no flow resistance from one layer to the next) or behave as a real contact (have an additional capillary resistance at the interface).

Not all these features are required for every analysis, though additional features may be needed in some applications (e.g., moisture flow through unintentional cracks and intentional openings, rain penetration through veneer walls and exterior cladding). To model these phenomena accurately, experiments may be needed to define subsystem performance under various loads (Straube and

Burnett 1997). It is usually preferable to take performance measurements of system and subsystems in field situations, because only then are all exterior loads and influences captured.

Validation, verification, and benchmarking of combined heat, air, and moisture models is a formidable task. Currently, only limited internationally accepted experimental data exist. The main difficulty lies in the fact that it is difficult to measure air and moisture fluxes and moisture transport potentials, even under laboratory conditions. In addition, even an already validated model should be verified for each new application.

In most full hygrothermal models, common outputs are air pressure; temperature; moisture content; relative humidity; and air, heat, and moisture fluxes. Results must be checked for consistency, accuracy, grid independence, and sensitivity to parameter changes. The results may be used to evaluate the moisture tolerance of an envelope system subjected to various interior and exterior loads. Heat fluxes may be used to determine thermal performance under the influence of moisture and airflow. Furthermore, the transient output data may be used for durability and indoor air quality assessment. Postprocessing tools concerning durability (e.g., corrosion, mold growth, freeze and thaw, hygrothermal stress and strain, indoor air humidity) have been developed or are under development. For instance, Carmeliet (1992) linked full hygrothermal modeling to probability-based fracture mechanics to predict the risk of crack development and growth in an exterior insulation finish system (EIFS) by weathering. A transient model to estimate the rate of mold growth was developed by Sedlbauer (2001).

Transient models have enabled timestep-by-timestep analysis of heat, air, and moisture conditions in building components, and give much more realistic results than steady-state conduction/diffusion and conduction/diffusion/airflow models. However, they are complex and usually not transparent, and require judgment and expertise on the part of the user. Existing models are one- or two-dimensional, requiring the user to devise a realistic representation of a three-dimensional building component. Users should be aware which transport phenomena and types of boundary conditions are included and which are not. For instance, some models are not able to handle air transport or rain wetting of the exterior. The results also tend to be very sensitive to the choice of indoor and outdoor conditions. Usually, exact conditions are not known. Indoor and outdoor conditions to be used have been established by proposed ASHRAE *Standard* 160P. More extensive data on material properties have become available (e.g., Kumaran 2006), but it can be problematic finding accurate data for all the materials in a component. Finally, interpretation of results is not easy: accurate data on the moisture and temperature conditions that materials can tolerate are often not available.

Combined heat, air, and moisture models also have limitations. Rain absorption, for example, can be modeled, but rainwater runoff and its consequences at joints, sills, and parapets cannot, although runoff followed by gravity-induced local penetration is one of the main causes of severe moisture problems. Even an apparently simple problem, such as predicting rain leakage through a brick veneer, is beyond many tools' capabilities. In such cases, simple qualitative schemes and field tests still are the way to proceed.

CRITERIA TO EVALUATE HYGROTHERMAL SIMULATION RESULTS

At the building assembly and whole building level, combined heat, air, and moisture transfer has consequences for thermal comfort, perceived indoor air quality, health, durability, and energy efficiency. The hygrothermal conditions in a building or within a building envelope assembly can be crucial for the overall performance of the construction and its mechanical systems. Therefore, simulation results should be compared to limit conditions and widely accepted performance criteria determined for the following performance issues.

Thermal Comfort

Thermal comfort, defined as a condition of mind that expresses satisfaction with the thermal environment (ASHRAE *Standard* 55), depends on two human parameters (clothing and metabolism) and a set of environmental variables, among them relative humidity. At effective temperatures below 77°F, relative humidity's effect on thermal comfort is minimal, but above 77°F, its importance increases as latent heat loss becomes a main mechanism in getting rid of metabolic heat. If, at those temperatures, the air feels too moist, the thermal environment is perceived as uncomfortable. At low relative humidity, polluted air can irritate the mucosa, and electric discharges when touching insulators (e.g., plastic chairs) are felt. However, in most residential buildings and in many offices, temperature is controlled but not relative humidity, except in hot and humid climates. Its instantaneous value depends on the equilibrium between vapor release indoors, ventilation, airflow among rooms, and temporary vapor storage by finishes and furnishings (often called moisture buffering). The average value over longer periods depends on ventilation and vapor release only, whereas buffering reduces temporary extremes only.

Perceived Air Quality

Air quality may be defined exactly by measuring the pollutants present. However, occupants typically perceive dryer, cooler air as smelling "fresher" than humid, warmer air. Thus, temperature and relative humidity affect perception of air freshness. Together, they define the air's enthalpy. Testing has shown that higher enthalpy lowers the perception of freshness (Fang et al. 1998). Despite this fact, in most buildings, relative humidity is an uncontrolled parameter.

Human Health

Mold in buildings is offensive to occupants. Mold will grow on most surfaces if the relative humidity at the surface is above a critical value, the surface temperature is conducive to growth, and the substrate provides nutritional value to the organism. The growth rate depends on the magnitude and duration of surface relative humidity. Surface relative humidity is a complex function of material moisture content, local surface temperature, and humidity conditions in the space. In recognition of the issue's complexity, the International Energy Agency established a surface relative humidity criterion for design purposes: monthly average values should remain below 80% (Hens 1990). Other proposals include the Canada Mortgage and Housing Corporation's stringent requirement of always keeping surface relative humidity below 65% (CMHC 1999). Although there still is no agreement on which criterion is most appropriate, mold growth can usually be avoided by allowing surface relative humidity over 80% only for short time periods. The relative humidity criterion may be relaxed for nonporous surfaces that are regularly cleaned. Most molds only grow at temperatures above 40°F. Moisture accumulation below 40°F may not cause mold growth if the material is allowed to dry out below the hygroscopic moisture content for a relative humidity of 80% before the temperature rises above 40°F. Mathematical models for predicting a mold growth index were developed by Hukka and Viitanen (1999) and Sedlbauer (2001); these can be linked to results from hygrothermal analysis.

Dust mites trigger allergies and asthma. Dust mites thrive at high relative humidities (over 70%) at room temperature, but will not survive sustained relative humidities below 50% (Burge et al. 1994). Note that these values relate to local conditions in the places that mites tend to inhabit (e.g., mattresses, carpets, soft furniture).

Durability of Finishes and Structure

Moisture behind paint films may cause paint failure, and water or condensation may also cause streaking or staining. Excessive changes in moisture content of wood-based panels or boards may cause buckling or warp. Excessive moisture in masonry and con-

crete may cause salt efflorescence, or, when combined with low temperatures, freeze/thaw damage and spalling (chipping).

Structural failures caused by wood decay are rare but have occurred (Merrill and TenWolde 1989). Decay generally requires wood moisture content at fiber saturation (usually about 30%) or higher and temperatures between 50 and 100°F. Such high wood moisture contents are possible in green lumber or by absorption of liquid water from condensation, leaks, groundwater, or saturated materials in contact with the wood. To maintain a safety margin, 20% moisture content is sometimes used as the maximum allowable moisture level. Because wood moisture content can vary widely with sample location, a local moisture content of 20% or higher may indicate fiber saturation elsewhere. Once established, decay fungi produce water that enables them to maintain moisture conditions conducive to their growth.

Rusting of nails, nail plates, or other metal building components is also a potential cause of structural failure. Corrosion may occur at relative humidities near the metal surface above 60% or as a result of liquid water from elsewhere. Wood moisture content over 20% encourages corrosion of steel fasteners in the wood, especially if the wood is treated with preservatives. In buildings, metal fasteners are often the coldest surfaces, encouraging condensation and corrosion.

Energy Efficiency

Moisture can significantly degrade the thermal performance of most insulation materials. Moisture contributes to heat transfer in both sensible and latent forms, as well as through mass transfer. The effect depends on the type of insulation material, moisture content, temperature of the insulation material and its thermal history, the location of moisture in the insulation material, and the building envelope's interior and exterior environments. Reported relationships between thermal performance of the insulation material and moisture content vary significantly. Kyle and Desjarlais (1994) estimated that water distribution accounts for a difference of up to 25% in heat flux in some cases. Evaporation on the warm side and condensation or adsorption on the cold side add important latent heat components to the heat flux (Kumaran 1987).

Hedlin (1988) and Shuman (1980) experimentally showed that, for building envelopes containing permeable fibrous insulations that were undergoing temperature reversals, the heat flux transferred by that moisture drive increased sharply as the moisture content increased to approximately 1% by volume. The rate of heat transfer increase diminished rapidly with further increases in moisture content. Heat transfer for permeable insulation with 1% moisture content by volume was roughly double that of dry insulation. Pedersen-Rode et al. (1991) analytically reproduced Hedlin's results. They demonstrated the high mobility of moisture in a permeable insulation and showed that latent effects are appreciable for a wide variety of North American climates. Latent effects typically add to the building's energy load and can increase peak energy demand. The extra load is added in the warm afternoon, and nearly the same amount of heat is removed in the cool evening.

Under conditions where water vapor pressure gradients change slowly or where the insulation layer has an extremely low water vapor permeance, little water vapor is transported, but moisture still affects sensible heat transfer in the building envelope component. Epstein and Putnam (1977) and Larsson et al. (1977) showed a nearly linear increase in sensible heat transfer of approximately 3 to 5% for each volume percent increase in moisture content in cellular plastic insulations. For example, an insulation material with a 5% moisture content by volume has 15 to 25% greater heat transfer than when dry. Other field studies by Dechow and Epstein (1978) and Ovstaas et al. (1983) showed similar results for insulations installed in below-grade applications such as foundation walls.

Air Barriers and Water Vapor Retarders..... 26.13
Air Transmission and Water Vapor Property Data..... 26.15
Moisture Storage Data..... 26.15

THIS chapter presents thermal and water vapor transmission data based on steady-state or equilibrium conditions. This information can be used in the simplified calculation methods described in Chapter 27, or in software-based methods that develop step-wise steady-state conditions into a time-dependent solution. Chapter 4 covers heat transfer under transient or changing temperature conditions. Chapter 25 discusses combined heat-air-moisture transport. For information on insulation for mechanical systems, see Chapter 23.

Ideal conditions of components and installations are assumed in calculating overall R-values (i.e., insulating materials are of uniform nominal thickness and thermal resistance, air spaces are of uniform thickness and surface temperature, moisture effects are not involved, and installation details are in accordance with design). Robinson et al. (1957) showed that measured values differ from calculated values for certain insulated constructions. To account for this, some engineers moderately decrease calculated R-values.

The overall thermal resistance of an assembly comprises its surface-to-surface conductance and the resistances to heat transfer between assembly surfaces and interior and exterior spaces. This chapter includes standardized surface and air cavity resistances in typical building assemblies. Typical thermal properties (density, thermal conductivity, and specific heat) are provided for a wide range of building materials.

Material properties related to hygric performance (e.g., water vapor permeance, permeability, air permeance, sorption isotherms) are also given for several materials.

THERMAL PROPERTIES

AIR SPACES

Surface Resistances

As explained in Chapter 25, the overall R-value of an assembly comprises its surface-to-surface conductance C and the resistances to heat transfer between assembly surfaces and interior and exterior spaces (R_i and R_o , respectively). Table 1 presents standardized surface resistances R as well as conductances h_i and h_o , which are sometimes referenced in fenestration applications [see Chapter 15 and ASHRAE (1998)]. As shown, the resistance to heat transfer from a heated area to the surface (or from the surface to a cooler area) through natural convection (called “still air” in Table 1, although air does move through buoyancy) depends on the position of the surface, direction of heat transfer, temperature of the surface and the air, difference between the surface temperature and that of the surroundings,

Table 1 Surface Conductances and Resistances for Air

Position of Surface	Direction of Heat Flow	Surface Emittance, ϵ					
		Nonreflective $\epsilon = 0.90$		Reflective			
		h_i	R	h_i	R	h_i	R
Still Air							
Horizontal	Upward	1.63	0.61	0.91	1.10	0.76	1.32
Sloping at 45°	Upward	1.60	0.62	0.88	1.14	0.73	1.37
Vertical	Horizontal	1.46	0.68	0.74	1.35	0.59	1.70
Sloping at 45°	Downward	1.32	0.76	0.60	1.67	0.45	2.22
Horizontal	Downward	1.08	0.92	0.37	2.70	0.22	4.55
Moving Air (any position)		h_o		R			
15 mph wind (for winter)	Any	6.00	0.17	—	—	—	—
7.5 mph wind (for summer)	Any	4.00	0.25	—	—	—	—

Notes:

1. Surface conductance h_i and h_o measured in $\text{Btu}/\text{h} \cdot \text{ft}^2 \cdot ^\circ\text{F}$; resistance R in $\text{h} \cdot \text{ft}^2 \cdot ^\circ\text{F}/\text{Btu}$.
2. No surface has both an air space resistance value and a surface resistance value.
3. Conductances are for surfaces of the stated emittance facing virtual black-body surroundings at same temperature as ambient air. Values based on surface/air temperature difference of 10°F and surface temperatures of 70°F.
4. See Chapter 4 for more detailed information.
5. Condensate can have significant effect on surface emittance (see Table 2).

and the surface’s long-wave emittance. Where air is moved by wind or fans, the resistance to heat transfer to or from the surface depends on air speed, surface temperature, difference between the surface temperature and that of the surroundings, and the surface’s long-wave emittance. Values in Table 1 are for typical situations encountered in construction. For other temperatures and conditions, use ASHRAE (1998) to determine surface conductances or resistances.

Note that it is not appropriate to compute an overall R-value that assigns both a surface resistance and an air-space resistance to the same air space; that should be considered double-counting, and is not an accurate representation of the thermal resistance of the assembly (see Note 2 in Table 1).

Air Cavities

When air is enclosed in the assembly, the enclosed cavity’s thermal resistance can contribute to the resistance of the overall assembly. Even under steady-state conditions, convective air movement driven by buoyancy defines the thermal resistance of the cavity. Like the surface condition described above, the magnitude of this resistance depends on the slope of the cavity, direction of heat transfer, mean temperature in the cavity, and temperature and long-wave emittance of cavity surfaces. Table 3 provides thermal resistance values for enclosed cavities for various conditions, depending on the

The preparation of this chapter is assigned to TC 4.4, Building Materials and Building Envelope Performance.

Table 2 Emittance Values of Various Surfaces and Effective Emittances of Air Spaces^a

Surface	Average Emittance ϵ	Effective Emittance ϵ_{eff} of Air Space	
		One Surface Emittance ϵ ; Other, 0.9	Both Surfaces Emittance ϵ
Aluminum foil, bright	0.05	0.05	0.03
Aluminum foil, with condensate just visible (>0.7 g/ft ²)	0.30 ^b	0.29	—
Aluminum foil, with condensate clearly visible(>2.9 g/ft ²)	0.70 ^b	0.65	—
Aluminum sheet	0.12	0.12	0.06
Aluminum coated paper, polished	0.20	0.20	0.11
Steel, galvanized, bright	0.25	0.24	0.15
Aluminum paint	0.50	0.47	0.35
Building materials: wood, paper, masonry, nonmetallic paints	0.90	0.82	0.82
Regular glass	0.84	0.77	0.72

^aValues apply in 4 to 40 μm range of electromagnetic spectrum.

^bValues based on data in Bassett and Trethowen (1984).

combined or **effective emittance** of the cavity's hot and cold surfaces. The effective emittance is the combined value of the emittances of both surfaces according to $1/\epsilon_{eff} = 1/\epsilon_1 + 1/\epsilon_2 - 1$. Some values for combined emittance are listed in Table 2, to be used to determine the resistance of cavities in Table 3.

Tables 2 and 3 give values for well-sealed cavities constructed with care. Field applications can differ substantially from laboratory test conditions. Air gaps into the cavity can seriously degrade thermal performance because of air movement through both natural and forced convection. Sabine et al. (1975) found that tabular values are not necessarily additive for multiple-layer, low-emittance air spaces, and tests on actual constructions should be conducted to accurately determine thermal resistance values.

Values for foil insulation products supplied by manufacturers must also be used with caution because they apply only to systems that are identical to the configuration in which the product was tested. In addition, surface oxidation, dust accumulation, condensation, and other factors that change the condition of the low-emittance surface can reduce the thermal effectiveness of these insulation systems (Hooper and Moroz 1952). Deterioration results from contact with several types of solutions, either acidic or basic (e.g., wet cement mortar, preservatives found in decay-resistant lumber). Polluted environments may cause rapid and severe material degradation. However, site inspections show a predominance of well-preserved installations, and only a small number of cases in which rapid and severe deterioration has occurred. An extensive review of the reflective building insulation system performance literature is provided by Goss and Miller (1989).

Note that reflective foils are only effective if the reflective surface faces an air space, because radiative heat transfer cannot be reduced where there is no air space to allow radiative heat transfer. Also, multiple layers of reflective foil are no more effective than a single layer, unless the reflective surfaces adjoin different air spaces in the assembly.

Figure 1 shows how surface conductance for surfaces with different roughness is affected by air movement. Other tests on smooth surfaces show that the average value of the convection part of surface conductance decreases as surface length increases.

The following conditions are assumed in calculating design R-values for construction assemblies:

- Equilibrium or steady-state heat transfer, disregarding effects of thermal storage

**Fig. 1** Surface Conductance for Different Surfaces as Affected by Air Movement

- Surrounding surfaces at ambient air temperature
- Exterior wind velocity of 15 mph for winter (surface with $R = 0.17 \text{ h} \cdot \text{ft}^2 \cdot ^\circ\text{F}/\text{Btu}$) and 7.5 mph for summer (surface with $R = 0.25 \text{ h} \cdot \text{ft}^2 \cdot ^\circ\text{F}/\text{Btu}$)
- Surface emittance of ordinary building materials is 0.9

BUILDING AND THERMAL INSULATION MATERIALS

Thermal Insulation Materials

When properly applied, thermal insulation materials retard conductive, convective, and radiative heat flux. Thermal insulation in building envelopes does at least one of the following:

- Conserves energy by reducing the building's heat loss or gain
- Controls surface temperatures for comfort
- Helps control temperatures in a structure
- Reduces the tendency for water condensation on inside and outside surfaces
- Reduces temperature fluctuations in unconditioned or partly conditioned spaces

Thermal insulation materials may also serve additional functions, although these should be consistent with the capabilities of the materials and their primary purpose:

- Adding structural strength to a wall, ceiling, or floor section
- Providing support for a surface finish
- Impeding water vapor transmission and air infiltration
- Preventing or reducing damage to structures from exposure to fire and freezing conditions
- Reducing noise and vibration

Poorly designed or improperly installed thermal insulation may promote interstitial moisture condensation and subsequent damage within a building envelope. When thermal insulation is used to control heat flow at all temperatures, the limiting value is its survival temperature.

^aSee Chapter 25. Thermal resistance values were determined from $R = 1/C$, where $C = h_c + \epsilon_{eff} h_r$, h_c is conduction/convection coefficient, $\epsilon_{eff} h_r$ is radiation coefficient $\approx 0.0068 \epsilon_{eff} [(t_m + 460)/100]^3$, and t_m is mean temperature of air space. Values for h_c were determined from data developed by Robinson et al. (1954). Equations (5) to (7) in Yarbrough (1983) show data in this table in analytic form. For extrapolation from this table to air spaces less than 0.5 in. (e.g., insulating window glass), assume $h_c = 0.159(1 + 0.0016 t_m)/l$, where l is air space thickness in in., and h_c is heat transfer through air space only.

^bValues based on data presented by Robinson et al. (1954). (Also see Chapter 4, Tables 5 and 6, and Chapter 33). Values apply for ideal conditions (i.e., air spaces of uniform thickness bounded by plane, smooth, parallel surfaces with no air leakage to or from the space). For greater accuracy, use overall U-factors determined

through calibrated hot box (ASTM Standard C976) or guarded hot box (ASTM Standard C236) testing. Thermal resistance values for multiple air spaces must be based on careful estimates of mean temperature differences for each air space.

^cA single resistance value cannot account for multiple air spaces; each air space requires a separate resistance calculation that applies only for established boundary conditions. Resistances of horizontal spaces with heat flow downward are substantially independent of temperature difference.

^dInterpolation is permissible for other values of mean temperature, temperature difference, and effective emittance ϵ_{eff} . Interpolation and moderate extrapolation for air spaces greater than 3.5 in. are also permissible.

^eEffective emittance ϵ_{eff} of air space is given by $1/\epsilon_{eff} = 1/\epsilon_1 + 1/\epsilon_2 - 1$, where ϵ_1 and ϵ_2 are emittances of surfaces of air space (see Table 2).

Basic Materials

Thermal insulation normally consists of the following basic materials and composites:

- Inorganic, fibrous, or cellular materials such as glass, rock, or slag wool
- Calcium silicate, bonded perlite, vermiculite, and ceramic products (asbestos was also used, but its use has been discouraged or banned for several years; use caution if it is encountered in existing buildings)
- Organic fibrous materials such as cellulose, cotton, wool, wood, pulp, cane, or synthetic fibers, and organic cellular materials such as cork, foamed rubber, polystyrene, polyurethane, and other polymers
- Metallic or metallized organic reflective membranes, which must face an air-filled, gas-filled, or evacuated space to be effective

Physical Structure and Form

Physical forms of building insulation include the following:

Loose-fill insulation consists of fibers, powders, granules, or nodules, usually poured or blown into walls or other spaces. **Insulating cement** is a loose material that is mixed with water or a suitable binder to obtain plasticity and adhesion. It is troweled or blown wet on a surface and dried in place. Both loose fill and insulating cement are suited for covering irregular spaces.

Flexible and semirigid insulation consists of organic and inorganic materials with and without binders and with varying degrees of compressibility and flexibility. This insulation is generally available as blanket, batt, or felt, and in either sheets or rolls. Coverings and facings may be fastened to one or both sides and serve as reinforcing, airflow or vapor retarders (or both), reflective surfaces, or surface finishes. These coverings include combinations of laminated foil, glass, cloth or plastics and paper, or wire mesh. Although standard sizes are generally used, thickness and shape of insulation can be any convenient dimension.

Rigid materials are available in rectangular blocks, boards, or sheets, which are preformed during manufacture to standard lengths, widths, and thickness.

Reflective materials are available in sheets and rolls of single-layer or multilayer construction and in preformed shapes with integral air spaces.

Formed-in-place insulations are available as liquid components or expandable pellets that can be poured, frothed, or sprayed in place to form rigid or semirigid foam insulation. Fibrous materials mixed with liquid binders can also be sprayed in place; in some products, the binder is also a foam.

Accessories for thermal insulation include mechanical and adhesive fasteners, exterior and interior finishes, vapor- and airflow-retarding coatings, sealants, lagging adhesives, membranes, and flashing compounds. ASTM *Standard C168* defines terms related to thermal insulating materials.

Apparent Thermal Conductivity

A low apparent thermal conductivity is the primary property of a thermal insulation, but selecting a material may also involve secondary criteria (e.g., resiliency or rigidity, acoustical energy absorption, water vapor permeability, airflow resistance, fire hazard and fire resistance, ease of application, applied cost, health and safety aspects, or other parameters), which can affect the choice among materials that have almost equal thermal performance.

Thermal conductivity k is a property of a homogeneous, nonporous material. Most thermal insulation is porous and consists of combinations of solid matter with small voids, which comprise 90% or more of the volume. Heat transmission is therefore a combination of gas and solid conduction, radiation, and convection, and is affected by factors such as length of heat flow paths, temperature,

temperature difference, and environmental conditions. In fact, a wide variety of physical, environmental, application, and, in some cases, aging factors affect the thermal performance of insulation. In some materials with low thermal conductivity (e.g., opacified silica aerogel, corkboard), heat transfer is almost purely conductive.

Although heat transmission characteristics are usually determined by measuring thermal conductivity, this property does not strictly apply to thermal insulation. A particular sample of a material has a unique value of thermal conductivity for a particular set of conditions. This value may not be representative of the material at other conditions and should be called **apparent thermal conductivity**. For details, refer to ASTM *Standards C168, C177, C335, C518, C976, and C1045*.

Reflective insulation reduces radiant heat transfer because the surfaces have high reflectance and low emittance values. Conventional calculation methods ascribe the radiative properties to the associated air cavity, rather than to the insulation layer, to avoid incorrectly ascribing the benefits of reflective insulation that does not face an air cavity. Tables 1 and 2 give typical design values for air cavities faced with reflective layers. Multiple layers of reflective materials and smooth and parallel sealed air spaces increase overall thermal resistance. Air exchange and movement must be inhibited, however, or the reduction in radiative heat transfer is overshadowed by increased convection.

Mass-type insulation can be combined with reflective surfaces and air spaces to increase thermal resistance. However, each design must be evaluated, because maximum thermal performance of these systems depends on factors such as condition of the insulation, shape and form of construction, means to avoid air leakage and movement, and condition and aging characteristics of installed reflective surfaces.

Design values of apparent thermal conductivity, thermal conductance, and thermal resistance for most common insulation materials are listed in Table 4. These values have been selected as typical and useful for engineering calculations. Test results of insulation under appropriate conditions give values for that particular case.

Insulation's form and physical structure, environment, and application conditions can affect its apparent thermal conductivity. Form and physical structure vary with the basic material and manufacturing process. Typical variations include density, cell size, diameter and arrangement of fibers or particles, degree and extent of bonding materials, transparency to thermal radiation, and type and pressure of gas within the insulation.

Figure 2 illustrates the variation with density of the apparent thermal conductivity at one mean temperature for a number of insulation materials used in building envelopes. For most mass-type insulation, there is a minimum that depends on the type and form of the material, temperature, and direction of heat flow. For fibrous materials, the values of density at which the minimum occurs increase as both the fiber diameter (or cell size) and the mean temperature increase. These effects are shown in Figures 3 (Lotz 1969) and 4.

Other structural factors that affect thermal performance include compaction and settling of insulation, air permeability, type and amount of binder used, additives that may influence the bond or contact between fibers or particles, and type and form of radiation transfer inhibitor, if used. In cellular materials, most factors that influence strength also control thermal conductivity: size, shape, and orientation of the cells, and thickness of the cell walls. However, gas contained in the cells and radiation characteristics of cell surfaces also influence the effective conductivity.

Density changes caused by compaction affect the apparent thermal conductivity of insulation powders. Insulating concretes made from lightweight aggregates can be produced in a wide range of densities, with corresponding thermal conductivity. Fibrous insulation reaches a minimum conductivity when fibers are uniformly spaced and perpendicular to the direction of heat flow. Generally, a decrease in fiber diameter lowers conductivity for the same density

Notes for Table 4

^aValues are for mean temperature of 75°F. Representative values for dry materials are intended as design (not specification) values for materials in normal use. Thermal values of insulating materials may differ from design values depending on in-situ properties (e.g., density and moisture content, orientation, etc.) and manufacturing variability. For properties of specific product, use values supplied by manufacturer or unbiased tests.

^bSymbol λ also used to represent thermal conductivity.

^cDoes not include paper backing and facing, if any. Where insulation forms boundary (reflective or otherwise) of airspace, see Tables 2 and 3 for insulating value of airspace with appropriate effective emittance and temperature conditions of space.

^dConductivity varies with fiber diameter (see Chapter 25). Batt, blanket, and loose-fill mineral fiber insulations are manufactured to achieve specified R-values, the most common of which are listed in the table. Because of differences in manufacturing processes and materials, the product thicknesses, densities, and thermal conductivities vary over considerable ranges for a specified R-value.

^eValues are for aged products with gas-impermeable facers on the two major surfaces. An aluminum foil facer of 0.001 in. thickness or greater is generally considered impermeable to gases. For change in conductivity with age of expanded polyisocyanurate, see SPI Bulletin U108.

^fCellular phenolic insulation may no longer be manufactured. Thermal conductivity and resistance values do not represent aged insulation, which may have higher thermal conductivity and lower thermal resistance.

^gInsulating values of acoustical tile vary, depending on density of board and on type, size, and depth of perforations.

^hValues for fully grouted block may be approximated using values for concrete with similar unit density.

ⁱValues for concrete block and concrete are at moisture contents representative of normal use.

^jValues for metal or vinyl siding applied over flat surfaces vary widely, depending on ventilation of the airspace beneath the siding; whether airspace is reflective or nonreflective; and on thickness, type, and application of insulating backing-board used. Values are averages for use as design guides, and were obtained from several guarded hot box tests (ASTM Standard C236) or calibrated hot box (ASTM Standard C976) on hollow-backed types and types made using backing of wood fiber, foamed plastic, and glass fiber. Departures of $\pm 50\%$ or more from these values may occur.

^kVinyl specific heat = 0.25 Btu/lb·°F

^lSee Adams (1971), MacLean (1941), and Wilkes (1979). Conductivity values listed are for heat transfer across the grain. Thermal conductivity of wood varies linearly with density, and density ranges listed are those normally found for wood species given. If density of wood species is not known, use mean conductivity value. For extrapolation to other moisture contents, the following empirical equation developed by Wilkes (1979) may be used:

$$k = 0.1791 + \frac{(1.874 \times 10^{-2} + 5.753 \times 10^{-4}M)\rho}{1 + 0.01M}$$

where ρ is density of moist wood in lb/ft³, and M is moisture content in percent.

^mFrom Wilkes (1979), an empirical equation for specific heat of moist wood at 75°F is as follows:

$$c_p = \frac{(0.299 + 0.01M)}{(1 + 0.01M)} + \Delta c_p$$

where Δc_p accounts for heat of sorption and is denoted by

$$\Delta c_p = M(1.921 \times 10^{-3} - 3.168 \times 10^{-5}M)$$

where M is moisture content in percent by mass.

ⁿBlank space in reference column indicates historical values from previous volumes of ASHRAE Handbook. Source of information could not be determined.

Fig. 2 Apparent Thermal Conductivity Versus Density of Several Thermal Insulations Used as Building Insulations

Fig. 3 Variation of Apparent Thermal Conductivity with Fiber Diameter and Density

(Figure 4). For cellular insulation, a specific combination of cell size, density, and gas composition produces optimum thermal conductivity.

At temperatures below 400 to 570°F, a large portion of heat transfer occurs by conduction through air or another gas in the insulation (Lander 1955; Rowley et al. 1952; Simons 1955; Verschoor and Greebler 1952). The overall heat transfer can be closely approximated by supposition of gas conduction with all other mechanisms, each determined separately. If the gas in the insulation is replaced by another gas with a different thermal conductivity, the apparent thermal conductivity changes by an amount approximately equal to the difference in conductivity of the two

Fig. 4 Typical Variation of Apparent Thermal Conductivity with Mean Temperature and Density for Fibrous Insulations

gases. For example, replacing air with a fluorinated hydrocarbon (HFC) can lower the apparent thermal conductivity of insulation by as much as 50%.

Fluorocarbon-expanded cellular plastic foams with a high proportion (greater than 90%) of closed cells retain the fluorocarbon for extended periods of time. Newly produced, they have apparent thermal conductivities of approximately 0.11 Btu·in/h·ft²·°F at 75°F, but this value increases with time as air diffuses into the cells and the fluorocarbon gas gradually dissolves in the polymer or diffuses out. Diffusion rates and increase in apparent thermal conductivity depend on several factors, including permeance of cell walls to the gases involved, foam age, temperature, geometry of the insulation (thickness), and integrity of the surface protection provided. Brandreth (1986) and Tye (1988) showed that aging of polyurethane and polyisocyanurate is reasonably well understood analytically and confirmed experimentally. The dominant parameters for minimum aging are as follows:

- Closed-cell content >90%, preferably >95%
- Small, uniform cell diameter <<0.04 in., with larger proportion of polymer in windows between cells
- Small anisotropy in cell structure
- High density
- Increased thickness
- High initial pressure of fluorocarbon blowing agent in cell
- Polymer highly resistant to gas diffusion and solubility
- Polymer distributed evenly in struts and windows of cells
- Low aging temperature

Aging is further reduced, particularly for laminated and spray-applied products, with higher-density polymer skins, or by well-adhered facings and coverings with low gas and moisture permeance. An oxygen diffusion rate of less than 0.02 in³/1000 ft²·day for a 0.001 in. thick barrier is one criterion used by some industry organizations for manufacturers of laminated products. The adhesion of any facing must be continuous, and every effort must be made during manufacturing to eliminate or minimize the shear plane layer at the foam/substrate interface (Ostrogorsky and Glicksman 1986). Before 1987, chlorinated fluorocarbons were commonly used as cell gas. Because of their high ozone-depleting potential, chlorofluorocarbons (CFCs) were phased out during the 1990s in accordance with the Montreal Protocol of 1987. Alternatives used today are fluorocarbons, CO₂, N-pentane, and C-pentane.

Closed-cell phenolic-type materials and products, which are blown with similar gases, age differently and much more slowly.

For homogeneous, dense materials, the primary mode of heat transfer is conduction. However, as temperatures increase, heat

transfer by radiation (and possibly convection) becomes a greater part of the total. The magnitude of radiation and convection depends on temperature difference, direction of heat flow, nature of the materials involved, and geometry. Because of radiative heat transfer in low-density insulation, measured apparent thermal conductivity depends on test thickness. That thickness effect increases the apparent thermal conductivity measured at installed thickness over that commonly determined at 1 in. (Pelanne 1979). From a thermal resistance standpoint, the effect is small, typically less than 10%, even for thin (e.g., 1 in. thick), low-density (e.g., 0.35 lb/ft³) insulation. The effect becomes negligible for typical building applications (e.g., 6 in. insulation with a density of 0.7 lb/ft³).

Environment and application conditions include mean temperature, temperature gradient, moisture content, air infiltration, orientation, and direction of heat flow. The magnitude of effect each has on apparent thermal conductivity varies according to insulation material and form.

The apparent thermal conductivity of insulating materials generally increases with temperature. The rate of change varies with material type and density. Figure 5 shows typical variations with mean temperature. However, some materials, such as fluorocarbon-expanded, closed-cell polyurethanes, have an inflection in the curve where the fluorocarbon changes phase from gas to liquid (see Table 7B in Chapter 25). The apparent thermal conductivity of a sample at one mean temperature (average of the two surface temperatures) only applies to the material at the particular thickness tested. Further testing is required to obtain values suitable for all thicknesses.

Fig. 5 Apparent Thermal Conductivity Versus Mean Temperature for Various Materials (in Air at Atmospheric Pressure)
(Glaser et al. 1967; Pelanne 1977)

Insulating materials that allow a large percentage of heat transfer by radiation, such as low-density fibrous and cellular products, show the greatest change in apparent thermal conductivity with temperature and surrounding surface emittance.

The effect of temperature on structural integrity is ordinarily not important for most insulation materials in low-temperature applications. In any case, decomposition, excessive linear shrinkage, softening, or other effects limit the maximum temperature for which a material is suited. At extreme temperatures, both high and low, selecting suitable materials is more difficult and must be based on experience and performance data (see Tables 4 and 7B in Chapter 25).

Convection and air infiltration in or through some insulation systems may increase heat transfer across them. Low-density, loose-fill, large open-cell, and fibrous insulation, and poorly designed or installed reflective systems are the most susceptible. The temperature difference across the insulation and the height and width of the insulated space influence the amount of convection. In some cases, natural convection may be inherent to the system (Wilkes and Childs 1992; Wilkes and Rucker 1983), but in many cases it is a consequence of careless design and/or careless construction of the insulated structure (Donnelly et al. 1976). Gaps between board- and batt-type insulations lower their effectiveness. Board-type insulation may not be perfectly square, may be installed improperly, and may be applied to uneven surfaces. A 4% void area around batt insulation can produce a 50% loss in effective thermal resistance for ceiling application with $R = 19 \text{ h}\cdot\text{ft}^2\cdot\text{°F}/\text{Btu}$ (Verschoor 1977). Similar results have been obtained for wall configurations (Brown et al. 1993; Hedlin 1985; Lecompte 1989; Lewis 1979; Rasmussen et al. 1993; Tye and Desjarlais 1981). As a solution, preformed joints in board-type insulation allow boards to fit together without air gaps. Boards and batts can be installed in two layers, with joints between layers offset and staggered.

The apparent thermal conductivity of insulation materials increases with moisture content. If moisture condenses in the insulation, it not only reduces thermal resistance, but may also physically damage the system. Reduction in thermal resistance depends on material, moisture content, and moisture distribution. Section A3 of the *CIBSE Guide A* (CIBSE 2006) covers thermal properties of building structures affected by moisture.

Apparent thermal conductivity for insulation materials and systems is obtained by standard methods listed in ASTM (2008). The methods apply mainly to laboratory measurements on dried or conditioned samples at specific mean temperatures and temperature gradient conditions. Although fundamental heat transmission characteristics of a material or system can be determined accurately, actual performance in a structure may vary from laboratory results; only field measurements can clarify the differences. Field-test procedures continue to be developed. Envelope design, construction, and material may all affect the procedure to be followed, as detailed in ASTM (1985a, 1985b, 1988, 1990, 1991).

Mechanical Properties

Some insulation is used occasionally to support load-bearing roofs and floors, form self-supporting partitions, or stiffen structural panels. For such applications, the material's strength in compression, tension, shear, impact, flexure, and resistance to vibration may be important. These properties vary with basic composition of the insulation, density, cell size, fiber diameter and orientation, type and amount of binder (if any), and temperature and environmental conditioning.

Health and Safety

Many thermal insulation materials have good resistance to fire, vermin, rot, objectionable odors, and vapors. Some are a potential risk to health and safety, presenting either (1) risk related to storage, handling, and installation or (2) risk that occurs after installation

(e.g., aging, fire, or physical disturbance). Potential hazards during manufacture are not considered here. Correct handling, installation, and precautionary measures may reduce or eliminate risks.

Combustion of insulation materials and accessories may release heat, hazardous gases, fibers, and particulates. Manufacturers' recommendations and applicable codes and standards (e.g., ASTM *Standard C930*) give more details.

Acoustics

Some thermal insulation with open, porous surfaces is used as sound absorption material, regardless of whether thermal performance is a design requirement. Thermal insulation with high density and resilient characteristics can act as vibration insulators, either alone or in combination with other materials. Some flexible and semirigid, formed-in-place fibrous materials and rigid fibrous insulation help reduce sound transmission when placed in a composite construction.

Sound-absorbing insulation is normally installed on interior surfaces or used as interior surfacing materials. Rigid sound-absorbing insulation is fabricated into tiles or blocks, edge-treated to facilitate mechanical or adhesive application, and prefinished during manufacture. Insulation units can have a natural porous surface or mechanical perforations to facilitate entry of sound waves; others use a diaphragm or decorative film surfacing attached only to the edges of the units, which allows sound waves to reach the fibrous backing by diaphragm action.

Flexible, semirigid, and formed-in-place fibrous materials used for sound absorption are available in a variety of thickness and densities that determine their sound absorption characteristics.

When density is increased by reducing material thickness, sound absorption is generally reduced; however, as thickness increases, the influence of density decreases.

A wall of staggered-stud construction, finished with airtight gypsum board, that uses resilient clips or channels on one side of the stud reduces sound transmission. Another option is resilient insulation boards of special manufacture to prevent acoustic coupling between surfaces. A sound absorption thermal insulation blanket in a wall cavity also reduces sound transmission, depending on the type of construction.

In floors, resilient channels or separate airtight finished floor and ceiling joists form a discontinuous construction. Sound-absorbing thermal insulation placed in this construction reduces sound transmission. Sound-deadening boards underlying finish flooring absorb impact sounds and reduce airborne and impact sound transmission.

Thermal insulation boards can be placed under mechanical equipment to isolate vibration. The imposed loading and natural resonant frequency of these materials are critical for proper design. Because material must deflect properly under load to provide isolation, the system should be neither over- nor underloaded.

For further information on sound and vibration control, refer to Chapter 47 of the 2007 *ASHRAE Handbook—HVAC Applications*.

Other Properties

Other properties of insulating materials that can be important, depending on application, include density, resilience, resistance to settling, air and vapor permeance, reuse or salvage value, ease of handling, dimensional uniformity and stability, resistance to chemical action and chemical change, resistance to moisture penetration, ease in fabrication, application of finishes, and sizes and thickness obtainable.

Building Materials

The values listed in Table 4 are typically for a mean temperature of 75°F. Thermal conductivity values may vary with temperature: polymers' conductivity generally decreases with temperature, until the glass-transition temperature is reached. This transition occurs at

different temperatures for different materials, but is typically at -22 or -40°F ; below this threshold, thermal conductivity increases quickly as the temperature decreases.

Table 4 also lists resistance values for materials of specific thickness. Where conductance is required for a material for which only the conductivity is listed, the conductance value can be determined by dividing the conductivity by the desired thickness x , or $C = k/x$. Thermal resistance is the reciprocal of conductance: $R = 1/C$. Resistivity (resistance per unit thickness) is the reciprocal of conductivity, or $1/k$.

Table 4 was revised as a result of ASHRAE research project RP-905 (McGowan 2007). Where possible, sources of data are shown in the Reference column; if no source is specified, the value for that material has been carried over from previous editions of this chapter.

Property Data

Building and Insulating Materials. Steady-state thermal resistances (R-values) of building assemblies (walls, floors, windows, roof systems, etc.) can be calculated from thermal properties of the materials in the component, provided by Table 4, or heat flow through the assembled component can be measured directly with laboratory equipment such as the guarded hot box (ASTM *Standard C236*) or the calibrated hot box (ASTM *Standard C976*). Direct measurement is the most accurate method of determining the overall thermal resistance for a combination of building materials assembled as a building envelope component. However, all combinations may not be conveniently or economically tested in this manner. For many simple constructions, calculated R-values agree reasonably well with values determined by hot box measurement.

Table 4's values were developed by testing under ideal conditions. In practice, overall thermal performance can be reduced significantly by factors such as improper installation, quality of workmanship and shrinkage, settling, or compression of the insulation (Tye 1985, 1986; Tye and Desjarlais 1983). Good workmanship becomes increasingly important as the insulation requirement becomes greater. Therefore, some engineers include additional insulation or other safety factors based on experience in their design.

Because commercially available materials vary, not all values apply to specific products.

Soils

Effective or apparent soil thermal conductivity is difficult to estimate precisely and may change substantially in the same soil at different times because of changed moisture conditions and freezing temperatures. Figure 6 shows the typical apparent soil thermal

Fig. 6 Trends of Apparent Thermal Conductivity of Moist Soils

Table 5 Typical Apparent Thermal Conductivity Values for Soils, Btu·in/h·ft²·°F

	Normal Range	Recommended Values for Design ^a	
		Low ^b	High ^c
Sands	4.2 to 17.4	5.4	15.6
Silts	6 to 17.4	11.4	15.6
Clays	6 to 11.4	7.8	10.8
Loams	6 to 17.4	6.6	15.6

^aReasonable values for use when no site- or soil-specific data are available.

^bModerately conservative values for minimum heat loss through soil (e.g., use in soil heat exchanger or earth-contact cooling calculations). Values are from Salomone and Marlowe (1989).

^cModerately conservative values for maximum heat loss through soil (e.g., use in peak winter heat loss calculations). Values are from Salomone and Marlowe (1989).

Table 6 Typical Apparent Thermal Conductivity Values for Rocks, Btu·in/h·ft²·°F

	Normal Range
Pumice, tuff, obsidian	3.6 to 15.6
Basalt	3.6 to 18.0
Shale	6 to 27.6
Granite	12 to 30
Limestone, dolomite, marble	8.4 to 30
Quartzose sandstone	9.6 to 54

conductivity as a function of moisture content for different general types of soil. The figure is based on data presented in Salomone and Marlowe (1989) using envelopes of thermal behavior coupled with field moisture content ranges for different soil types. In Figure 6, “well-graded” applies to granular soils with good representation of all particle sizes from largest to smallest. “Poorly graded” refers to granular soils with either uniform gradation, in which most particles are about the same size, or skip (or gap) gradation, in which particles of one or more intermediate sizes are not present.

Although thermal conductivity varies greatly over the complete range of possible moisture contents, this range can be narrowed if it is assumed that the moisture contents of most field soils lie between the “wilting point” of the soil (i.e., the moisture content of a soil below which a plant cannot alleviate its wilting symptoms) and the “field capacity” of the soil (i.e., the moisture content of a soil that has been thoroughly wetted and then drained until the drainage rate has become negligibly small). After a prolonged dry spell, moisture is near the wilting point, and after a rainy period, soil has moisture content near its field capacity. Moisture contents at these limits have been studied by many agricultural researchers, and data for different types of soil are given by Kersten (1949) and Salomone and Marlowe (1989). Shaded areas in Figure 6 approximate (1) the full range of moisture contents for different soil types and (2) a range between average values of each limit.

Table 5 summarizes design values for thermal conductivities of the basic soil classes. Table 6 gives ranges of thermal conductivity for some basic classes of rock. The value chosen depends on whether heat transfer is being calculated for minimum heat loss through the soil, as in a ground heat exchange system, or a maximum value, as in peak winter heat loss calculations for a basement. Hence, high and low values are given for each soil class.

As heat flows through soil, moisture tends to move away from the heat source. This moisture migration provides initial mass transport of heat, but it also dries the soil adjacent to the heat source, thus lowering the apparent thermal conductivity in that zone of soil.

Typically, when other factors are held constant,

- k increases with moisture content
- k increases with increasing dry density of a soil
- k decreases with increasing organic content of a soil

- k tends to decrease for soils with uniform gradations and rounded soil grains (because grain-to-grain contacts are reduced)
- k of a frozen soil may be higher or lower than that of the same unfrozen soil (because the conductivity of ice is higher than that of water but lower than that of typical soil grains). Differences in k below moisture contents of 7 to 8% are quite small. At approximately 15% moisture content, k may vary up to 30% from unfrozen values.

When calculating annual energy use, choose values that represent typical site conditions as they vary during the year. In climates where ground freezing is significant, accurate heat transfer simulations should include the effect of the latent heat of fusion of water. Energy released during this phase change significantly retards the progress of the frost front in moist soils.

For further information, see Chapter 17, which includes a method for estimating heat loss through foundations.

AIR TRANSMISSION AND HYGRIC PROPERTIES

AIR BARRIERS AND WATER VAPOR RETARDERS

Although the functions of water vapor and air barriers are different, a single component may serve both purposes. The designer should assess needs for vapor and air movement control in the building envelope and provide a system that guarantees the required vapor and air barrier properties.

Air Barriers

An effective air barrier must

- Meet material permeability requirements.
- Be continuous when installed (i.e., tight joints in the air barrier assembly, effective bonds in air barrier materials at intersections such as wall/roof and wall/foundation, tightly sealed penetrations).
- Accommodate dimensional changes caused by temperature or shrinkage without damage to joints or air barrier material.
- Be strong enough to support the stresses applied to the air barrier material or assembly. The air barrier must not be ruptured or excessively deformed by wind or stack effect. Where an adhesive is used to complete a joint, the assembly must be designed to withstand forces that might gradually peel the air barrier material away. Where the air barrier material is not strong enough to withstand anticipated wind and other loads, it must be supported on both sides to account for positive and negative wind gust pressures.

In addition, the following properties may be important, depending on the application:

- Elasticity
- Thermal stability
- Fire and flammability resistance
- Inertness to deteriorating elements
- Ease of fabrication, application, and joint sealing

Control of airflow requires an effective air barrier (also called an **airflow retarder** or **air infiltration barrier**) as well as a vapor retarder. Although flow of dry air may accelerate drying of a wet building component (Karagiozis and Salonvaara 1999a, 1999b), without effective control of airflow, vapor retarders are completely ineffective.

A retarder may control both vapor and airflow (i.e., act as an air/vapor retarder). Many designs are based on this idea, with measures taken to ensure that the vapor retarder is continuous to control airflow. Some designs treat airflow and vapor retarders as separate entities, but an airflow retarder should not be where it can cause moisture to condense if it also has vapor-retarding properties. For

example, an air barrier placed on the cold side of a building envelope may cause condensation, particularly if the vapor retarder at the other side is ineffective. Instead, a carefully installed, sealed cold-side air/vapor retarder that has sufficient thermal resistance may lower the potential for condensation by raising the temperature at its indoor surface during the cold season (Ojanen et al. 1994).

Air leakage characteristics can be determined with the ASTM *Standard* E1186 test method for air barriers on the interior side of the building envelope, and described according to ASTM *Standard* E1677. Specific air leakage criteria for air barriers in cold heating climates can be found in Di Lenardo et al. (1995). These specifications call for maximum permissible air leakage rates between 0.01 and 0.04 cfm per square foot (as measured with an air pressure difference of 0.3 in. of water), depending on the water vapor permeance of the outermost layer of the building envelope. The highest leakage rate applies if the permeance of the outermost layer is greater than 10 perms; the lowest rate applies if the permeance is less than 1 perm. Intermediate values are provided. The recommendations apply only to heating climates. (See the section on Air Transmission and Water Vapor Property Data for water vapor permeances of various building materials.)

The required air permeance of an air barrier material has been set by some building codes at 0.004 cfm per square foot at a pressure difference of 0.3 in. of water. An addendum to ASHRAE *Standard* 90.1 in 2008 also referenced this value. ASTM *Standard* E1677 provides an alternative minimum air barrier testing and criteria specifically suitable for framed walls of low-rise buildings.

Air leakage characteristics of an air barrier assembly can be determined with the ASTM *Standard* E2357 test method, which determines the air leakage of three wall specimens: (1) with the air barrier material installed using air barrier accessories alone, (2) with the air barrier material installed and connected to air barrier components (window, doors, and other premanufactured elements) using air barrier accessories, and (3) with an air barrier wall assembly connected to a foundation assembly and roof assembly using air barrier accessories. The test method reports the air leakage rate at a reference pressure difference of 0.3 in. of water.

Specific air leakage criteria for air barrier assemblies can be found in Di Lenardo et al (1995), as well as a 2008 addendum to ASHRAE *Standard* 90.1. These specifications provides classes for air leakage rates of 0.01, 0.02, 0.03, and 0.04 cfm per square foot when measured with an air pressure difference of 0.3 in. of water, depending on the water vapor permeance of the outermost layer of the building envelope. The highest leakage rate applies if the permeance of the outermost layer is greater than 10 perm; the lowest rate applies if the permeance is less than 1 perm. ASTM *Standard* E1677's alternative minimum air barrier testing and criteria are specifically suitable for framed walls of low-rise buildings.

All of the building assemblies are put together and the various air barrier assemblies are connected to form an air barrier system affecting the whole building. A building's air leakage characteristics can be determined with the ASTM *Standard* E779 test method. A 2008 addendum to ASHRAE *Standard* 90.1 referenced a requirement of 0.4 cfm per square foot at 0.3 in. of water pressure difference.

The effectiveness of an air barrier can be greatly reduced if openings, even small ones, exist in it. These openings can be caused by poor design, poor workmanship during application, insufficient coating thickness, improper caulking and flashing, uncompensated thermal expansion, mechanical forces, aging, and other forms of degradation. Faults or leaks typically occur at electrical boxes, plumbing penetrations, telephone and television wiring, and other unsealed openings in the structure. A ceiling air barrier should be continuous at chases for plumbing, ducts, flues, and electrical wiring. In flat roofing, mechanical fasteners are sometimes used to adhere the system to the deck, and often penetrate the air barrier. In heating climates, the resulting holes may allow air exfiltration and

accompanying water vapor leakage into the roof. ASTM *Standard* E1186 describes several techniques for locating air leakage sites in building envelopes and air barrier systems.

Because air barrier materials and assemblies resist airflow, they must withstand pressures exerted by chimney (stack) effects, wind effects, or both, during construction and over the building's life. The magnitude of pressure may vary, depending on the type of building and sequence of construction. At one extreme, single-family dwellings may be built with exterior cladding partly or entirely installed and insulation in place before the air barrier is added. Chimney effects in these buildings are small, even in cold weather, so stresses on the air barrier during construction are small. At the other extreme, in tall buildings, wind and chimney-effect forces are much greater. A fragile, unprotected sheet material should not be used as an air barrier or vapor retarder because it will probably be torn by wind before construction is completed.

Note that a small penetration across an air barrier assembly may seriously affect its performance by concentrating air/vapor flow in a small area, resulting in large deposits of water (in some cases turning into ice). As mentioned, calculations of water vapor flow, interstitial condensation, and related moisture accumulation using only water vapor resistances are useless when airflow is involved. More information on air leakage in buildings may be found in Chapter 16.

Vapor Retarders

Water vapor retarders need to be considered in every building design. The need for and type of water vapor retarder used depend on the climate zone, construction type, and building use. Water vapor retarders were designed to protect building elements from water vapor permeating through building materials and then condensing. It is now recognized that it is just as important to allow the building assembly to dry as it is to keep the building assembly from getting wet. In some cases, to allow the building assembly to dry, a water vapor retarder may not be needed or may need to be semipermeable. In other cases, the environmental conditions, building construction, and building use may dictate that a material with very low water vapor permeance should be installed to protect the building components.

The 2007 supplement to the International Codes now lists three water vapor retarder classes:

- **Class I:** 0.1 perm or less
- **Class II:** more than 0.1 perm but less than or equal to 1.0 perm
- **Class III:** more than 1.0 perm but less than or equal to 10 perm

The designer determines the appropriate type of water vapor retarder and its proper location in the building assembly based on climate conditions, other materials used in the building assembly, and the building's use (e.g., intended relative humidity).

Functions and Properties

A vapor retarder slows the rate of water vapor diffusion, but does not totally prevent it. Requirements for vapor retarders in building components are not extremely stringent, because conditions on the inside and outside of buildings vary continually, air movement and ventilation can provide wetting as well as drying at various times, and water vapor entering one side of a building component can be stored and released later.

If conditions are conducive to condensation, water vapor retarders help (1) keep insulation dry; (2) prevent structural damage by rot, corrosion, or expansion of freezing water; and (3) reduce paint problems on exterior wall construction (ASTM *Standard* C755). Vapor retarders control vapor diffusion, so that water vapor enters an assembly more slowly than it leaves. If this can be accomplished through judicious placement of a vapor retarder, the assembly tends to dry out. Another way to look at vapor retarders is that they are the most vapor-resistant layer in the assembly; a capable designer knows

where this layer is and ensures that it does not promote condensation or prevent the assembly from drying.

In addition to vapor permeance, the following properties of vapor retarders are important, depending on the application:

- Mechanical strength in tension, shear, impact, and flexure
- Adhesion
- Elasticity
- Thermal stability
- Fire and flammability resistance
- Resistance to other deteriorating elements (e.g., chemicals, UV radiation)
- Ease of fabrication, application, and joint sealing

The vapor retarder's effectiveness depends on its vapor permeance, installation, and location in the insulated section. It is usually located at or near the surface exposed to higher water vapor pressure and higher temperature. For residences with heating systems, this is usually the winter-warm side.

Vapor retarder material is usually a thin sheet or coating. However, a construction of several materials, some perhaps of substantial thickness, can also constitute a vapor retarder system. In fact, designers have many options. For example, airflow and moisture movement might be controlled using an interior finish, such as drywall, to provide strength and stiffness, along with a low-permeability coating, such as vapor-retarding paint, to provide the required low permeance. Other designs may use more than one component. However, (1) any component that qualifies as a vapor retarder usually also impedes airflow, and is thus subject to pressure differences that it must resist; and (2) any component that impedes airflow may also retard vapor movement and promote condensation or frost formation.

Several studies found a significant increase in apparent permeance as a result of small holes in the vapor retarder. For example, Seiffert (1970) reported a 100-fold increase in the vapor permeance of aluminum foil when it is 0.014% perforated, and a 4000-fold increase when 0.22% of the surface is perforated. In general, penetrations particularly degrade a vapor retarder's effectiveness if it has very low permeance (e.g., polyethylene or aluminum foil). In addition, perforations may lead to air leakage, which further erodes effectiveness.

Smart vapor retarders allow substantial summer drying while functioning as effective vapor retarders during the cold season. One type of smart vapor retarder has low permeance to vapor, but is permeable to liquid water, allowing condensed moisture to dry. Korsgaard and Pedersen (1989, 1992) describe such a vapor retarder composed of synthetic fabric sandwiched between staggered strips of plastic film. The fabric wicks free water from the building envelope while the plastic film retards vapor flow into it.

Another type of smart vapor retarder provides low vapor permeance at low relative humidities, but much higher permeance at high relative humidity. During the heating season, indoor humidity usually is below 50% and the smart vapor retarder's permeance is low. In the summer, and on winter days with high solar-heat gains, when the temperature gradient is inward, moisture moving from the exterior of the wall or roof raises the relative humidity at the vapor retarder. This leads to higher vapor permeance and the potential for the wall or roof to dry out. One such vapor retarder is described by Kuenzel (1999). Below 50% rh, the film's permeance is less than 1 perm, but it increases above 60% rh, reaching 36 perm at 90% rh.

Water vapor permeances and permeabilities of some vapor retarders and other building materials are given in Tables 7 and 8. Additional information on control of moisture and airflow using vapor and air barriers may be found in Construction Specifications Canada (1990) and Kumaran (1989).

Classifications

Historically, a material or system with permeance of 1 perm or less qualified as a vapor retarder. Refining this, the Canadian General Standards Board (CGSB) specifies type I vapor retarders as having a permeance of 0.25 perm, and type II as having a permeance of 0.8 perm or less before aging and 1 perm or less after aging.

Water vapor retarders are classified as rigid, flexible, or coating materials. **Rigid retarders** include reinforced plastics, aluminum, and stainless steel. These usually are mechanically fastened in place and are vapor-sealed at the joints. **Flexible retarders** include metal foils, laminated foil and treated papers, coated felts and papers, and plastic films or sheets. They are supplied in roll form or as an integral part of a building material (e.g., insulation). Accessory materials are required for sealing joints. **Coating retarders** may be semifluid or mastic; paint (arbitrarily called surface coatings); or hot melt, including thermofusible sheet materials. Their basic composition may be asphaltic, resinous, or polymeric, with or without pigments and solvents, as required to meet design conditions. They can be applied by spray, brush, trowel, roller, dip or mop, or in sheet form, depending on the type of coating and surface to which it is applied. Potentially, each of these materials is an air barrier; however, to meet air barrier specifications, it must satisfy requirements for strength, continuity, and air permeance.

AIR TRANSMISSION AND WATER VAPOR PROPERTY DATA

Table 7 gives typical water vapor permeance and permeability values for common building materials. These values can be used to calculate water vapor flow through building components and assemblies using equations in Chapter 25.

Water vapor permeability of most building materials is a function of their moisture content, which, in turn, is a function of ambient relative humidity. Permeability values at various relative humidities are presented in Table 8 for several building materials. The same data are presented in Figure 7 for oriented strand board (OSB) and plywood samples. Data in this table and chart are from Kumaran (2002).

Users of the dew-point method may use constant values found in Table 7. However, if condensation in the assembly is predicted, then a more appropriate value should be used. Transient hygrothermal modeling typically uses vapor permeability values that vary with relative humidity, such as those given in Table 8. Table 8 also gives mean air permeability data.

MOISTURE STORAGE DATA

Transient analysis of assemblies requires consideration of the materials' moisture storage capacity. Some materials (called hygroscopic) adsorb or reject moisture to achieve equilibrium with adjacent air. Storage capacity of these materials is typically illustrated by graphs of moisture content versus humidity. The curve showing uptake of moisture (the **sorption isotherm**) is usually above the curve showing drying (the **desorption isotherm**) because the material's uptake of moisture is inhibited by surface tension, as is its release of moisture. Table 9 provides data for these curves for several hygroscopic materials, and Kumaran (1996, 2002) and McGowan (2007) provide actual curves, additional data, and conditions under which they were determined.

Values in Table 9 express moisture content as percentage of dry weight, followed by a subscript value of the relative air humidity at which this moisture content occurs. Note that these values are based on measurement of materials that have reached equilibrium with their surroundings, which in some cases can take many weeks. Most hygrothermal simulation software programs that use these values assume that equilibrium is achieved instantaneously.

Table 7 Typical Water Vapor Permeance and Permeability for Common Building Materials^a

Material	Weight, lb/100 ft ²	Thickness, in.	Permeance, perm			Permeability, perm-in.
			Dry-Cup	Wet-Cup	Other Method

Polyamide film, 2 mil			1.10	20.53		

^aThis table allows comparisons of materials, but when selecting vapor retarder materials, exact values for permeance or permeability should be obtained from manufacturer or from laboratory tests. Values shown indicate variations among mean values for materials that are similar but of different density, orientation, lot, or source. Values should not be used as design or specification data. Values from dry- and wet-cup methods were usually obtained from investigations using ASTM Standards C355 and E96; other values were obtained by two-temperature, special cell, and air velocity methods.

^bUsually installed as vapor retarders, although sometimes used as exterior finish and elsewhere near the cold side, where special considerations are then required for warm-side barrier effectiveness.

^cLow-permeance sheets used as vapor retarders. High permeance used elsewhere in construction.

*Historical data, no reference available

N/A = Not available

Maximum values in Table 9 are those that could be realistically measured in laboratory conditions, so not all materials have a listing for a maximum moisture content at 100% rh. For those that do, there are sometimes two listings: the moisture content measured when the material's capillary pores were saturated (shown as 100c) and the value at total saturation (shown as 100t). It is understood that the moisture content of any material would be 0.0 at a theoretical relative humidity of 0%, so this point is not shown in the table.

Figure 8 shows example of as a conventional sorption isotherm graph. Curves show sorption (wetting) and desorption (drying), for data in Table 9 and from Kumaran (2002). As Figure 8 illustrates, data in Table 9 were selected to provide an accurate representation of the sorption isotherm, although not all data from the original source are represented.

CHAPTER 27

HEAT, AIR, AND MOISTURE CONTROL IN BUILDING ASSEMBLIES—EXAMPLES

<i>HEAT TRANSFER</i> 27.1	<i>Wall or Roof with Insulated Sheathing</i> 27.8
<i>One-Dimensional U-Factor Calculation</i> 27.1	<i>Vapor Pressure Profile (Glaser or Dew-Point) Analysis</i> 27.8
<i>Two-Dimensional U-Factor Calculation</i> 27.3	<i>TRANSIENT HYGTHERMAL MODELING</i> 27.11
<i>MOISTURE TRANSPORT</i> 27.8	<i>AIR MOVEMENT</i> 27.12

THERMAL and moisture design as well as long-term performance must be considered during the planning phase of buildings. Installing appropriate insulation layers and taking appropriate air and moisture control measures can be much more economical during construction than later. Design and material selection should be based on

- Building use
- Interior and exterior climate
- Space availability
- Thermal and moisture properties of materials
- Other properties required by location of materials
- Durability of materials
- Compatibility with adjacent materials
- Performance expectations of the assembly

Designers and builders often rely on generic guidelines and past building practice as the basis for system and material selection. In many cases, this may still be a valuable approach, but for more difficult cases, selections and performance expectations should be set through engineering analysis. Recent developments have increased the capabilities of available tools and methods of thermal and moisture analysis.

This chapter draws on Chapter 25’s fundamental information on heat, air and moisture transport in building assemblies, as well as Chapter 26’s material property data. Examples here demonstrate calculation of heat, moisture, and air transport in typical assemblies. For design guidance for common building envelope assemblies and conditions, see Chapter 43 of the 2007 *ASHRAE Handbook—HVAC Applications*.

Insulation specifically for mechanical systems is discussed in Chapter 23. For specific industrial applications of insulated assemblies, see the appropriate chapter in other ASHRAE Handbook volumes. In the 2006 *ASHRAE Handbook—Refrigeration*, for refrigerators and freezers, see Chapters 46, 47, and 48; for insulation systems for refrigerant piping, see Chapter 33; for refrigerated facility design, see Chapters 14 and 39; for trucks, trailers, rail cars, and containers, see Chapter 30; for marine refrigeration, see Chapter 31. For environmental test facilities, see Chapter 37 in the 2002 *ASHRAE Handbook—Refrigeration*.

Engineering practice is predicated on the assumption that performance effects can be viewed in functional format, where discrete input values lead to discrete output values that may be assessed for acceptability. Heat transfer in solids lends itself to engineering analysis because material properties are relatively constant and easy to characterize, the transport equations are well established, analysis results tend toward linearity, and, for well-defined input values, output values are well defined. Airflow and moisture transport analysis, in contrast, is difficult: material properties are difficult to characterize, transport equations are not well-defined, analysis results tend

toward nonlinearity, and both input and output values include great uncertainty. Air movement is even more difficult to characterize than moisture transport.

Engineering makes use of the continuum in understanding from physical principles, to simple applications, to complex applications, to design guidance. Complex design applications can be handled by computers; however, this chapter presents simpler examples as a learning tool. Because complex applications are built up from simpler ones, understanding the simpler applications ensures that a critical engineering oversight of complex (computer) applications is retained. Computers have facilitated the widespread use of two- and three-dimensional analysis as well as transient (time-dependent) calculations. As a consequence, steady-state calculations are less widely used. Design guidance, notably guidance regarding use of air and vapor barriers, faces changes in light of sophisticated transient calculations. ASHRAE *Standard 160P* creates a framework for using transient hygrothermal calculations in building envelope design.

HEAT TRANSFER

ONE-DIMENSIONAL U-FACTOR CALCULATION

Wall U-Factor

The U-factor for a building envelope assembly determines the rate of steady-state heat conduction through the assembly. One-dimensional heat flow through building envelope assemblies is the starting point for determining whole-building heat transmittance.

Example 1. Calculate the system R-value R_{system} , average total resistance $[R_{T(av)}]$, and U-factor of the structural insulated panel assembly shown in Figure 1, assuming winter conditions.

Solution: Determine indoor and outdoor air film resistances from Table 1 in Chapter 26, and thermal resistance of all components from Table 4 in that chapter. If any elements are described by conductivity

Fig. 1 Structural Insulated Panel Assembly (Example 1)

The preparation of this chapter is assigned to TC 4.4, Building Materials and Building Envelope Performance.

(independent of thickness) rather than thermal resistance (thickness-dependent), then calculate the resistance.

Element	$R, \text{h} \cdot \text{ft}^2 \cdot ^\circ\text{F}/\text{Btu}$
1. Outdoor air film	0.17
2. Vinyl siding (hollow backed)	0.62
3. Vapor-permeable felt	0.06
4. Oriented strand board (OSB), 7/16 in.	0.62
5. 6 in. expanded polystyrene, extruded (smooth skin)	30.0
6. 0.5 in. gypsum wallboard	0.45
7. Indoor air film	0.68
Total	32.6

The conductivity k of expanded polystyrene is $0.20 \text{ Btu} \cdot \text{in}/\text{h} \cdot \text{ft}^2 \cdot ^\circ\text{F}$. For 6 in. thickness,

$$R_{\text{foam}} = x/k = 6/0.20 = 30.0 \text{ h} \cdot \text{ft}^2 \cdot ^\circ\text{F}/\text{Btu}$$

To calculate the system's R-value in the example, sum the R-values of the system components only, disregarding indoor and outdoor air films.

$$R_{\text{system}} = 0.62 + 0.06 + 0.62 + 30.0 + 0.45 = 31.75 \text{ h} \cdot \text{ft}^2 \cdot ^\circ\text{F}/\text{Btu}$$

The average total R-value ($R_{T(av)}$) consists of the system's R-value plus the thermal resistance of the interior and exterior air films.

$$R_{T(av)} = R_o + R_{\text{system}} + R_i = 32.6 \text{ h} \cdot \text{ft}^2 \cdot ^\circ\text{F}/\text{Btu}$$

The U-factor for the wall is $1/R_{T(av)}$, or $0.031 \text{ Btu}/\text{h} \cdot \text{ft}^2 \cdot ^\circ\text{F}$.

Roof U-Factor

Example 2. Find the U-factor of the roof assembly shown in Figure 2, assuming summer conditions.

Solution: The calculation procedure is similar to that shown in Example 1. Note the U-factor of nonvertical assemblies depends on the direction of heat flow [i.e., whether the calculation is for winter (heat flow up) or summer (heat flow down)], because the resistances of indoor air films and plane air spaces in ceilings differ, based on the heat flow direction (see Table 3 in Chapter 26). The effects of mechanical fasteners are not addressed in this example.

Element	$R, \text{h} \cdot \text{ft}^2 \cdot ^\circ\text{F}/\text{Btu}$
1. Indoor air film	0.92
2. 4 in. concrete, $120 \text{ lb}/\text{ft}^3$ and $k = 8$	0.5
3. 3 in. cellular polyisocyanurate (CFC-11 exp.) (gas-impermeable facers)	28.2
4. 1 in. mineral fiberboard	2.94
5. 3/8 in. built-up roof membrane	0.33
6. Outdoor air film	0.25
Total	33.1

Using $U = 1/R_{T(av)}$, the U-factor is $0.030 \text{ Btu}/\text{h} \cdot \text{ft}^2 \cdot ^\circ\text{F}$.

Fig. 2 Roof Assembly (Example 2)

Attics

During sunny periods, unconditioned attics may be hotter than outdoor air. Peak attic temperatures on a hot, sunny day may be 20 to 80°F above outdoor air temperature, depending on factors such as shingle color, roof framing type, air exchange rate through vents, and use of radiant barriers. Energy efficiency estimates can be obtained using models such as Wilkes (1991).

Basement Walls and Floors

Heat transfer through basement walls and floors to the ground depends on the following factors: (1) the difference between the air temperature in the room and that of the ground and outside air, (2) the material of the walls or floor, and (3) the thermal conductivity of surrounding earth. The latter varies with local conditions and is usually unknown. Because of the great thermal inertia of surrounding soil, ground temperature varies with depth, and there is a substantial time lag between changes in outdoor air temperatures and corresponding changes in ground temperatures. As a result, ground-coupled heat transfer is less amenable to steady-state representation than above-grade building elements. However, there are several simplified procedures for estimating ground-coupled heat transfer. These fall into two main categories: (1) those that reduce the ground heat transfer problem to a closed-form solution, and (2) those that use simple regression equations developed from statistically reduced multidimensional transient analyses.

Closed-form solutions, including Latta and Boileau's (1969) procedure discussed in Chapter 17, generally reduce the problem to one-dimensional, steady-state heat transfer. These procedures use simple, "effective" U-factors or ground temperatures or both. Methods differ in the various parameters averaged or manipulated to obtain these effective values. Closed-form solutions provide acceptable results in climates that have a single dominant season, because the dominant season persists long enough to allow a reasonable approximation of steady-state conditions at shallow depths. The large errors (percentage) that are likely during transition seasons should not seriously affect building design decisions, because these heat flows are relatively insignificant compared to those of the principal season.

The ASHRAE arc-length procedure (Latta and Boileau 1969) is a reliable method for wall heat losses in cold winter climates. Chapter 17 discusses a slab-on-grade floor model developed by one study. Although both procedures give results comparable to transient computer solutions for cold climates, their results for warmer U.S. climates differ substantially.

Research conducted by Dill et al. (1945) and Hougten et al. (1942) indicates a heat flow of approximately $2.0 \text{ Btu}/\text{h} \cdot \text{ft}^2$ through an uninsulated concrete basement floor with a temperature difference of 20°F between the basement floor and the air 6 in. above it. A U-factor of $0.10 \text{ Btu}/\text{h} \cdot \text{ft}^2 \cdot ^\circ\text{F}$ is sometimes used for concrete basement floors on the ground. For basement walls below grade, the temperature difference for winter design conditions is greater than for the floor. Test results indicate that, at the mid-height of the below-grade portion of the basement wall, the unit area heat loss is approximately twice that of the floor.

For small concrete slab floors (equal in area to a 25 by 25 ft house) in contact with the ground at grade level, tests indicate that heat loss can be calculated as proportional to the length of exposed edge rather than total area. This amounts to $0.81 \text{ Btu}/\text{h}$ per linear foot of exposed edge per degree temperature difference between indoor air and the average outdoor air temperature. This value can be reduced appreciably by installing insulation under the ground slab and along the edge between the floor and abutting walls. In most calculations, if the perimeter loss is calculated accurately, no other floor losses need to be considered. Chapter 17 contains data for load calculations and heat loss values for below-grade walls and floors at different depths.

The second category of simplified procedures uses transient two-dimensional computer models to generate ground heat transfer data,

which are then reduced to compact form by regression analysis (Mitalas 1982, 1983; Shipp 1983). These are the most accurate procedures available, but the database is very expensive to generate. In addition, these methods are limited to the range of climates and constructions specifically examined. Extrapolating beyond the outer bounds of the regression surfaces can produce significant errors.

Guide details and recommendations related to application of concepts for basements are provided in Chapter 43 of the 2007 *ASHRAE Handbook—HVAC Applications*. Detailed analysis of heat transfer through foundation insulation may also be found in the *Building Foundation Design Handbook* (Labs et al. 1988).

TWO-DIMENSIONAL U-FACTOR CALCULATION

The following examples show three methods of two-dimensional, steady-state conductive heat transfer analysis through wall assemblies. They offer approximations to overall rates of heat transfer (U-factor) when assemblies contain a layer composed of dissimilar materials. The methods are described in Chapter 25. The **parallel-path method** is used when the thermal conductivity of the dissimilar materials in the layer are rather close in value (within the same order of magnitude), as with wood-frame walls. The **isothermal-planes method** is appropriate for materials with conductivities moderately different from those of adjacent materials (e.g., masonry). The **zone method** and the **modified zone method** are appropriate for materials with a very high difference in conductivity (two orders of magnitude or more), such as with assemblies containing metal.

Two-dimensional, steady-state heat transfer analysis is often conducted using computer-based finite difference methods. If the resolution of the analysis is sufficiently fine, computer methods provide better simulations than any of the methods described here, and the results typically show better agreement with measured values.

The methods described here do not take into account heat storage in the materials, nor do they account for varying material properties (e.g., when thermal conductivity is affected by moisture content or temperature). Transient analysis is often used in such cases.

Wood-Frame Walls

The average overall R-values and U-factors of wood-frame walls can be calculated by assuming either parallel heat flow paths through areas with different thermal resistances or by assuming isothermal planes. Equation (15) in Chapter 25 provides the basis for the two methods.

The **framing factor** expresses the fraction of the total building component (wall or roof) area that is framing. The value depends on the specific type of construction, and may vary based on local construction practices, even for the same type of construction. For stud walls 16 in. on center (OC), the fraction of insulated cavity may be as low as 0.75, where the fraction of studs, plates, and sills is 0.21 and the fraction of headers is 0.04. For studs 24 in. OC, the respective values are 0.78, 0.18, and 0.04. These fractions contain an allowance for multiple studs, plates, sills, extra framing around windows, headers, and band joists. These assumed framing fractions are used in Example 3, to illustrate the importance of including the effect of framing in determining a building's overall thermal conductance. The actual framing fraction should be calculated for each specific construction.

Example 3. Calculate the U-factor of the 2 by 4 stud wall shown in Figure 3. The studs are at 16 in. OC. There is 3.5 in. mineral fiber batt insulation (R-13) in the stud space. The inside finish is 0.5 in. gypsum wallboard, and the outside is finished with rigid foam insulating sheathing (R-4) and vinyl siding. The insulated cavity occupies approximately 75% of the transmission area; the studs, plates, and sills occupy 21%; and the headers occupy 4%.

Solution: Obtain the R-values of the various building elements from Tables 1 and 4 of Chapter 26. Assume $R = 1.25 \text{ h}\cdot\text{ft}^2\cdot\text{°F}/\text{Btu}$ per inch

for the wood framing ($k = 0.8 \text{ Btu}\cdot\text{in}/\text{h}\cdot\text{ft}^2\cdot\text{°F}$). Also, assume the headers are solid wood, and group them with the studs, plates, and sills.

Two simple methods may be used to determine the U-factor of wood frame walls: parallel path and isothermal planes. For highly conductive framing members such as metal studs, the modified zone method must be used.

Parallel-Path Method:

Element	R (Insulated Cavity), h·ft ² ·°F/Btu	R (Studs, Plates, and Headers), h·ft ² ·°F/Btu
1. Outside air film, 15 mph wind	0.17	0.17
2. Vinyl siding (hollow-backed)	0.62	0.62
3. Rigid foam insulating sheathing	4.0	4.0
4. Mineral fiber batt insulation, 3.5 in.	11.7	—
5. Wood stud, nominal 2 × 4	—	4.38
6. Gypsum wallboard, 0.5 in.	0.45	0.45
7. Inside air film, still air	0.68	0.68
	$R_1 = 17.79$	$R_2 = 10.3$

Individual U-factors are reciprocals of the R-value, so $U_1 = 0.052$ and $U_2 = 0.095 \text{ Btu}/\text{h}\cdot\text{ft}^2\cdot\text{°F}$. If the wood framing is accounted for using the parallel-path flow method, the wall's U-factor is determined using Equation (15) from Chapter 25. The fractional area of insulated cavity is 0.75 and the fractional area of framing members is 0.25.

$$U_{av} = (0.75 \times 0.052) + (0.25 \times 0.095) = 0.063 \text{ Btu}/\text{h}\cdot\text{ft}^2\cdot\text{°F}$$

$$R_{T(av)} = 1/U_{av} = 15.87 \text{ h}\cdot\text{ft}^2\cdot\text{°F}/\text{Btu}$$

With the isothermal-planes method, the fractional areas are applied only to the building layer that contains the studs and cavity-fill insulation. The average R-value for this layer (R_{avs}) is added to the R-values of the other components for a total R for the assembly.

Isothermal-Planes Method:

Element	R (Stud Cavity Elements), h·ft ² ·°F/Btu	R (Studs, Plates, and Headers), h·ft ² ·°F/Btu
1. Outside air film, 15 mph wind		0.17
2. Vinyl siding (hollow-backed)		0.62
3. Rigid foam insulating sheathing		4.0
4. Mineral fiber batt insulation, 3.5 in.	11.7	8.71 (R_{avs})
5. Wood stud, nominal 2 × 4		4.38
6. Gypsum wallboard, 0.5 in.		0.45
7. Inside air film, still air		0.68
		$R_T = 14.63$

The average R-value R_{avs} of the stud cavity is calculated using the fractional area of stud and insulation using Equation (15) from Chapter 25.

$$U_{avs} = 0.75(1/13.0) + 0.25(1/4.38) = 0.115$$

Fig. 3 (A) Wall Assembly for Example 3, with Equivalent Electrical Circuits: (B) Parallel Path and (C) Isothermal Planes

$$R_{avs} = 1/U_{avs} = 8.71 \text{ h} \cdot \text{ft}^2 \cdot ^\circ\text{F}/\text{Btu}$$

If the wood framing is included using the isothermal-planes method, the U-factor of the wall is determined using Equations (10) and (11) from Chapter 25 as follows:

$$R_T = 14.8 \text{ h} \cdot \text{ft}^2 \cdot ^\circ\text{F}/\text{Btu}$$

$$U_{av} = 1/R_T = 0.067 \text{ Btu}/\text{h} \cdot \text{ft}^2 \cdot ^\circ\text{F}$$

For a frame wall with a 24 in. OC stud space, the average overall R-value is $15.18 \text{ h} \cdot \text{ft}^2 \cdot ^\circ\text{F}/\text{Btu}$. Similar calculation procedures may be used to evaluate other wall designs, except those with thermal bridges.

Masonry Walls

The average overall R-values of masonry walls can be estimated by assuming a combination of layers in series, one or more of which provides parallel paths. This method is used because heat flows laterally through block face shells so that transverse isothermal planes result. Average total resistance $R_{T(av)}$ is the sum of the resistances of the layers between such planes, each layer calculated as shown in Example 4.

Example 4. Calculate the overall thermal resistance and average U-factor of the 7 5/8 in. thick insulated concrete block wall shown in Figure 4. The two-core block has an average web thickness of 1 in. and a face shell thickness of 1 1/4 in. Overall block dimensions are 7 5/8 by 7 5/8 by 15 5/8 in. Measured thermal resistances of 112 lb/ft³ concrete and 7 lb/ft³ expanded perlite insulation are 0.10 and $2.90 \text{ h} \cdot \text{ft}^2 \cdot ^\circ\text{F}/\text{Btu}$ per inch, respectively.

Solution: The equation used to determine the overall thermal resistance of the insulated concrete block wall is derived from Equations (7) and (15) from Chapter 25 and is given below:

$$R_{T(av)} = R_i + R_f + \left(\frac{a_w}{R_w} + \frac{a_c}{R_c} \right)^{-1} + R_o$$

where

$R_{T(av)}$ = overall thermal resistance based on assumption of isothermal planes

R_i = thermal resistance of inside air surface film (still air)

R_o = thermal resistance of outside air surface film (15 mph wind)

R_f = total thermal resistance of face shells

R_c = thermal resistance of cores between face shells

R_w = thermal resistance of webs between face shells

a_w = fraction of total area transverse to heat flow represented by webs of blocks

a_c = fraction of total area transverse to heat flow represented by cores of blocks

From the information given and the data in Tables 3 and 4, Chapter 26, determine the values needed to compute the overall thermal resistance.

$$R_i = 0.68$$

$$R_o = 0.17$$

$$R_f = (2)(1.25)(0.10) = 0.25$$

$$R_c = (5.125)(2.90) = 14.86$$

$$R_w = (5.125)(0.10) = 0.51$$

$$a_w = 3/15.625 = 0.192$$

$$a_c = 12.625/15.625 = 0.808$$

Fig. 4 Insulated Concrete Block Wall (Example 4)

Using the equation given, the overall thermal resistance and average U-factor are calculated as follows:

$$R_{T(av)} = 0.68 + 0.25 + \frac{0.51 \times 14.86}{(0.808 \times 0.51) + (0.192 \times 14.86)} + 0.17$$

$$= 3.43 \text{ h} \cdot \text{ft}^2 \cdot ^\circ\text{F}/\text{Btu}$$

$$U_{av} = 1/3.43 = 0.29 \text{ Btu}/\text{h} \cdot \text{ft}^2 \cdot ^\circ\text{F}$$

Based on guarded hot-box tests of this wall without mortar joints, Tye and Spinney (1980) measured the average R-value for this insulated concrete block wall as $3.13 \text{ h} \cdot \text{ft}^2 \cdot ^\circ\text{F}/\text{Btu}$.

Assuming parallel heat flow only, the calculated resistance is higher than that calculated on the assumption of isothermal planes. The actual resistance generally is some value between the two calculated values. In the absence of test values, examination of the construction usually reveals whether a value closer to the higher or lower calculated R-value should be used. Generally, if the construction contains a layer in which lateral conduction is high compared with transmittance through the construction, the calculation with isothermal planes should be used. If the construction has no layer of high lateral conductance, the parallel heat flow calculation should be used.

Hot-box tests of insulated and uninsulated masonry walls constructed with block of conventional configuration show that thermal resistances calculated using the isothermal planes heat flow method agree well with measured values (Shu et al. 1979; Valore 1980; Van Geem 1985). Neglecting horizontal mortar joints in conventional block can result in thermal transmittance values up to 16% lower than actual, depending on the masonry's density and thermal properties, and 1 to 6% lower, depending on the core insulation material (McIntyre 1984; Van Geem 1985). For aerated concrete block walls, other solid masonry, and multicore block walls with full mortar joints, neglecting mortar joints can cause errors in R-values up to 40% (Valore 1988). Horizontal mortar joints, usually found in concrete block wall construction, are neglected in Example 4.

Constructions Containing Metal

Curtain and metal stud-wall constructions often include metallic and other thermal bridges, which can significantly reduce the thermal resistance. However, the capacity of the adjacent facing materials to transmit heat transversely to the metal is limited, and some contact resistance between all materials in contact limits the reduction. Contact resistances in building structures are only 0.06 to $0.6 \text{ h} \cdot \text{ft}^2 \cdot ^\circ\text{F}/\text{Btu}$, too small to be of concern in many cases. However, the contact resistances of steel framing members may be important. Also, in many cases (as illustrated in Example 5), the area of metal in contact with the facing greatly exceeds the thickness of metal, which mitigates contact resistance effects.

Thermal characteristics for panels of sandwich construction can be computed by combining the thermal resistances of the layers. R-values for assembled sections should be determined on a representative sample by using a hot-box method. If the sample is a wall section with air cavities on both sides of fibrous insulation, the sample must be of representative height because convective airflow can contribute significantly to heat flow through the test section. Computer modeling can also be useful, but all heat transfer mechanisms must be considered.

The metal studs in Examples 5 and 7 are 3.5 in. deep and placed at 16 in. on center. In Example 5, the metal member is only 0.020 in. thick, but it is in contact with adjacent facings over a 1.25 in. wide area. The steel member is 3.5 in. deep, has a thermal resistance of approximately $0.011 \text{ h} \cdot \text{ft}^2 \cdot ^\circ\text{F}/\text{Btu}$, and is virtually isothermal. The calculation involves careful selection of the thickness for the steel member. If the member is assumed to be 0.020 in. thick, the fact that the flange transmits heat to the adjacent facing is ignored, and heat flow through the steel is underestimated. If the member is assumed to be 1.25 in. thick, heat flow through the steel is overestimated. In

Example 5, the steel member behaves in much the same way as a rectangular member 1.25 in. thick and 3.5 in. deep with a thermal resistance of $(1.25/0.020) \times 0.011 = 0.69 \text{ h} \cdot \text{ft}^2 \cdot ^\circ\text{F}/\text{Btu}$.

Example 5. Calculate the system R (i.e., the R -value of the assembly less the resistances of indoor and outdoor air films) of the insulated steel frame wall shown in Figure 5. The C -factor is the reciprocal of the system R . Assume that the steel member has an R -value of $0.69 \text{ h} \cdot \text{ft}^2 \cdot ^\circ\text{F}/\text{Btu}$ and that the framing behaves as though it occupies approximately 8% of the transmission area.

Solution: Obtain the R -values of the various building elements from Table 4 in Chapter 26.

Element	R (Insul.)	R (Framing)
1. 0.5 in. gypsum wallboard	0.45	0.45
2. 3.5 in. mineral fiber batt insulation	11	—
3. Steel framing member	—	0.69
4. 0.5 in. gypsum wallboard	0.45	0.45
	$R_1 = 11.90$	$R_2 = 1.59$

Because $C = 1/R$, $C_1 = 0.084$ and $C_2 = 0.629 \text{ Btu}/\text{h} \cdot \text{ft}^2 \cdot ^\circ\text{F}$.

If the steel framing (thermal bridging) is not considered, the C -factor of the wall is calculated using Equation (11) from Chapter 25 as follows:

$$C_{av} = C_1 = 1/R_1 = 0.084 \text{ Btu}/\text{h} \cdot \text{ft}^2 \cdot ^\circ\text{F}$$

If the steel framing is accounted for using the parallel-flow method, the wall's C -factor is determined using Equation (15) from Chapter 25 as follows:

$$C_{av} = (0.92 \times 0.084) + (0.08 \times 0.629) = 0.128 \text{ Btu}/\text{h} \cdot \text{ft}^2 \cdot ^\circ\text{F}$$

$$R_{T(av)} = 7.81 \text{ h} \cdot \text{ft}^2 \cdot ^\circ\text{F}/\text{Btu}$$

If the steel framing is included using the isothermal planes method, the C -factor of the wall is determined using Equations (10) and (11) from Chapter 25 as follows:

$$R_{T(av)} = 0.45 + 1/[(0.92/11.00) + (0.08/0.69)] + 0.45 = 5.91 \text{ h} \cdot \text{ft}^2 \cdot ^\circ\text{F}/\text{Btu}$$

$$C_{av} = 0.169 \text{ Btu}/\text{h} \cdot \text{ft}^2 \cdot ^\circ\text{F}$$

For this insulated steel frame wall, Farouk and Larson (1983) measured an average R -value of $6.61 \text{ h} \cdot \text{ft}^2 \cdot ^\circ\text{F}/\text{Btu}$. For the same assembly, the recommended modified zone method (see Example 7) gives an average R -value of $6.73 \text{ h} \cdot \text{ft}^2 \cdot ^\circ\text{F}/\text{Btu}$. Two-dimensional analysis (THERM) yields $U_{av} = 0.1775$ or $R = 5.63 \text{ h} \cdot \text{ft}^2 \cdot ^\circ\text{F}/\text{Btu}$. ASHRAE/IESNA Standard 90.1 describes how to determine the thermal resistance of wall assemblies containing metal framing by using insulation/framing adjustment factors in Table A9.2B of the standard. For 2 by 4 steel framing, 16 in. OC, $F_c = 0.50$. Using the correction factor method, an R -value of $6.40 \text{ h} \cdot \text{ft}^2 \cdot ^\circ\text{F}/\text{Btu}$ [$0.45 + 11(0.50) + 0.45$] is obtained for the wall described here.

Zone Method of Calculation

For structures with widely spaced metal members of substantial cross-sectional area, the isothermal planes method can give thermal resistance values that are too low. For these constructions, the **zone method** can be used. This method involves two separate computations: one for a chosen limited portion, zone A, containing the

Fig. 5 Insulated Steel Frame Wall (Example 5)

highly conductive element; the other for the remaining portion of simpler construction, zone B. The two computations are then combined using the parallel-flow method, and the average transmittance per unit overall area is calculated. The basic laws of heat transfer are applied by adding the area conductances CA of elements in parallel, and adding area resistances R/A of elements in series.

The surface shape of zone A is determined by the metal element. For a metal beam (see Figure 6), the zone A surface is a strip of width W that is centered on the beam. For a rod perpendicular to panel surfaces, it is a circle of diameter W . The value of W is calculated from Equation (1), which is empirical. The value of d should not be less than 0.5 in. for still air.

$$W = m + 2d \tag{1}$$

where

- m = width or diameter of metal heat path terminal, in.
- d = depth from panel surface to metal, in.

Generally, W should be calculated using Equation (1) for each end of the metal heat path; the larger value, within the limits of the basic area, should be used as illustrated in Example 6.

Example 6. Calculate transmittance of the roof deck shown in Figure 6. Tee-bars at 24 in. OC support glass fiber form boards, gypsum concrete, and built-up roofing. Conductivities of components are: steel, $314.4 \text{ Btu} \cdot \text{in}/\text{h} \cdot \text{ft}^2 \cdot ^\circ\text{F}$; gypsum concrete, $1.66 \text{ Btu} \cdot \text{in}/\text{h} \cdot \text{ft}^2 \cdot ^\circ\text{F}$; and glass fiber form board, $0.25 \text{ Btu} \cdot \text{in}/\text{h} \cdot \text{ft}^2 \cdot ^\circ\text{F}$. Conductance of built-up roofing is $3.00 \text{ Btu}/\text{h} \cdot \text{ft}^2 \cdot ^\circ\text{F}$.

Solution: The basic area is 2 ft^2 (24 by 12 in.) with a tee-bar (12 in. long) across the middle. This area is divided into zones A and B. Zone A is determined from Equation (1) as follows:

$$\text{Top side } W = m + 2d = 0.625 + (2 \times 1.5) = 3.625 \text{ in.}$$

$$\text{Bottom side } W = m + 2d = 2.0 + (2 \times 0.5) = 3.0 \text{ in.}$$

Using the larger value of W , the area of zone A is $(12 \times 3.625)/144 = 0.302 \text{ ft}^2$. The area of zone B is $2.0 - 0.302 = 1.698 \text{ ft}^2$.

To determine area transmittance for zone A, divide the structure within the zone into five sections parallel to the top and bottom surfaces (Figure 6). The area conductance CA of each section is calculated by adding the area conductances of its metal and nonmetal paths. Area

Fig. 6 Gypsum Roof Deck on Bulb Tees (Example 6)

conductances of the sections are converted to area resistances R/A and added to obtain the total resistance of zone A.

Section	Area	Conductance = CA	$\frac{1}{CA} = \frac{R}{A}$
Air (outside, 15 mph)	0.302	$\times 6.00 = 1.81$	0.55
1. Roofing	0.302	$\times 3.00 = 0.906$	1.10
2. Gypsum concrete	0.302	$\times 1.66/1.125 = 0.446$	2.24
3. Steel	0.052	$\times 314.4/0.625 = 26.2$	0.04
Gypsum concrete	0.250	$\times 1.66/0.625 = 0.664$	
4. Steel	0.010	$\times 314.4/1.00 = 3.14$	0.31
Glass fiberboard	0.292	$\times 0.25/1.00 = 0.073$	
5. Steel	0.167	$\times 314.4/0.125 = 420.0$	0.002
Air (inside)	0.302	$\times 1.63 = 0.492$	2.03
Total $R/A =$			6.27

Area transmittance of zone A = $1/(R/A) = 1/6.27 = 0.159$.

For zone B, the unit resistances are added and then converted to area transmittance.

Section	Resistance R
Air (outside, 15 mph)	$1/6.00 = 0.17$
Roofing	$1/3.00 = 0.33$
Gypsum concrete	$1.75/1.66 = 1.05$
Glass fiberboard	$1.00/0.25 = 4.00$
Air (inside)	$1/1.63 = 0.61$
Total resistance = 6.16	

Because unit transmittance = $1/R = 0.162$, the total area transmittance UA is calculated as follows:

Zone B = 1.698×0.162	= 0.275
Zone A	= 0.159
Total area transmittance of basic area	= 0.434
Transmittance per $\text{ft}^2 = 0.434/2.0$	= 0.217
Resistance per ft^2	= 4.61

Overall R-values of 4.57 and 4.85 $\text{h} \cdot \text{ft}^2 \cdot \text{°F}/\text{Btu}$ were measured in two guarded hot-box tests of a similar construction.

When the steel member represents a relatively large proportion of the total heat flow path, as in Example 6, detailed calculations of resistance in sections 3, 4, and 5 of zone A are unnecessary; if only the steel member is considered, the final result of Example 6 is the same. However, if the heat flow path represented by the steel member is small, as for a tie rod, detailed calculations for sections 3, 4, and 5 are necessary. A panel with an internal metallic structure and bonded on one or both sides to a metal skin or covering presents special problems of lateral heat flow not covered by the zone method.

Modified Zone Method for Metal Stud Walls with Insulated Cavities

The modified zone method is similar to the parallel-path and zone methods; all three are based on parallel-path calculations.

Fig. 7 Wall Section and Equivalent Electrical Circuit (Example 7)

Figure 7 shows the width w of the zone of thermal anomalies around a metal stud. This zone can be assumed to equal the length of the stud flange L (parallel-path method), or can be calculated as a sum of the length of stud flange and a distance double that from wall surface to metal $\sum d_i$ (zone method). In the modified zone method, the width of the zone depends on three parameters:

- Ratio between thermal resistivity of sheathing material and cavity insulation
- Size (depth) of stud
- Thickness of sheathing material

Example 7. Calculate the U-factor of the wall section shown in Figure 7 using the modified zone method.

Solution: The wall cross section is divided into two zones: the zone of thermal anomalies around the metal stud (zone W), and the cavity zone (zone cav). Wall material layers are grouped into exterior and interior surface sections A (sheathing, siding) and B (wallboard), and interstitial sections I and II (cavity insulation, metal stud flange).

Assuming that the wall materials in section A are thicker than those in section B, as shown, they can be described as follows:

$$\sum_{i=1}^n d_i \geq \sum_{j=1}^m d_j$$

where

n = number of material layer (of thickness d_i) between metal stud flange and wall surface for section A

m = number of material layer (of thickness d_j) for section B

Then, the width W of zone W can be estimated by

$$W = L + z_f \sum_{i=1}^n d_i$$

where

L = stud flange size

d_i = thickness of material layer in section A

z_f = zone factor, shown in Figure 8 ($z_f = 2$ for zone method)

Kosny and Christian (1995) verified the accuracy of the modified zone method for over 200 simulated cases of metal frame walls with insulated cavities. For all configurations considered, the discrepancy between results were within $\pm 2\%$. Hot-box-measured R-values for 15 metal stud walls tested by Barbour et al. (1994) were compared with results obtained by Kosny and Christian (1995) and McGowan and Desjarlais (1997). The modified zone method was found to be the most accurate simple method for estimating the clear-wall R-value of light-gage steel stud walls with insulated cavities. However, this analysis does not apply to construction with metal sheathing. Also, ASHRAE Standard 90.1 may require a different method of analysis.

Use $z_f = -0.5$ for walls when total thickness of layer of materials attached to one side of metal frame $\leq 5/8$ in. and thermal resistivity of sheathing $\leq 1.5 \text{ h}\cdot\text{ft}^2\cdot^\circ\text{F}/\text{Btu}\cdot\text{in.}$

Use $z_f = +0.5$ for walls when total thickness of layer of materials attached to one side of metal frame $\leq 5/8$ in. and thermal resistivity of sheathing $> 1.5 \text{ h}\cdot\text{ft}^2\cdot^\circ\text{F}/\text{Btu}\cdot\text{in.}$

Find z_f in chart above for walls when total thickness of layer of materials attached to one side of metal frame $> 5/8$ in.

Fig. 8 Modified Zone Factor for Calculating R-Value of Metal Stud Walls with Cavity Insulation

Step 1. Determine zone factor z_f , and the ratio of the exterior sheathing material’s resistivity to the cavity material’s resistivity. Resistivity r is the reciprocal of conductivity; Table 4 in Chapter 26, lists conductivities of various materials.

Element	Symbol	Value	Units
Stud spacing	s	16	in.
Resistivity of sheathing material	r_i	5.00	$\text{h}\cdot\text{ft}^2\cdot^\circ\text{F}/\text{Btu}\cdot\text{in.}$
Resistivity of cavity insulation	r_{ins}	3.45	$\text{h}\cdot\text{ft}^2\cdot^\circ\text{F}/\text{Btu}\cdot\text{in.}$
Ratio r_i/r_{ins}		1.449	(no units)
Zone factor from chart	z_f	1.71	(no units)

Step 2. Calculate width W of affected zone W :

$$W = L + z_f \sum d_i$$

Element	Symbol	Value	Units
Cavity thickness	d_s	3.5	in.
Thickness of metal	d_{II}	0.04	in.
Interior dimension between flanges	d_I	3.42	in.
Thickness of exterior insulating materials		2	in.
Flange length	L	1.5	in.
Affected zone thickness	W	4.920	in.

Step 3. Calculate the exterior and interior thermal resistances, using conductivity or thermal resistance values from step 1.

Element	Symbol	Value	Units
Exterior materials			
Thickness of first exterior material	d_e	1.5	in.
Resistivity of first exterior material	r_e	5.00	$\text{h}\cdot\text{ft}^2\cdot^\circ\text{F}/\text{Btu}\cdot\text{in.}$
Resistance of first material		7.50	$\text{h}\cdot\text{ft}^2\cdot^\circ\text{F}/\text{Btu}$
Resistances of other materials		0.825	
Sum of resistances of exterior materials	R_A	8.33	$\text{h}\cdot\text{ft}^2\cdot^\circ\text{F}/\text{Btu}$

Element	Symbol	Value	Units
Interior materials			
Thickness of interior material	d_j	0.05	in.
Resistivity of interior material	r_j	0.90	$\text{h}\cdot\text{ft}^2\cdot^\circ\text{F}/\text{Btu}\cdot\text{in.}$
Resistance of interior material	R_B	0.245	$\text{h}\cdot\text{ft}^2\cdot^\circ\text{F}/\text{Btu}$

Step 4. Calculate the thermal resistance of the sections in zone around the metal element. The building elements in series from outside to inside are shown in Figure 7.

Element	Symbol	Value	Units
Resistivity of steel	r_{met}	0.0030	$\text{h}\cdot\text{ft}^2\cdot^\circ\text{F}/\text{Btu}\cdot\text{in.}$
R_{ins}^I	d_{xri}^I	11.80	$\text{h}\cdot\text{ft}^2\cdot^\circ\text{F}/\text{Btu}$
R_{ins}^{II}	d_{xri}^{II}	0.138	$\text{h}\cdot\text{ft}^2\cdot^\circ\text{F}/\text{Btu}$
R_{met}^I	d_{xmet}^I	0.0102	$\text{h}\cdot\text{ft}^2\cdot^\circ\text{F}/\text{Btu}$
R_{met}^{II}	d_{xmet}^{II}	0.00012	$\text{h}\cdot\text{ft}^2\cdot^\circ\text{F}/\text{Btu}$

The particular thermal resistances of the zone elements are then calculated.

Zone W is the zone at the web of the metal member. For width W , the thermal conductance C is calculated as the sum of the contributory areas. Because the thickness of the web of the metal member is d_I and the length along the flange section is L ,

$$C_I = \frac{W-d_I}{W} C_{ins} + \frac{d_I}{W} C_{met} \quad \text{and} \quad C_{II} = \frac{W-L}{W} C_{ins} + \frac{L}{W} C_{met}$$

Using resistance rather than conductance, the contributing R-values are calculated as

$$R_I = \frac{R_{met}^I R_{ins}^I W}{d_I (R_{ins}^I - R_{met}^I) + W R_{met}^I} \quad \text{and} \quad R_{II} = \frac{R_{met}^{II} R_{ins}^{II} W}{L (R_{ins}^{II} - R_{met}^{II}) + W R_{met}^{II}}$$

At the cavity, the sum of the series R-values is

$$\sum R_{cav} = R_A + R_B + R_{ins}^I + 2R_{ins}^{II}$$

In zone W , the sum of the R-values is

$$\sum R_W = R_A + R_B + R_I + 2R_{II}$$

The total conductivity across the length s is proportional to the contributing lengths of zone W and the cavity:

$$C_{tot} = \frac{W}{s} C_W + \frac{cav}{s} C_{cav}$$

or

$$R_{tot} = \frac{\sum R_W \sum R_{cav} s}{W (\sum R_{cav} - \sum R_W) + s \sum R_W}$$

Element	Symbol	Value	Units
Resistance at web	R_I	1.141	$\text{h}\cdot\text{ft}^2\cdot^\circ\text{F}/\text{Btu}$
Resistance at flange	R_{II}	0.00039	$\text{h}\cdot\text{ft}^2\cdot^\circ\text{F}/\text{Btu}$
Sum of resistances at cavity	$\sum R_{cav}$	20.65	$\text{h}\cdot\text{ft}^2\cdot^\circ\text{F}/\text{Btu}$
Sum of resistances at zone W	$\sum R_W$	9.712	$\text{h}\cdot\text{ft}^2\cdot^\circ\text{F}/\text{Btu}$
Total R	R_{tot}	15.34	$\text{h}\cdot\text{ft}^2\cdot^\circ\text{F}/\text{Btu}$
Total U	U_{tot}	0.0652	$\text{Btu}/\text{h}\cdot\text{ft}^2\cdot^\circ\text{F}$

In this example, the calculated total R-value for the wall is $15.34 \text{ h}\cdot\text{ft}^2\cdot^\circ\text{F}/\text{Btu}$, and the wall’s U-factor is $0.0652 \text{ Btu}/\text{h}\cdot\text{ft}^2\cdot^\circ\text{F}$.

Complex Assemblies

Building enclosure geometry of two- and three-dimensional assemblies may be complex, including corners, terminations of materials, and junctures of different materials. Such assemblies cannot be analyzed effectively with explicit calculations; rather, they require iterative calculations using computers.

Figure 9 shows a corner composed of homogeneous material. Surface temperatures can be estimated from the intersections of isotherms and the surface. If, in this figure, the interior were warm with respect to outside, then the line at the corner would be colder than the

Fig. 9 Corner Composed of Homogeneous Material Showing Locations of Isotherms

Fig. 10 Insulating Material Installed on Conductive Material, Showing Temperature Anomaly (Point A) at Insulation Edge

remainder of the interior surface. This effect may be exacerbated by the air film at the corner, which would have a greater effective thickness than on the plane of the wall, and would therefore offer greater thermal resistance, further lowering the corner temperature.

Figure 10 shows an insulating material applied to a conductive material. Insulation is placed at the inside, during a period of cold outdoor temperatures. A computer program may be used to trace the isotherms. The interior isotherm is cut where the insulating material is interrupted, indicating lowered temperature at that location (point A). In fact, the temperature at the edge of the interrupted insulation is even lower than the temperature at the surface of the uninsulated wall. Interruptions in insulation can lead to thermal bridges. For this reason, insulation of conductive assemblies such as masonry or concrete is often more successful when applied to the outside rather than to the inside of the building.

Windows and Doors

Table 4 of Chapter 15 lists U-factors for various fenestration products. For heat transmission coefficients for wood and steel doors, see Table 6 in Chapter 15. All U-factors are approximate, because a significant portion of the resistance of a window or door is contained in the air film resistances, and some parameters that may have important effects are not considered. For example, the listed U-factors assume the surface temperatures of surrounding bodies are equal to the ambient air temperature. However, the indoor surface of a window or door in an actual installation may be exposed to nearby radiating surfaces, such as radiant heating panels, or opposite walls with much higher or lower temperatures than the indoor air. Air movement across the surface of a window or door, such as that caused by nearby heating and cooling outlet grilles or by wind outdoors, increases the U-factor.

MOISTURE TRANSPORT

The following examples build on the previous sections by discussing methods that combine heat and moisture transport analysis. The methods include fundamental calculations that can be performed by hand as well as more advanced transient calculations that require computer modeling.

WALL OR ROOF WITH INSULATED SHEATHING

When insulating materials with low water vapor permeability are included in a building assembly, a simple moisture test can provide

Fig. 11 Roof Assembly Using Foam Insulation

a satisfactory estimate of condensation resistance. This test assumes that interior surfaces may have little or no resistance to air or vapor flow. The section on Surface Condensation in Chapter 25 describes how to determine the risk of condensation on low-permeability surfaces.

Example 8. For the assembly shown in Figure 11, determine the range of indoor relative humidity for which condensation does not occur on the underside of the insulating sheathing. Assume a design outdoor temperature of 30°F, and indoor temperature of 70°F. Assume that the cavity air is at the same vapor pressure as the indoor air, which can occur with openings through the ceiling. Ignore radiant effects on the roof surface. Assume the rigid insulation is vapor impermeable, and interior materials have little resistance to air or vapor flow.

Air Film or Material	Thermal Resistance, h·ft ² ·°F/Btu
1. Indoor air film coefficient	0.68
2. Gypsum wallboard	0.32
3. Mineral fiber insulation	19
4. 1 in. extruded polystyrene	7
5. OSB sheathing, 1/2 in.	0.68
6. Asphalt shingles	0.44
7. Exterior air film coefficient	0.17
Total R-value	
	28.29

Solution: The temperature difference is 40°F. The sum of the R-values from the foam/mineral fiber interface inward is 20.0 h·ft²·°F/Btu. The sum of the R-values from that interface outward is 8.29 h·ft²·°F/Btu. The temperature difference ratio [Equation (14), Chapter 25] is 8.29/28.29, or 0.29. The interface temperature is 41.7°F. The saturation vapor pressure of indoor air is 0.74 in. Hg, and the saturation vapor pressure at the interface is 0.26 in. Hg (see Chapter 1). The upper bound for indoor relative humidity is therefore 0.26/0.74, or 35% rh.

Many factors influence the likelihood (or not) of damage in an assembly such as this with exterior rigid insulation. Solar effects generally ensure a period of high temperatures that allows drying. On the other hand, cold sky temperatures may increase heat loss from the assembly, which lowers the surface temperature below ambient. Even when indoor humidity is high enough that condensation at the interface is indicated, the rate of water formation may be slowed by airtightness at the ceiling and by vapor diffusion protection.

VAPOR PRESSURE PROFILE (GLASER OR DEW-POINT) ANALYSIS

The common steady-state one-dimension tool for evaluating moisture accumulation and drying within exterior envelopes (walls, roofs, and ceilings) is the dew-point or Glaser method. Users should recognize its limitations, which include the following:

- Strictly speaking, condensation is a phase change from vapor to liquid. Water that is attached to the surfaces of building materials is adsorbed or absorbed water, not liquid water. Increase in the moisture content of porous and hygroscopic building materials is properly called sorption, not condensation. Dew-point method results have often been interpreted to indicate condensation,

when, in fact, increases in moisture content were through sorption, not condensation.

- Heat and moisture storage effects are not included in dew-point analysis. Experience shows storage effects to play a significant role in heat and moisture performance of assemblies.
- Diffusion is the only moisture transport mechanism considered. Airflow, capillary transport, rain wetting, initial conditions, latent effects, solar effects, and ventilation cannot be included in the method, and they may have a dominant effect on building assembly performance.
- The dew-point method allows calculation of a rate of moisture accumulation or rate of drying from a critical location within the assembly. However, the method has not shown how to estimate damage associated with any rate of accumulation or drying.

Chapter 25 discusses the Glaser method and its limitations in more detail.

ASHRAE does not recommend the dew-point method as the sole basis for hygrothermal design of building envelope assemblies. ASHRAE *Standard* 160P is being developed to assist in hygrothermal analysis for design purposes. The dew-point method is presented here for reasons of historical continuity, and because it serves as an illustration of the fundamental principles of conduction in heat transport and diffusion in moisture transport.

Winter Wall Wetting Examples

Example 9. For a wood-framed wall, assume monthly mean conditions of 70°F, 50% rh indoors and 20°F, 70% rh outdoors. Indoor and outdoor vapor pressures are 0.370 and 0.072 in. Hg, respectively.

Solution:

Step 1. List the components in the building assembly, with their R-values and permeances.

Air Film or Material	Thermal Resistance, h·°F·ft ² /Btu	Proportional Temperature Drop	Vapor Permeance, perm	Vapor Diffusion Resistance, rep	Proportional Vapor Pressure Drop
1. Air film coefficient	0.68	0.049	160	0.006	0.003
2. Gypsum board, painted, cracked joints	0.45	0.032	5	0.200	0.088
3. Insulation, mineral fiber	11	0.790	30	0.033	0.015
4. OSB sheathing	0.62	0.045	0.5	2.0	0.881
5. Wood siding	1.0	0.072	35	0.029	0.013
6. Air film coefficient	0.17	0.012	1000	0.001	0.000
Totals	13.92	1.000		2.27	1.000

Step 2. List the indoor and outdoor temperature and relative humidity. Vapor pressure at indoor and outdoor locations is determined by multiplying the saturation vapor pressure at that temperature by the relative humidity.

Boundary or Interface Between Materials	Temperature, °F	Saturation Vapor Pressure, in. Hg	Relative Humidity, %	Initial Vapor Pressure, in. Hg	Corrected Vapor Pressure, in. Hg
Indoor air	70	0.740	50	0.370	0.370
1-2 interface	67.6	0.680		0.369	0.364
2-3 interface	65.9	0.643		0.343	0.171
3-4 interface	26.4	0.139		0.339	0.139
4-5 interface	24.2	0.126		0.076	0.073
5-6 interface	20.6	0.106		0.072	0.072
Outdoor air	20	0.103	70	0.072	0.072
Difference	50		Difference	0.298	

Step 3. Calculate the proportional temperature drop across each layer. The temperature drop is proportional to the R-value:

$$\frac{\Delta t_{layer}}{t_i - t_o} = \frac{R_{layer}}{R_T}$$

The table in step 1 lists the resulting proportional temperature drops. Calculate the proportional water vapor pressure drops across each layer. These are calculated the same way as the proportional temperature drops in step 1:

$$\frac{\Delta p_{layer}}{p_i - p_o} = \frac{Z_{layer}}{Z_T}$$

where

Z_T = total water vapor diffusion resistance of wall (sum of diffusion resistances of all layers), rep

p = partial water vapor pressure, in. Hg

Step 4. Determine the temperature at each interface, using the temperature difference from indoors to outdoors, and the proportional temperature drop. Find the saturation water vapor pressure corresponding to the interface temperatures from step 1. These values can be found in Table 2 in Chapter 1.

Step 5. From step 1, the total water vapor diffusion resistance of the wall without the vapor retarder is

$$Z_{wall} = 1/160 + 1/5 + 1/30 + 1/0.5 + 1/35 + 1/1000 = 2.27 \text{ rep}$$

The partial water vapor pressure drop across the whole wall is calculated from the indoor and outdoor saturation water vapor pressures and relative humidities (see the table in step 2).

$$p_{wall} = p_i - p_o = (50/100)0.740 - (70/100)0.103 = 0.298 \text{ in. Hg}$$

Step 6. Figure 12 shows the calculated saturation and partial water vapor pressures. Comparison reveals that the calculated partial water vapor pressure on the interior surface of the sheathing is well above saturation. This indicates incipient accumulation of water (condensation or sorption), probably on the surface of the sheathing, not within the insulation. If the accumulation rate is of interest, two additional steps are necessary.

Step 7. The calculated water vapor pressure exceeds the saturation water vapor pressure by the greatest amount at the back side of the sheathing (Figure 12). Therefore, this is the most likely location for accumulation. Under conditions of phase change (condensation or sorption), the water vapor pressure should equal the saturation water vapor pressure at that interface (see the corrected vapor pressure column in step 2 of Example 9).

Step 8. The change of water vapor pressure on the OSB sheathing alters all other partial water vapor pressures as well as water vapor flux through the wall. Calculating partial water vapor pressures is similar to

Fig. 12 Dew-Point Calculation in Wood-Framed Wall (Example 9)

the calculation in step 3, but the wall is now divided in two parts: one on the interior of the condensation interface (i.e., gypsum board and insulation) and the other on the exterior (OSB sheathing and wood siding). Water vapor pressure drop over the first (interior) part of the wall is

$$\Delta p_1 = 0.370 - 0.139 = 0.230 \text{ in. Hg}$$

and over the second (exterior) part is

$$\Delta p_2 = 0.139 - 0.072 = 0.067 \text{ in. Hg}$$

The diffusion resistances of both parts of the wall are

$$Z_1 = 1/160 + 1/5 + 1/30 = 0.239 \text{ rep}$$

$$Z_2 = 1/0.5 + 1/35 + 1/1000 = 2.03 \text{ rep}$$

The water vapor pressure drops across each material can be calculated from the part between the inside and sheathing

$$\frac{\Delta p_{layer}}{p_i - p'_{sheathing}} = \frac{Z_{layer}}{Z_i^{sheathing}}$$

and the part between the sheathing and outside

$$\frac{\Delta p_{layer}}{p'_{sheathing} - p_o} = \frac{Z_{layer}}{Z_o^{sheathing}}$$

	Z_{tot} h·ft ² ·in. Hg/ gr	Vapor Pressure Difference, in. Hg	Vapor Flow, gr/ft ² ·h
Indoor air to critical interface	0.239	0.230	0.9628
Critical interface to outdoor air	2.030	0.067	0.0332
Net accumulation, gr/ft ² ·h			0.9295

As shown in Figure 12, final calculations of water vapor pressure no longer exceed saturation, which means that the condensation plane was chosen correctly. However, vapor flux is no longer the same throughout the wall. The flux from inside increases; to the outside it decreases. The difference between both is the rate of moisture accumulation by interstitial condensation at the back side of the sheathing:

$$m_c = \frac{p_i - p'_{sheathing}}{Z_i^{sheathing}} - \frac{p'_{sheathing} - p_o}{Z_o^{sheathing}}$$

In this case $m_c = 0.9295 \text{ gr/ft}^2\cdot\text{h}$. (One grain equals 1/7000 of a pound.) Assume the 0.5 in. OSB sheathing (density of 34 lb/ft³) begins with moisture content of 10%. The weight of dry OSB at that thickness is 1.42 lb/ft², so the weight of water is 0.14 lb. If these conditions persist for 30 days (720 h), then the amount of accumulated water is 0.04 lb. This raises the moisture content of the wood to 12.5%. It is evident that wetting by diffusion is very slow.

The Glaser method should not be used to show simply that calculated vapor pressure at one location exceeds saturation vapor pressure at that location. If that condition is detected, then the rate of accumulation must be calculated and the results compared to the affected material's estimated storage potential. Unfortunately, guidance on interpretation of accumulated water with the Glaser method is not available. Considerations of moisture storage potential in building materials can be addressed only with transient modeling, not with steady-state methods.

Example 10. A wood-framed construction has a wet layer inside. The wall layers include a 6 mil (0.006 in.) polyethylene membrane between insulation and gypsum board, and an exterior insulation and finish system (EIFS) with 1.5 in. of expanded polystyrene as substrate and a spun-glass reinforced stucco finish. If the OSB sheathing became soaked because of rain infiltration at the windows, how long before the OSB reaches hygroscopic equilibrium after leaks are sealed? Solve for two monthly mean conditions: winter, with 70°F, 40% rh indoors and 20°F, 50% rh outdoors; and summer, with 77°F, 70% rh indoors and 73°F, 70% rh outdoors.

Solution:

Step 1. List the components in the building assembly, with their R-values and permeances.

Air Film or Material	Thermal Resistance R, h·ft ² ·°F/Btu	Proportional Temperature Drop	Vapor Permeance, perm	Vapor Diffusion Resistance, h·ft ² ·in. Hg/gr	Proportional Vapor Pressure Drop
1. Air film coefficient	0.68	0.035	160	0.006	0.000
2. Gypsum board, painted	0.45	0.023	5	0.200	0.002
3. Polyethylene foil	0.0	0.000	0.01	125	0.974
4. Insulation, mineral fiber	11.0	0.573	30	0.033	0.000
5. OSB sheathing	0.62	0.032	0.5	2.000	0.016
6. EPS	5.7	0.297	1.3	0.769	0.006
7. EIFS stucco lamina and finish	0.57	0.030	3.2	0.313	0.002
8. Air film coefficient	0.17	0.009	1000	0.001	0.000
Total	19.19	1.000		128	1.000

Step 2. List the indoor and outdoor temperature and relative humidity. As in Example 9, indoor and outdoor vapor pressure is determined by multiplying the saturation vapor pressure at that temperature by the relative humidity.

Winter conditions:

	Temperature, °F	Saturated Vapor Pressure, in. Hg	Relative Humidity, %	Initial Vapor Pressure, in. Hg	Vapor Pressure, in. Hg
Indoors	70	0.740	40	0.296	0.296
1 and 2	68.22	0.696		0.296	0.296
2 and 3	67.05	0.668		0.295	0.296
3 and 4	67.05	0.668		0.057	0.233
4 and 5	38.39	0.233		0.057	0.233
5 and 6	36.78	0.218		0.053	0.218
6 and 7	21.93	0.113		0.052	0.215
7 and 8	20.44	0.105		0.051	0.177
Outdoors	20	0.103	50	0.051	0.051
Difference	50		Difference	0.244	

Summer conditions:

	Temperature, °F	Saturated Vapor Pressure, in. Hg	Relative Humidity, %	Initial Vapor Pressure, in. Hg	Vapor Pressure, in. Hg
Indoors	77	0.936	70	0.655	0.655
1 and 2	76.9	0.931		0.655	0.680
2 and 3	76.8	0.929		0.655	0.705
3 and 4	76.8	0.929		0.575	0.731
4 and 5	74.5	0.860		0.575	0.860
5 and 6	74.3	0.857		0.574	0.857
6 and 7	73.2	0.823		0.573	0.764
7 and 8	73.0	0.820		0.573	0.669
Outdoors	73	0.819	70	0.573	0.573
Difference	4		Difference	0.082	

Step 3. Indoor and outdoor vapor pressures are calculated from the given conditions of temperature and relative humidity. The vapor pressure at each side of the OSB sheathing is assigned the value of the saturation vapor pressure at that temperature (see bold values in the summer and winter condition tables).

Step 4. Calculate the total vapor resistance on either side of the critical OSB layer. Between inside and sheathing,

$$\frac{\Delta p_{layer}}{p_i - p'_{sheathing}} = \frac{Z_{layer}}{Z_i^{sheathing}}$$

Between sheathing and outside,

$$\frac{\Delta p_{layer}}{p'_{sheathing} - p_o} = \frac{Z_{layer}}{Z'_{sheathing}}$$

From the summer and winter condition tables, the diffusion resistances of both parts of the wall are

$$Z_1 = 0.0062 + 0.20 + 125 + 3.31 \times 10^{-2} = 125.21 \text{ rep}$$

$$Z_2 = 0.79 + 0.31 + 1.00 \times 10^{-3} = 1.10 \text{ rep}$$

Step 5. Calculate the vapor pressure difference on either side of the critical OSB layer (the last column in the summer and winter condition tables). From the vapor resistance on each side and the vapor pressure difference on each side, vapor flow in each direction can be calculated.

Winter

$$m_{i,sheathing} = \frac{p_i - p'_{sheathing}}{Z'_{sheathing}} = 0.0005 \text{ gr/ft}^2 \cdot \text{h}$$

$$m_{sheathing,o} = \frac{p'_{sheathing} - p_o}{Z_i^{sheathing}} = 0.154 \text{ gr/ft}^2 \cdot \text{h}$$

	Z_{tot} h·ft ² ·in. Hg/ gr	Vapor Pressure Difference, in. Hg	Vapor Flow, gr/ft ² ·h
Indoor air to critical interface	125.2	0.063	0.0005
Critical interface to outdoor air	1.10	0.167	0.1543
		Net drying	0.1538
		Net drying, gr/ft ² per month	111

Summer

$$m_{i,sheathing,i} = \frac{p_i - p'_{sheathing}}{Z'_{sheathing}} = -0.0016 \text{ gr/ft}^2 \cdot \text{h}$$

$$m_{sheathing,o} = \frac{p'_{sheathing} - p_o}{Z_o^{sheathing}} = 0.262 \text{ gr/ft}^2 \cdot \text{h}$$

	Z_{tot} h·ft ² ·in. Hg/ gr	Vapor Pressure Difference, in. Hg	Vapor Flow, gr/ft ² ·h
Indoor air to critical interface	125.2	-0.205	-0.0016
Critical interface to outdoor air	1.10	0.283	0.2618
		Net drying	0.2634
		Net drying, gr/ft ² per month	187

Drying consequently amounts to 111 gr/ft² per month in winter and 187 gr/ft² per month in summer. OSB soaked with water can have excess moisture content of up to 0.98 lb/ft². Drying only by one-dimensional diffusion would appear to take several years at this rate. Radiation, air movement, and two- and three-dimensional effects can change the rate of drying.

Figures 13 and 14 show the calculated water vapor pressure in winter and summer. The OSB is at water vapor saturation pressure; saturation is not reached at any other interface.

TRANSIENT HYGROTHERMAL MODELING

Fundamentals of hygrothermal modeling tools, including modeling criteria and method of reporting, are discussed in Chapter 25. Although this chapter does not provide a complete example, it introduces input data commonly required by these programs and discusses considerations for analyzing output when using these tools.

For many applications and for design guide development, actual behavior of an assembly under transient climatic conditions may be simulated to account for short-term processes such as driving rain absorption, summer condensation, and phase changes. Computer

Fig. 13 Drying Wet Sheathing, Winter (Example 10)

Fig. 14 Drying Wet Sheathing, Summer (Example 10)

simulations allow designers to model these conditions over time. It is important, however, to understand the model's application limits.

Applying one of these models requires at least the following information: exterior climate conditions, indoor temperature and humidity, and building assembly materials and sizes. Many programs include a material property database and exterior climate and indoor condition data, allowing simple modeling to be performed without customization. However, using generic material property and weather data may not accurately recreate actual target conditions.

Features of a complete moisture analysis model include

- Transient heat, air, and moisture transport formulation, incorporating the physics of
 - Airflow
 - Water vapor transport by advection (combination of water vapor diffusion and air-driven vapor flow)
 - Liquid transport by capillary action, gravity, and pressure differences
 - Heat flow by apparent conduction, convection, and radiation
 - Heat and moisture storage/capacity of materials
 - Condensation and evaporation processes with linked latent-to-sensible heat transformation
 - Freezing and thawing processes with linked latent-to-sensible heat transformation and based on laws of conservation of heat, mass, and momentum
- Material properties as functions of moisture content, relative humidity, and temperature, such as
 - Density
 - Air properties: permeability and permance

- Thermal properties: specific heat capacity, apparent thermal conductivity, Nusselt numbers, and long-wave emittance (for cavities and air spaces)
- Moisture properties: porosity, sorption curve, water retention curve, vapor permeability, water permeability, or liquid diffusivity
- Boundary conditions (generally on an hourly basis)
 - Outside temperature and relative humidity
 - Incident short-wave solar and long-wave sky radiation (depending on inclination and orientation)
 - Wind speed, orientation, and pressures
 - Wind-driven rain at exterior surfaces (depending on location and aerodynamics)
 - Interior temperature, air pressure excess, relative humidity (or interior moisture sources and ventilation flows), and air stratification
 - Surface conditions
 - Heat transfer film coefficients (combined convection and radiation, separate for convection and radiation)
 - Mass transfer film coefficients
 - Short-wave absorptance of exterior surfaces
 - Long-wave emittance of exterior surfaces
 - Contact conditions between layers and materials. Interfaces may be bridgeable for vapor diffusion, airflow, and gravity or pressure liquid flow only. They may be ideally capillary, introduce additional capillary resistance, or behave as real contact.

Not all these features are required for every analysis, and some applications may need additional information (e.g., moisture flow through unintentional cracks and intentional openings, rain penetration through veneer walls and exterior cladding). To model these phenomena accurately, experiments may be needed to define systems and subsystems in field situation, because only then are all exterior loads and influences captured.

It is important to recognize that simulation results are based on input data. Therefore, the more accurate the input data used, the closer the results will match real-world conditions. Exterior weather conditions, material properties, and interior operating conditions all vary widely, so it is important to get the best data available on materials being modeled. For most users, this is a difficult task. Many product manufacturers do not provide the material property data needed for the simulations. Developing weather data for a particular site is also beyond the expertise of many.

Combined heat, air, and moisture models also have limitations. Users should be aware which transport phenomena and types of boundary conditions are included and which are not. For instance, some models cannot handle air transport or rain wetting of the exterior. Even an apparently simple problem, such as predicting rain leakage through a brick veneer, is beyond existing tools' capabilities. In such cases, simple qualitative schemes and field tests still are the way to proceed. In addition, results also tend to be very sensitive to the choice of indoor and outdoor conditions. Usually, exact conditions are not known.

Outputs from these programs typically include the moisture content of materials as well as relative humidity within the assembly. Interpretation of results is not easy: accurate data on moisture and temperature conditions that materials can tolerate are often not available. Although moisture accumulation may result in indoor air quality issues or material degradation, the effect of moisture accumulation in building assemblies depends on many factors, including choice of construction materials, and varies by building, making interpretation of results even more difficult.

AIR MOVEMENT

Research has demonstrated that air movement is more effective than water vapor diffusion for transporting water vapor within

building envelopes. To minimize moisture penetration by air leakages, the building envelope should be as airtight as possible. The air-flow retarder must also be sufficiently strong and well supported to resist wind loads.

In older residential buildings, air leakage provided sufficient ventilation and rarely led to interstitial condensation. However, in airtight buildings, mechanical ventilation is needed to ensure acceptable air quality and prevent moisture and health problems caused by excessive indoor humidity. Ventilation or drainage must go to the outside of the airtight layer of construction, or it will increase building air leakage. To avoid condensation on the airtight layer, either the layer temperature must be kept above the dew point by locating it on the warm side of the insulation, or the layer permeance must allow vapor transmission.

As described in detail in the section on Leakage Distribution in Chapter 16, air leakage through building envelopes is not confined to doors and windows. Although 6 to 22% of air leakage occurs there, 18 to 50% typically takes place through walls, and 3 to 30% through the ceiling. Leakage often occurs between sill plate and foundation, through interior walls, electrical outlets, plumbing penetrations, and cracks at top and bottom of exterior walls.

Not all cracks and openings can be sealed in existing buildings, nor can absolutely tight construction be achieved in new buildings. Provide as tight an enclosure as possible to reduce leakage, minimize potential condensation within the envelope, and reduce energy loss.

Moisture accumulation in building envelopes can also be minimized by controlling the dominant direction of airflow by operating the building at a small negative or positive air pressure, depending on climate. In cooling climates, pressure should be positive to keep out humid outside air. In heating climates, pressure should be neither strongly negative, which could risk drawing soil gas or combustion products indoors, nor strongly positive, which could risk driving moisture into building envelope cavities.

Equivalent Permeance

Dew-point analysis allows simple estimation of the effect of wall and roof cavity ventilation on heat and vapor transport by using parallel thermal and vapor diffusion resistances (TenWolde and Carll 1992; Trethowen 1979). These parallel resistances account for heat and vapor that bypass exterior material layers with ventilation air from outside. Equivalent thermal and water vapor diffusion resistances are approximated from the following equations:

$$R_{par} = \frac{S}{Q\rho c_p}$$

$$Z_{par} = \frac{S}{Q\rho c}$$

where

R_{par} = parallel equivalent thermal resistance, h·ft²·°F/Btu

Z_{par} = parallel equivalent water vapor diffusion vapor flow resistance, rep

S = surface area of wall or ceiling, ft²

Q = cavity ventilation airflow rate, ft³/h

ρ = density of air, lb/ft³

c = ratio of humidity ratio and vapor pressure, approximately 145 gr/lb·in. Hg

c_p = specific heat, Btu/lb·°F

CHAPTER 28

COMBUSTION AND FUELS

<i>Principles of Combustion</i>	28.1	<i>Solid Fuels</i>	28.8
<i>Fuel Classification</i>	28.5	<i>Combustion Calculations</i>	28.9
<i>Gaseous Fuels</i>	28.5	<i>Efficiency Calculations</i>	28.13
<i>Liquid Fuels</i>	28.6	<i>Combustion Considerations</i>	28.14

PRINCIPLES OF COMBUSTION

COMBUSTION is a chemical reaction in which an oxidant reacts rapidly with a fuel to liberate stored energy as thermal energy, generally in the form of high-temperature gases. Small amounts of electromagnetic energy (light), electric energy (free ions and electrons), and mechanical energy (noise) are also produced during combustion. Except in special applications, the oxidant for combustion is oxygen in the air. The oxidation normally occurs with the fuel in vapor form. One notable exception is oxidation of solid carbon, which occurs directly with the solid phase.

Conventional fuels contain primarily hydrogen and carbon, in elemental form or in various compounds (hydrocarbons). Their complete combustion produces mainly carbon dioxide (CO_2) and water (H_2O); however, small quantities of carbon monoxide (CO) and partially reacted flue gas constituents (gases and liquid or solid aerosols) may form. Most conventional fuels also contain small amounts of sulfur, which is oxidized to sulfur dioxide (SO_2) or sulfur trioxide (SO_3) during combustion, and noncombustible substances such as mineral matter (ash), water, and inert gases. Flue gas is the product of complete or incomplete combustion and includes excess air (if present), but not dilution air (air added to flue gas downstream of the combustion process, such as through the relief opening of a draft hood).

Fuel combustion rate depends on the (1) rate of chemical reaction of combustible fuel constituents with oxygen, (2) rate at which oxygen is supplied to the fuel (mixing of air and fuel), and (3) temperature in the combustion region. The reaction rate is fixed by fuel selection. Increasing the mixing rate or temperature increases the combustion rate.

With **complete combustion** of hydrocarbon fuels, all hydrogen and carbon in the fuel are oxidized to H_2O and CO_2 . Generally, complete combustion requires excess oxygen or excess air beyond the amount theoretically required to oxidize the fuel. Excess air is usually expressed as a percentage of the air required to completely oxidize the fuel.

In **stoichiometric combustion** of a hydrocarbon fuel, fuel is reacted with the exact amount of oxygen required to oxidize all carbon, hydrogen, and sulfur in the fuel to CO_2 , H_2O , and SO_2 . Therefore, exhaust gas from stoichiometric combustion theoretically contains no incompletely oxidized fuel constituents and no unreacted oxygen (i.e., no carbon monoxide and no excess air or oxygen). The percentage of CO_2 contained in products of stoichiometric combustion is the maximum attainable and is referred to as the **stoichiometric CO_2** , **ultimate CO_2** , or **maximum theoretical percentage of CO_2** .

Stoichiometric combustion is seldom realized in practice because of imperfect mixing and finite reaction rates. For economy and safety, most combustion equipment should operate with some excess air. This ensures that fuel is not wasted and that combustion is complete despite variations in fuel properties and supply rates of

fuel and air. The amount of excess air to be supplied to any combustion equipment depends on (1) expected variations in fuel properties and in fuel and air supply rates, (2) equipment application, (3) degree of operator supervision required or available, and (4) control requirements. For maximum efficiency, combustion at low excess air is desirable.

Incomplete combustion occurs when a fuel element is not completely oxidized during combustion. For example, a hydrocarbon may not completely oxidize to carbon dioxide and water, but may form partially oxidized compounds, such as carbon monoxide, aldehydes, and ketones. Conditions that promote incomplete combustion include (1) insufficient air and fuel mixing (causing local fuel-rich and fuel-lean zones), (2) insufficient air supply to the flame (providing less than the required amount of oxygen), (3) insufficient reactant residence time in the flame (preventing completion of combustion reactions), (4) flame impingement on a cold surface (quenching combustion reactions), or (5) flame temperature that is too low (slowing combustion reactions).

Incomplete combustion uses fuel inefficiently, can be hazardous because of carbon monoxide production, and contributes to air pollution.

Combustion Reactions

The reaction of oxygen with combustible elements and compounds in fuels occurs according to fixed chemical principles, including

- Chemical reaction equations
- Law of matter conservation: the mass of each element in the reaction products must equal the mass of that element in the reactants
- Law of combining masses: chemical compounds are formed by elements combining in fixed mass relationships
- Chemical reaction rates

Oxygen for combustion is normally obtained from air, which is a mixture of nitrogen, oxygen, small amounts of water vapor, carbon dioxide, and inert gases. For practical combustion calculations, dry air consists of 20.95% oxygen and 79.05% inert gases (nitrogen, argon, etc.) by volume, or 23.15% oxygen and 76.85% inert gases by mass. For calculation purposes, nitrogen is assumed to pass through the combustion process unchanged (although small quantities of nitrogen oxides form). Table 1 lists oxygen and air requirements for stoichiometric combustion and the products of stoichiometric combustion of some pure combustible materials (or constituents) found in common fuels.

Flammability Limits

Fuel burns in a self-sustained reaction only when the volume percentages of fuel and air in a mixture at standard temperature and pressure are within the upper and lower flammability limits (UFL and LFL), also called explosive limits (UEL and LEL; see Table 2). Both temperature and pressure affect these limits. As mixture temperature increases, the upper limit increases and the lower limit decreases. As the pressure of the mixture decreases below atmospheric

The preparation of this chapter is assigned to TC 6.10, Fuels and Combustion.

Table 1 Combustion Reactions of Common Fuel Constituents

Constituent	Mole- cular Formula	Combustion Reactions	Stoichiometric Oxygen and Air Requirements				Flue Gas from Stoichiometric Combustion with Air

pressure, the upper limit decreases and the lower limit increases. However, as pressure increases above atmospheric, the upper limit increases and the lower limit is relatively constant.

Ignition Temperature

Ignition temperature is the lowest temperature at which heat is generated by combustion faster than it is lost to the surroundings and combustion becomes self-propagating. (See Table 2). The fuel/air mixture will not burn freely and continuously below the ignition temperature unless heat is supplied, but chemical reaction between the fuel and air may occur. Ignition temperature is affected by a large number of factors.

The ignition temperature and flammability limits of a fuel/air mixture, together, are a measure of the potential for ignition (*Gas Engineers Handbook* 1965).

Combustion Modes

Combustion reactions occur in either continuous or pulse flame modes. **Continuous combustion** burns fuel in a sustained manner

as long as fuel and air are continuously fed to the combustion zone and the fuel/air mixture is within the flammability limits. Continuous combustion is more common than pulse combustion and is used in most fuel-burning equipment.

Pulse combustion is an acoustically resonant process that burns various fuels in small, discrete fuel/air mixture volumes in a very rapid series of combustions.

The introduction of fuel and air into the pulse combustor is controlled by mechanical or aerodynamic valves. Typical combustors consist of one or more valves, a combustion chamber, an exit pipe, and a control system (ignition means, fuel-metering devices, etc.). Typically, combustors for warm-air furnaces, hot-water boilers, and commercial cooking equipment use mechanical valves. Aerodynamic valves are usually used in higher-pressure applications, such as thrust engines. Separate valves for air and fuel, a single valve for premixed air and fuel, or multiple valves of either type can be used. Premix valve systems may require a flame trap at the combustion chamber entrance to prevent flashback.

In a mechanically valved pulse combustor, air and fuel are forced into the combustion chamber through the valves under pressures less than 0.5 psi. An ignition source, such as a spark, ignites the fuel/air mixture, causing a positive pressure build-up in the combustion chamber. The positive pressure causes the valves to close, leaving only the exit pipe of the combustion chamber as a pressure relief opening. Combustion chamber and exit pipe geometry determine the resonant frequency of the combustor.

The pressure wave from initial combustion travels down the exit pipe at sonic velocity. As this wave exits the combustion chamber, most of the flue gases present in the chamber are carried with it into the exit pipe. Flue gases remaining in the combustion chamber begin to cool immediately. Contraction of cooling gases and momentum of gases in the exit pipe create a vacuum inside the chamber that opens the valves and allows more fuel and air into the chamber. While the fresh charge of fuel/air enters the chamber, the pressure wave reaches the end of the exit pipe and is partially reflected from the open end of the pipe. The fresh fuel/air charge is ignited by residual combustion and/or heat. The resulting combustion starts another cycle.

Typical pulse combustors operate at 30 to 100 cycles per second and emit resonant sound, which must be considered in their application. The pulses produce high convective heat transfer rates.

Heating Value

Combustion produces thermal energy (heat). The quantity of heat generated by complete combustion of a unit of specific fuel is constant and is called the **heating value, heat of combustion, or caloric value** of that fuel. A fuel's heating value can be determined by measuring the heat evolved during combustion of a known quantity of the fuel in a calorimeter, or it can be estimated from quantitative chemical analysis of the fuel and the heating values of the various chemical elements in the fuel. For information on calculating heating values, see the sections on Characteristics of Fuel Oils and Characteristics of Coal.

Higher heating value (HHV), gross heating value, or total heating value includes the latent heat of vaporization and is determined when water vapor in the fuel combustion products is cooled and condensed at standard temperature and pressure. Conversely, **lower heating value (LHV) or net heating value** does *not* include latent heat of vaporization. In the United States, when the heating value of a fuel is specified without designating higher or lower, it generally means the higher heating value. (LHV is mainly used for internal combustion engine fuels.)

Heating values are usually expressed in Btu/ft³ for gaseous fuels, Btu/gal for liquid fuels, and Btu/lb for solid fuels. Heating values are always given in relation to standard temperature and pressure, usually 60, 68, or 77°F and 14.735 psia (30.00 in. Hg), depending on the particular industry practice. Heating values in the United States and Canada are based on standard conditions of 60°F (520°R) and 14.735 psia (30.00 in. Hg), dry. Heating values of several substances in common fuels are listed in Table 3.

With incomplete combustion, not all fuel is completely oxidized, and the heat produced is less than the heating value of the fuel. Therefore, the quantity of heat produced per unit of fuel consumed decreases (lower combustion efficiency).

Not all heat produced during combustion can be used effectively. The greatest heat loss is the thermal energy of the increased temperature of hot exhaust gases above the temperature of incoming air and fuel. Other heat losses include radiation and convection heat transfer from the outer walls of combustion equipment to the environment.

Altitude Compensation

Air at altitudes above sea level is less dense and has less mass of oxygen per unit volume. The volume concentration of oxygen, however, remains the same as sea level. Therefore, combustion at

Table 3 Heating Values of Substances Occurring in Common Fuels

Substance	Molecular Formula	Higher Heating Values, ^a Btu/ft ³	Higher Heating Values, ^a Btu/lb	Lower Heating Values, ^a Btu/lb	Specific Volume, ^b ft ³ /lb

^c*North American Combustion Handbook* (1986).

altitudes above sea level has less available oxygen to burn with the fuel unless compensation is made for the altitude. Combustion occurs, but the amount of excess air is reduced. If excess air is reduced enough by an increase in altitude, combustion is incomplete or ceases.

When gas-fired appliances operate at altitudes substantially above sea level, three notable effects occur (see Chapter 30 of the 2008 *ASHRAE Handbook—HVAC Systems and Equipment*):

- Oxygen available for combustion is reduced in proportion to the atmospheric pressure reduction.
- With gaseous fuels, the heat of combustion per unit volume of fuel gas (gas heat content) is reduced because of reduced fuel gas density in proportion to the atmospheric pressure reduction.
- Reduced air density affects the performance and operating temperature of heat exchangers and appliance cooling mechanisms.

Altitude compensation matches fuel and air supply rates to attain complete combustion without too much excess air or too much fuel. This can be done at increased altitude by increasing the air supply rate to the combustion zone with a combustion air blower, or by decreasing the fuel supply rate to the combustion zone by decreasing the fuel input (derating).

Power burners use combustion air blowers and can increase the air supply rate to compensate for altitude. The combustion zone can be pressurized to attain the same air density in the combustion chamber as that at sea level.

Derating can be used as an alternative to power combustion. U.S. fuel gas codes generally do not require derating of nonpower burners at altitudes up to 2000 ft. At altitudes above 2000 ft, many fuel gas codes require that burners be derated 4% for each 1000 ft above sea level (NFPA/AGA *National Fuel Gas Code*). Chimney or vent operation also must be considered at high altitudes (see Chapter 34 of the 2008 *ASHRAE Handbook—HVAC Systems and Equipment*).

ASHRAE research project RP-1182 (Fleck et al. 2007) concluded that the tested fan-assisted furnaces experienced a natural derate of 1.8% in gas input rate per 1000 ft increase in altitude above sea level. Such a gas input derate for altitude may provide safe combustion operation (less than 400 parts per million of carbon monoxide concentration in air-free flue gas) for fan-assisted residential gas furnaces up to 6700 ft altitude. These tests suggest

Note: Natural derating applies for fixed injector (orifice) size and pressure.

Fig. 1 Altitude Effects on Gas Combustion Appliances

that some furnaces as currently designed and constructed can be installed and operated safely and acceptably at some high altitudes with no modifications to the sea-level gas orifices, gas manifold pressure, etc., as are currently needed for the 4% per 1000 ft altitude derating requirements. However, the research project did not sufficiently evaluate furnace operation for high-altitude effects on heat exchanger and other component temperatures, endurance, and performance, which should be considered by manufacturers and standards developers. New research is under way to evaluate the effects of high-altitude on gas-fired water heaters and boilers.

In addition to reducing the gas heat content of fuel gas, reduced fuel gas density also causes increased gas velocity through flow metering orifices. The net effect is for gas input rate to decrease naturally with increases in altitude, but at less than the rate at which atmospheric oxygen decreases. This effect is one reason that derating is required when appliances are operated at altitudes significantly above sea level. Early research with draft hood-equipped appliances established that appliance input rates should be reduced at the rate of 4% per 1000 ft above sea level, for altitudes higher than 2000 ft above sea level (Figure 1).

Experience with recently developed appliances having fan-assisted combustion systems demonstrated that the 4% rule may not apply in all cases. It is therefore important to consult the manufacturer's listed appliance installation instructions, which are based on how the combustion system operates, and on other factors, such as impaired heat transfer. Note also that manufacturers of appliances having tracking-type burner systems may not require derating at altitudes above 2000 ft. In those systems, fuel gas and combustion airflow are affected in the same proportion by density reduction.

It is important for appliance specifiers to be aware that the heating capacity of appliances is substantially reduced at altitudes significantly above sea level. To ensure adequate delivery of heat, derating of heating capacity must also be considered and quantified.

By definition, fuel gas HHV value remains constant for all altitudes because (in North America) it is based on standard conditions of 14.735 psia (30.00 in. Hg), dry, and 60°F (520°R). Some fuel gas suppliers at high altitudes (e.g., at Denver, Colorado, at 5000 ft) may report fuel gas heat content at local barometric pressure instead of standard pressure. This can be calculated using the following equation:

$$HC = HHV \times \frac{B}{P_s} \quad (1)$$

where

HC = local gas heat content at local barometric pressure and standard temperature conditions, Btu/ft³

HHV = gas higher heating value at standard temperature and pressure of 520°R and 14.735 psia, respectively, Btu/ft³

B = local barometric pressure, psia (not corrected to sea level: do not use barometric pressure as reported by weather forecasters, because it is corrected to sea level)

P_s = standard pressure = 14.735 psia

For example, at 5000 ft, the barometric pressure is 12.23 psia. If the HHV of a fuel gas sample is 1000 Btu/ft³ (at standard temperature and pressure), local gas heat content is 830 Btu/ft³ at 12.23 psia barometric pressure 5000 ft above sea level.

$$HC = 1000 \text{ Btu/ft}^3 \times 12.23 \text{ psia}/14.735 \text{ psia} = 830 \text{ Btu/ft}^3$$

Therefore, local gas heat content of a sample of fuel gas can be expressed as 830 Btu/ft³ at local barometric pressure of 12.23 psia and standard temperature, or as 1000 Btu/ft³ (HHV). Both gas heat contents are correct, but the application engineer must understand the difference to use each one correctly. As described earlier, local heat content HC can be used to determine appliance input rate.

When gas heat value (either HHV or HC) is used to determine gas input rate, the gas pressure and temperature in the meter must also be considered. Add the gage pressure of gas in the meter to the local barometric pressure to calculate the heat content of the gas at the pressure in the meter. Gas temperature in the meter also affects the heat content of the gas in the meter. Gas heat value is directly proportional to gas pressure and inversely proportional to its absolute temperature in accordance with the perfect gas laws, as illustrated in the following example calculations for gas input rate with either the HHV or local heat content method.

Example 1. Calculate the gas input rate for 1000 Btu/ft³ HHV fuel gas, 100 ft³/h volumetric flow rate of 75°F fuel gas at 12.23 psia barometer pressure (5000 ft altitude) with 7 in. of water fuel gas pressure in the gas meter.

HHV Method:

$$Q = HHV \times VFR_s$$

where

Q = fuel gas input rate, Btu/h

HHV = fuel gas higher heating value at standard temperature and pressure, Btu/ft³

VFR_s = fuel gas volumetric flow rate adjusted to standard temperature and pressure, ft³/h
 $= VFR(T_s \times P)/(T \times P_s)$

VFR = fuel gas volumetric flow rate at local temperature and pressure conditions, ft³/h

T_s = standard temperature, 520°R (60°F + 460°R)

P = gas meter absolute pressure, psia (local barometer pressure + gas pressure in meter relative to barometric pressure)
 $= 12.23 \text{ psia} + (7 \text{ in. of water} \times 0.03613 \text{ psi/in. of water})$
 $= 12.48291 \text{ psia}$ gas meter absolute pressure

T = absolute temperature of fuel gas, °R (fuel gas temperature in °F + 460°R)

P_s = standard pressure, 14.735 psia

Substituting given values into the equation for VFR_s gives

$$VFR_s = \frac{100 \text{ ft}^3/\text{h} \times 520^\circ\text{R} \times 12.48291 \text{ psia}}{(75^\circ\text{F} + 460^\circ\text{R})14.735 \text{ psia}} = 82.341 \text{ ft}^3/\text{h}$$

Then,

$$Q = 1000 \text{ Btu/ft}^3 \times 82.341 \text{ ft}^3/\text{h} = 82,341 \text{ Btu/h}$$

Local Gas Heat Content Method: The local gas heat content is simply the HHV adjusted to local gas meter pressure and temperature conditions. The gas input rate is simply the observed volumetric gas flow rate times the local gas heat content.

$$Q = HC \times VFR$$

where

Q = fuel gas input rate, Btu/h

HC = fuel gas heat content at local gas meter pressure and temperature conditions, Btu/ft³

VFR = fuel gas volumetric flow rate, referenced to local gas meter

pressure and temperature conditions, ft³/h

$$HC = HHV(T_s \times P)/(T \times P_s)$$

T_s = standard temperature, 520°R (60°F + 460°R)

P = gas meter absolute pressure, psia (local barometer pressure + gas pressure in gas meter relative to barometric pressure)

P_s = standard pressure = 14.735 psia

P_l = local barometric pressure = 12.230 psia

T = absolute temperature of fuel gas, 535°R (75°F fuel gas temperature + 460°R)

Substituting given values into the equation for HC gives

$$HC = \frac{1000 \times 520[12.23 + (7.0 \times 0.03613)]}{535 \times 14.735} = 823.41 \text{ Btu/ft}^3$$

Then,

$$Q = 823.41 \text{ Btu/ft}^3 \times 100 \text{ ft}^3/\text{h} = 82,341 \text{ Btu/h}$$

The gas input rate is exactly the same for both calculation methods.

FUEL CLASSIFICATION

Generally, hydrocarbon fuels are classified according to physical state (gas, liquid, or solid). Different types of combustion equipment are usually needed to burn fuels in the different physical states. Gaseous fuels can be burned in premix or diffusion burners. Liquid fuel burners must include a means for atomizing or vaporizing fuel and must provide adequate mixing of fuel and air. Solid fuel combustion equipment must (1) heat fuel to vaporize sufficient volatiles to initiate and sustain combustion, (2) provide residence time to complete combustion, and (3) provide space for ash containment.

Principal fuel applications include space heating and cooling of residential, commercial, industrial, and institutional buildings; service water heating; steam generation; and refrigeration. Major fuels for these applications are natural and liquefied petroleum gases (LPG), fuel oils, diesel and gas turbine fuels (for on-site energy applications), and coal. Fuels of limited use, such as manufactured gases, kerosene, liquid fuels derived from biological materials (wood, vegetable oils, and animal fat products), briquettes, wood, and coke, are not discussed here.

Fuel choice is based on one or more of the following:

Fuel factors

- Availability, including dependability of supply
- Convenience of use and storage
- Economy
- Cleanliness, including amount of contamination in unburned fuel [affecting (1) usability in fuel-burning equipment and (2) environmental impact]

Combustion equipment factors

- Operating requirements
- Cost
- Service requirements
- Ease of control

GASEOUS FUELS

Although various gaseous fuels have been used as energy sources in the past, heating and cooling applications are presently limited to natural gas and liquefied petroleum gases.

Types and Properties

Natural gas is a nearly odorless, colorless gas that accumulates in the upper parts of oil and gas reservoirs. Raw natural gas is a mixture of methane (55 to 98%), higher hydrocarbons (primarily ethane), and noncombustible gases. Some constituents, principally water vapor, hydrogen sulfide, helium, liquefied petroleum gases, and gasoline, are removed before distribution.

Natural gas used as fuel typically contains methane, CH₄ (70 to 96%); ethane, C₂H₆ (1 to 14%); propane, C₃H₈ (0 to 4%); butane, C₄H₁₀ (0 to 2%); pentane, C₅H₁₂ (0 to 0.5%); hexane, C₆H₁₄ (0 to 2%); carbon dioxide, CO₂ (0 to 2%); oxygen, O₂ (0 to 1.2%); and nitrogen, N₂ (0.4 to 17%).

The composition of natural gas depends on its geographical source. Because the gas is drawn from various sources, the composition of gas distributed in a given location can vary slightly, but a fairly constant heating value is usually maintained for control and safety. Local gas utilities are the best sources of current gas composition data for a particular area.

Heating values of natural gases vary from 900 to 1200 Btu/ft³; the usual range is 1000 to 1050 Btu/ft³ at sea level. The heating value for a particular gas can be calculated from the composition data and values in Table 3.

For safety purposes, odorants (e.g., mercaptans) are added to natural gas and LPG to give them noticeable odors.

Liquefied petroleum gases (LPG) consist primarily of propane and butane, and are usually obtained as a byproduct of oil refinery operations or by stripping liquefied petroleum gases from the natural gas stream. Propane and butane are gaseous under usual atmospheric conditions, but can be liquefied under moderate pressures at normal temperatures.

Commercial propane consists primarily of propane but generally contains about 5 to 10% propylene. Its heating value is about 21,560 Btu/lb, about 2500 Btu/ft³ of gas, or about 91,000 Btu/gal of liquid propane. At atmospheric pressure, commercial propane has a boiling point of about -44°F. The low boiling point of propane allows it to be used during winter in the northern United States and southern Canada. Tank heaters and vaporizers allow its use also in colder climates and where high fuel flow rates are required. The American Society for Testing and Materials (ASTM) *Standard D1835* and Gas Processors Association (GPA) *Standard 2140*, which are similar, provide formulating specifications for required properties of liquefied petroleum gases at the time of delivery. Propane is shipped in cargo tank vehicles, rail cars, and barges. It is stored at consumer sites in tanks that comply with requirements of the ASME *Boiler and Pressure Vessel Code* or transportable cylinders that comply with requirements of the U.S. Department of Transportation.

HD-5 propane is a special LPG product for use in internal combustion engines under moderate to high severity. Its specifications are included in ASTM *Standard D1835* and GPA *Standard 2140*.

Propane/air mixtures are used in place of natural gas in small communities and by natural gas companies to supplement normal supplies at peak loads. Table 4 lists heating values and specific gravities for various fuel/air ratios.

Commercial butane consists primarily of butane but may contain up to 5% butylene. It has a heating value of about 21,180 Btu/lb, about 3200 Btu/ft³ of gas, or about 102,000 Btu/gal of liquid butane. At atmospheric pressure, commercial butane has a relatively high boiling point of about 32°F. Therefore, butane cannot be used in cold weather unless the gas temperature is maintained above 32°F or the partial pressure is decreased by dilution with a gas having a lower boiling point. Butane is usually available in bottles, tank trucks, or tank cars, but not in cylinders.

Butane/air mixtures are used in place of natural gas in small communities and by natural gas companies to supplement normal supplies at peak loads. Table 4 lists heating values and specific gravities for various fuel/air ratios.

Commercial propane/butane mixtures with various ratios of propane and butane are available. Their properties generally fall between those of the unmixed fuels.

Manufactured gases are combustible gases produced from coal, coke, oil, liquefied petroleum gases, or natural gas. For more detailed information, see the *Gas Engineers Handbook* (1965). These

^bValues used for calculation: 3261 Btu/ft³; 2.01 specific gravity.

fuels are used primarily for industrial in-plant operations or as specialty fuels (e.g., acetylene for welding).

LIQUID FUELS

Significant liquid fuels include various fuel oils for firing combustion equipment and engine fuels for on-site energy systems. Liquid fuels, with few exceptions, are mixtures of hydrocarbons derived by refining crude petroleum. In addition to hydrocarbons, crude petroleum usually contains small quantities of sulfur, oxygen, nitrogen, vanadium, other trace metals, and impurities such as water and sediment. Refining produces a variety of fuels and other products. Nearly all lighter hydrocarbons are refined into fuels (e.g., liquefied petroleum gases, gasoline, kerosene, jet fuels, diesel fuels, and light heating oils). Heavy hydrocarbons are refined into residual fuel oils and other products (e.g., lubricating oils, waxes, petroleum coke, and asphalt).

Crude petroleum from different oil fields vary in hydrocarbon molecular structure. Crude is paraffin-base (principally chain-structured paraffin hydrocarbons), naphthene- or asphaltic-base (containing relatively large quantities of saturated ring-structural naphthenes), aromatic-base (containing relatively large quantities of unsaturated, ring-structural aromatics, including multi-ring compounds such as asphaltenes), or mixed- or intermediate-base (between paraffin- and naphthene-base crudes). Except for heavy fuel oils, the crude type has little significant effect on resultant distillate products and combustion applications.

Types of Fuel Oils

Fuel oils for heating are broadly classified as **distillate fuel oils** (lighter oils) or **residual fuel oils** (heavier oils). ASTM *Standard D396* has specifications for fuel oil properties that subdivide the oils into various grades. Grades No. 1 and 2 are distillates; grades 4, 5 (Light), 5 (Heavy), and 6 are residual. Specifications for the grades are based on required characteristics of fuel oils for use in different types of burners.

Grade No. 1 is a light distillate intended for vaporizing-type burners. High volatility is essential to continued evaporation with minimum residue. This fuel is also used in extremely cold climates for residential heating using pressure-atomizing burners.

Grade No. 2 is heavier than No. 1 and is used primarily with pressure-atomizing (gun) burners that spray oil into a combustion chamber. Vapor from the atomized oil mixes with air and burns. This grade is used in most domestic burners and many medium-capacity commercial/industrial burners. A dewaxed No. 2 oil with a pour

point of -58°F is supplied only to areas where regular No. 2 oil would jell. Grade No. 2—low sulfur is a relatively new category that has a sulfur content of 0.05%. Lower fuel sulfur content reduces fouling rates of boiler heat exchangers (Butcher et al. 1997).

Grade No. 4 is an intermediate fuel that is considered either a heavy distillate or a light residual. Intended for burners that atomize oils of higher viscosity than domestic burners can handle, its permissible viscosity range allows it to be pumped and atomized at relatively low storage temperatures.

Grade No. 5 (Light) is a residual fuel of intermediate viscosity for burners that handle fuel more viscous than No. 4 without preheating. Preheating may be necessary in some equipment for burning and, in colder climates, for handling.

Grade No. 5 (Heavy) is a residual fuel more viscous than No. 5 (Light), but intended for similar purposes. Preheating is usually necessary for burning and, in colder climates, for handling.

Grade No. 6, sometimes referred to as Bunker C, is a high-viscosity oil used mostly in commercial and industrial heating. It requires preheating in the storage tank to allow pumping, and additional preheating at the burner to allow atomizing.

Low-sulfur residual oils are marketed in many areas to allow users to meet sulfur dioxide emission regulations. These fuel oils are produced (1) by refinery processes that remove sulfur from the oil (hydrodesulfurization), (2) by blending high-sulfur residual oils with low-sulfur distillate oils, or (3) by a combination of these methods. These oils have significantly different characteristics from regular residual oils. For example, the viscosity/temperature relationship can be such that low-sulfur fuel oils have viscosities of No. 6 fuel oils when cold, and of No. 4 when heated. Therefore, normal guidelines for fuel handling and burning can be altered when using these fuels.

Another liquid fuel of increasing interest is biodiesel. It is made from biological sources (e.g., vegetable oils, used cooking oils, tallow). ASTM's recent *Standard D6751* addresses biodiesel; requirements are largely similar to those for petroleum diesel (cetane number, flash point, etc.; see the section on Types and Properties of Liquid Fuels for Engines). In practice, biodiesel is almost always blended, most often with ASTM heating oils when used for stationary heating applications, because of cost and cold-flow properties of 100% biodiesel. However, the benefits of a renewable fuel that has very low net carbon dioxide emission in its life cycle, reduced particulate and sulfur emissions, and lower NO_x emissions in many heating applications balance the need for mixing.

Fuel oil grade selection for a particular application is usually based on availability and economic factors, including fuel cost, clean air requirements, preheating and handling costs, and equipment cost. Installations with low firing rates and low annual fuel consumption cannot justify the cost of preheating and other methods that use residual fuel oils. Large installations with high annual fuel consumption cannot justify the premium cost of distillate fuel oils.

Characteristics of Fuel Oils

Characteristics that determine grade classification and suitability for given applications are (1) viscosity, (2) flash point, (3) pour point, (4) water and sediment content, (5) carbon residue, (6) ash, (7) distillation qualities or distillation temperature ranges, (8) specific gravity, (9) sulfur content, (10) heating value, (11) carbon/hydrogen content, (12) aromatic content, and (13) asphaltene content. Not all of these are included in ASTM *Standard D396*.

Viscosity is an oil's resistance to flow. It is significant because it indicates the ease with which oil flows or can be pumped and the ease of atomization. Differences in fuel oil viscosities are caused by variations in the concentrations of fuel oil constituents and different refining methods. Approximate viscosities of fuel oils are shown in Figure 2.

* 1 Saybolt Second (SSU, or SUS) = time required for 60 mL to gravity-flow through Saybolt universal viscometer. (Furul = Fuel and Road Oils)

Fig. 2 Approximate Viscosity of Fuel Oils

Flash point is the lowest temperature to which an oil must be heated for its vapors to ignite in a flame. Minimum permissible flash point is usually prescribed by state and municipal laws.

Pour point is the lowest temperature at which a fuel can be stored and handled. Fuels with higher pour points can be used when heated storage and piping facilities are provided.

Water and sediment content should be low to prevent fouling the facilities. Sediment accumulates on filter screens and burner parts. Water in distillate fuels can cause tanks to corrode and emulsions to form in residual oil.

Carbon residue is obtained by a test in which the oil sample is destructively distilled in the absence of air. When commercial fuels are used in proper burners, this residue has almost no relationship to soot deposits, except indirectly when deposits are formed by vaporizing burners.

Ash is the noncombustible material in an oil. An excessive amount indicates the presence of materials that cause high wear on burner pumps.

The **distillation** test shows the volatility and ease of vaporization of a fuel.

Specific gravity is the ratio of the density of a fuel oil to the density of water at a specific temperature. Specific gravities cover a range in each grade, with some overlap between distillate and residual grades. **API gravity** (developed by the American Petroleum Institute) is a parameter widely used in place of specific gravity. It is obtained by the following formula:

$$\text{Degrees API} = \frac{141.5}{\text{Sp Gr at } 60/60^\circ\text{F}} - 131.5 \quad (2)$$

where Sp Gr at 60/60°F is the ratio of the mass of a given volume of oil at 60°F to the mass of the same volume of water at 60°F. The API gravity of water at 60°F is 10.0.

Air pollution considerations are important in determining the allowable **sulfur content** of fuel oils. Sulfur content is frequently limited by legislation aimed at reducing sulfur oxide emissions from combustion equipment; usual maximum allowable sulfur content levels are 1.0, 0.5, or 0.3%. Table 5 lists sulfur levels of some marketed fuel oils. New research (Lee et al. 2002a, 2002b) suggests that

Table 5 Sulfur Content of Marketed Fuel Oils

Grade of Oil	No. 1	No. 2	No. 4	No. 5 (Light)	No. 5 (Heavy)	No. 6

Data for No. 4, 5, and 6 oil derived from Shelton (1974).

Table 6 Typical API Gravity, Density, and Higher Heating Value of Standard Grades of Fuel Oil

Grade No.	API Gravity	Density, lb/gal	Higher Heating Value, Btu/gal
1	38 to 45	6.950 to 6.675	137,000 to 132,900
2	30 to 38	7.296 to 6.960	141,800 to 137,000
4	20 to 28	7.787 to 7.396	148,100 to 143,100
5L	17 to 22	7.940 to 7.686	150,000 to 146,800
5H	14 to 18	8.080 to 7.890	152,000 to 149,400
6	8 to 15	8.448 to 8.053	155,900 to 151,300

fuel sulfur content affects the sulfate content of particulate emissions, which are reported to be associated with adverse health effects.

Sulfur in fuel oils is also undesirable because sulfur compounds in flue gas are corrosive. Although low-temperature corrosion can be minimized by maintaining the stack at temperatures above the dew point of the flue gas, this limits the overall thermal efficiency of combustion equipment. The presence of sulfur oxides in the flue gas raises the dew point temperature (see the section on Combustion Calculations).

For certain industrial applications (e.g., direct-fired metallurgy, where work is performed in the combustion zone), fuel sulfur content must be limited because of adverse effects on product quality. Sulfur contents of typical fuel oils are listed in Table 5.

Heating value is an important property, although ASTM *Standard* D396 does not list it as one of the criteria for fuel oil classification. Heating value can generally be correlated with the API gravity. Table 6 shows the relationship between heating value, API gravity, and density for several oil grades. In the absence of more specific data, heating values can be calculated as shown in the *North American Combustion Handbook* (1978):

$$\text{Higher heating value, Btu/lb} = 22,320 - 3780(\text{Specific gravity})^2 \quad (3)$$

Distillate fuel oils (grades 1 and 2) have a **carbon/hydrogen content** of 84 to 86% carbon, with the remainder predominantly hydrogen. Heavier residual fuel oils (grades 4, 5, and 6) may contain up to 88% carbon and as little as 11% hydrogen. An approximate relationship for determining the hydrogen content of fuel oils is

$$\text{Hydrogen, \%} = 26 - (15 \times \text{Specific gravity}) \quad (4)$$

ASTM *Standard* D396 is more a classification than a specification, distinguishing between six generally nonoverlapping grades, one of which characterizes any commercial fuel oil. Quality is not defined, as a refiner might control it; for example, the standard lists the distillation temperature 90% point for grade No. 2 as having a maximum of 640°F, whereas commercial practice rarely exceeds 600°F.

Types and Properties of Liquid Fuels for Engines

The primary stationary engine fuels are diesel and gas turbine oils, natural gases, and LPGs. Other fuels include sewage gas, manufactured gas, and other commercial gas mixtures. Gasoline and the JP series of gas turbine fuels are rarely used for stationary engines.

Only properties of diesel and gas turbine fuel oils are covered here; properties of natural and liquefied petroleum gases are found in the section on Gaseous Fuels. For properties of gasolines and JP turbine fuel, consult texts on internal combustion engines and gas turbines. Properties of currently marketed gasolines can be found in ASTM *Standard* D4814.

Properties of the three **grades of diesel fuel oils** (1-D, 2-D, and 4-D) are listed in ASTM *Standard* D975.

Grade No. 1-D includes the class of volatile fuel oils from kerosene to intermediate distillates. They are used in high-speed engines with frequent and relatively wide variations in loads and speeds and where abnormally low fuel temperatures are encountered.

Grade No. 2-D includes the class of lower-volatility distillate gas oils. They are used in high-speed engines with relatively high loads and uniform speeds, or in engines not requiring fuels with the higher volatility or other properties specified for grade No. 1-D.

Grade No. 4-D covers the more viscous distillates and blends of these distillates with residual fuel oils. They are used in low- and medium-speed engines involving sustained loads at essentially constant speed.

Property specifications and test methods for grade No. 1-D, 2-D, and 4-D diesel fuel oils are essentially identical to specifications of grade No. 1, 2, and 4 fuel oils, respectively. However, diesel fuel oils have an additional specification for **cetane number**, which measures ignition quality and influences combustion roughness. Cetane number requirements depend on engine design, size, speed and load variations, and starting and atmospheric conditions. An increase in cetane number over values actually required does not improve engine performance. Thus, the cetane number should be as low as possible to ensure maximum fuel availability. ASTM *Standard* D975 provides several methods for estimating cetane number from other fuel oil properties.

ASTM *Standard* D2880 for gas turbine fuel oils relates gas turbine fuel oil grades to fuel and diesel fuel oil grades. Test methods for determining properties of gas turbine fuel oils are essentially identical to those for fuel oils. However, gas turbine specifications limit quantities of some trace elements that may be present, to prevent excessive corrosion in gas turbine engines. For a detailed discussion of fuels for gas turbines and combustion in gas turbines, see Chapters 5 and 9, respectively, in Hazard (1971).

SOLID FUELS

Solid fuels include coal, coke, wood, and waste products of industrial and agricultural operations. Of these, only coal is widely used for heating and cooling applications.

Coal's complex composition makes classification difficult. Chemically, coal consists of carbon, hydrogen, oxygen, nitrogen, sulfur, and a mineral residue, ash. Chemical analysis provides some indication of quality, but does not define its burning characteristics sufficiently. Coal users are principally interested in the available energy per unit mass of coal and the amount of ash and dust produced, but are also interested in burning characteristics and handling and storing properties. A description of coal qualities and characteristics from the U.S. Bureau of Mines as well as other information can be obtained from the U.S. Geological Survey at <http://energy.er.usgs.gov/products/databases/USCoal/index.htm> and the Energy Information Administration at www.eia.doe.gov/fuelcoal.html.

Types of Coals

Commonly accepted definitions for classifying coals are listed in Table 7. This classification is arbitrary because there are no distinct demarcation lines between coal types.

Anthracite is a clean, dense, hard coal that creates little dust in handling. It is comparatively hard to ignite, but burns freely once started. It is noncaking and burns uniformly and smokelessly with a short flame.

Semianthracite has a higher volatile content than anthracite. It is not as hard and ignites more easily. Otherwise, its properties are similar to those of anthracite.

Table 7 Classification of Coals by Rank^a

Class	Group	Limits of Fixed Carbon or Energy Content, Mineral-Matter-Free Basis	Requisite Physical Properties
I Anthracite	1. Metaanthracite	Dry FC, 98% or more (Dry VM, 2% or less)	Nonagglomerating
	2. Anthracite	Dry FC, 92% or more, and less than 98% (Dry VM, 8% or less, and more than 2%)	
	3. Semianthracite	Dry FC, 86% or more, and less than 92% (Dry VM, 14% or less, and more than 8%)	
II Bituminous ^d	1. Low-volatile bituminous coal	Dry FC, 78% or more, and less than 86% (Dry VM, 22% or less, and more than 14%)	Either agglomerating ^b or nonweathering ^f
	2. Medium-volatile bituminous coal	Dry FC, 69% or more, and less than 78% (Dry VM, 31% or less, and more than 22%)	
	3. High-volatile Type A bituminous coal	Dry FC, less than 69% (Dry VM, more than 31%), and moist, ^c about 14,000 Btu/lb ^e or more	
	4. High-volatile Type B bituminous coal	Moist, ^c about 13,000 Btu/lb or more, and less than 14,000 Btu/lb ^e	
	5. High-volatile Type C bituminous coal	Moist, ^c about 11,000 Btu/lb or more, and less than 13,000 Btu/lb ^e	
III Subbituminous	1. Subbituminous Type A coal	Moist, ^c about 11,000 Btu/lb or more, and less than 13,000 Btu/lb ^e	Both weathering and nonagglomerating ^b
	2. Subbituminous Type B coal	Moist, ^c about 9,500 Btu/lb or more, and less than 11,000 Btu/lb ^e	
	3. Subbituminous Type C coal	Moist, ^c about 8,300 Btu/lb or more, and less than 9,500 Btu/lb ^e	
IV Lignitic	1. Lignite	Moist, ^c less than 8,300 Btu/lb	Consolidated
	2. Brown coal	Moist, ^c less than 8,300 Btu/lb	Unconsolidated

Source: Adapted from ASTM *Standard* D388.

FC = fixed carbon; VM = volatile matter; MMF = mineral-matter-free

^aClassification does not include a few coals of unusual physical and chemical properties that come within limits of fixed carbon or energy content of high-volatile bituminous and subbituminous ranks. All these coals either contain less than 48% dry, MMF FC, or have more than about 15,500 Btu/lb, which is moist, MMF.

^bIf agglomerating, classify in group 1 of class II.

^cMoist refers to coal containing natural bed moisture but without visible water on coal surface.

^dThere may be noncaking varieties in each group of class II.

^eCoals with 69% or more fixed carbon on dry, MMF basis are classified according to FC, regardless of energy content.

^fThere are three varieties of coal in group 5: variety 1, agglomerating and nonweathering; variety 2, agglomerating and weathering; and variety 3, nonagglomerating and nonweathering.

Bituminous coal includes many types of coal with distinctly different compositions, properties, and burning characteristics. Coals range from high-grade bituminous, such as those found in the eastern United States, to low-rank coals, such as those found in the western United States. Caking properties range from coals that melt or become fully plastic, to those from which volatiles and tars are distilled without changing form (classed as noncaking or free-burning). Most bituminous coals are strong and nonfriable enough to allow screened sizes to be delivered free of fines. Generally, they ignite easily and burn freely. Flame length is long and varies with different coals. If improperly fired, much smoke and soot are possible, especially at low burning rates.

Semibituminous coal is soft and friable, and handling creates fines and dust. It ignites slowly and burns with a medium-length flame. Its caking properties increase as volatile matter increases, but the coke formed is weak. With only half the volatile matter content of bituminous coals, burning produces less smoke; hence, it is sometimes called smokeless coal.

Subbituminous coal, such as that found in the western United States, is high in moisture when mined and tends to break up as it dries or is exposed to the weather; it is likely to ignite spontaneously when piled or stored. It ignites easily and quickly, has a medium-length flame, and is noncaking and free-burning. The lumps tend to break into small pieces if poked. Very little smoke and soot are formed.

Lignite is woody in structure, very high in moisture when mined, of low heating value, and clean to handle. It has a greater tendency than subbituminous coals to disintegrate as it dries and is also more likely to ignite spontaneously. Because of its high moisture, freshly mined lignite ignites slowly and is noncaking. The char left after moisture and volatile matter are driven off burns very easily, like charcoal. The lumps tend to break up in the fuel bed and pieces of char that fall into the ash pit continue to burn. Very little smoke or soot forms.

Characteristics of Coal

The characteristics of coals that determine classification and suitability for given applications are the proportions of (1) volatile matter, (2) fixed carbon, (3) moisture, (4) sulfur, and (5) ash. Each of these is reported in the proximate analysis. Coal analyses can be reported on several bases: as-received, moisture-free (or dry), and mineral-matter-free (or ash-free). As-received is applicable for combustion calculations; moisture-free and mineral-matter-free, for classification purposes.

Volatile matter is driven off as gas or vapor when the coal is heated according to a standard temperature test. It consists of a variety of organic gases, generally resulting from distillation and decomposition. Volatile products given off by heated coals differ materially in the ratios (by mass) of the gases to oils and tars. No heavy oils or tars are given off by anthracite, and very small quantities are given off by semianthracite. As volatile matter increases to as much as 40% of the coal (dry and ash-free basis), increasing amounts of oils and tars are released. However, for coals of higher volatile content, the quantity of oils and tars decreases and is relatively low in the subbituminous coals and in lignite.

Fixed carbon is the combustible residue left after the volatile matter is driven off. It is not all carbon. Its form and hardness are an indication of fuel coking properties and, therefore, guide the choice of combustion equipment. Generally, fixed carbon represents that portion of fuel that must be burned in the solid state.

Moisture is difficult to determine accurately because a sample can lose moisture on exposure to the atmosphere, particularly when reducing the sample size for analysis. To correct for this loss, total moisture content of a sample is customarily determined by adding the moisture loss obtained when air-drying the sample to the measured moisture content of the dried sample. Moisture does not represent all of the water present in coal; water of decomposition

Table 8 Typical Ultimate Analyses for Coals

Rank	As Received, Btu/lb	Constituents, Percent by Mass					
		O	H	C	N	S	Ash
Anthracite	12,700	5.0	2.9	80.0	0.9	0.7	10.5
Semianthracite	13,600	5.0	3.9	80.4	1.1	1.1	8.5
Low-volatile bituminous	14,350	5.0	4.7	81.7	1.4	1.2	6.0
Medium-volatile bituminous	14,000	5.0	5.0	81.4	1.4	1.5	6.0
High-volatile bituminous							
Type A	13,800	9.3	5.3	75.9	1.5	1.5	6.5
B	12,500	13.8	5.5	67.8	1.4	3.0	8.5
C	11,000	20.6	5.8	59.6	1.1	3.5	9.4
Subbituminous							
Type B	9,000	29.5	6.2	52.5	1.0	1.0	9.8
C	8,500	35.7	6.5	46.4	0.8	1.0	9.6
Lignite	6,900	44.0	6.9	40.1	0.7	1.0	7.3

(combined water) and of hydration are not given off under standardized test conditions.

Ash is the noncombustible residue remaining after complete coal combustion. Generally, the mass of ash is slightly less than that of mineral matter before burning.

Sulfur is an undesirable constituent in coal, because sulfur oxides formed when it burns contribute to air pollution and cause combustion system corrosion. Table 8 lists the sulfur content of typical coals. Legislation has limited the sulfur content of coals burned in certain locations.

Heating value may be reported on an as-received, dry, dry and mineral-matter-free, or moist and mineral-matter-free basis. Higher heating values of coals are frequently reported with their proximate analysis. When more specific data are lacking, the higher heating value of higher-quality coals can be calculated by the Dulong formula:

$$\text{Higher heating value, Btu/lb} = 14,544C + 62,028[H - (O/8)] + 4050S \tag{5}$$

where C, H, O, and S are the mass fractions of carbon, hydrogen, oxygen, and sulfur in the coal obtained from the ultimate analysis.

Other important parameters in judging coal suitability include

- **Ultimate analysis**, which is another method of reporting coal composition. Percentages of C, H, O, N, S, and ash in the coal sample are reported. Ultimate analysis is used for detailed fuel studies and for computing a heat balance when required in heating device testing. Typical ultimate analyses of various coals are shown in Table 8.
- **Ash-fusion temperature**, which indicates the fluidity of the ash at elevated temperatures. It is helpful in selecting coal to be burned in a particular furnace and in estimating the possibility of ash handling and slagging problems.
- The **grindability index**, which indicates the ease with which a coal can be pulverized and is helpful in estimating ball mill capacity with various coals. There are two common methods for determining the index: Hardgrove (see Hardgrove Grindability Index at www.energy.psu.edu/HGI) and ball mill.
- The **free-swelling index**, which denotes the extent of coal swelling on combustion on a fuel bed and indicates the coking characteristics of coal.

COMBUSTION CALCULATIONS

Calculations of the quantities of (1) air required for combustion and (2) flue gas products generated during combustion are frequently needed for sizing system components and as input to efficiency calculations. Other calculations, such as values for excess air

and theoretical CO₂, are useful in estimating combustion system performance.

Frequently, combustion calculations can be simplified by using molecular mass. The molecular mass of a compound equals the sum of the atomic masses of the elements in the compound. Molecular mass can be expressed in any mass units. The pound molecular weight or pound mole is the molecular weight of the compound expressed in pounds. The molecular weight of any substance contains the same number of molecules as the molecular weight of any other substance.

Corresponding to measurement standards common to the industries, calculations involving gaseous fuels are generally based on volume, and those involving liquid and solid fuels generally use mass.

Some calculations described here require data on concentrations of carbon dioxide, carbon monoxide, and oxygen in the flue gas. Gas analyses for CO₂, CO, and O₂ can be obtained by volumetric chemical analysis and other analytical techniques, including electromechanical cells used in portable electronic flue gas analyzers.

Air Required for Combustion

Stoichiometric (or theoretical) air is the exact quantity of air required to provide oxygen for complete combustion.

The three most prevalent components in hydrocarbon fuels (C, H₂, and S) are completely burned as in the following fundamental reactions:

In the reactions, C, H₂, and S can be taken to represent 1 lb mole of carbon, hydrogen, and sulfur, respectively. Using approximate atomic masses (C = 12, H = 1, S = 32, and O = 16), 12 lb of C are oxidized by 32 lb of O₂ to form 44 lb of CO₂, 2 lb of H₂ are oxidized by 16 lb of O₂ to form 18 lb of H₂O, and 32 lb of S are oxidized by 32 lb of O₂ to form 64 lb of SO₂. These relationships can be extended to include hydrocarbons.

The mass of dry air required to supply a given quantity of oxygen is 4.32 times the mass of the oxygen. The mass of air required to oxidize the fuel constituents listed in Table 1 was calculated on this basis. Deduct oxygen contained in the fuel, except the amount in ash, from the amount of oxygen required, because this oxygen is already combined with fuel components. In addition, when calculating the mass of supply air for combustion, allow for water vapor, which is always present in atmospheric air.

Combustion calculations for gaseous fuels are based on volume. **Avogadro's law** states that, for any gas, one mole occupies the same volume at a given temperature and pressure. Therefore, in reactions involving gaseous compounds, the gases react in volume ratios identical to the pound mole ratios. That is, to oxidize hydrogen in the preceding reaction, one volume (or one lb mole) of hydrogen reacts with one-half volume (or one-half lb mole) of oxygen to form one volume (or one lb mole) of water vapor.

The volume of air required to supply a given volume of oxygen is 4.78 times the volume of oxygen. The volumes of dry air required to oxidize the fuel constituents listed in Table 1 were calculated on this basis. Volume ratios are not given for fuels that do not exist in vapor form at reasonable temperatures or pressures. Again, oxygen contained in the fuel should be deducted from the quantity of oxygen required, because this oxygen is already combined with fuel components. Allow for water vapor, which increases the volume of dry air by 1 to 3%.

From the relationships just described, the theoretical mass m_a of dry air required for stoichiometric combustion of a unit mass of any hydrocarbon fuel is

$$m_a = 0.0144(8C + 24H + 3S - 3O) \quad (6)$$

where C, H, S, and O are the mass percentages of carbon, hydrogen, sulfur, and oxygen in the fuel.

Analyses of gaseous fuels are generally based on hydrocarbon components rather than elemental content.

If fuel analysis is based on mass, the theoretical mass m_a of dry air required for stoichiometric combustion of a unit mass of gaseous fuel is

$$\begin{aligned} m_a &= 2.47CO + 34.28H_2 + 17.24CH_4 + 16.09C_2H_6 \\ &\quad + 15.68C_3H_8 + 15.47C_4H_{10} + 13.27C_2H_2 \\ &\quad + 14.78C_2H_4 + 6.08H_2S - 4.32O_2 \end{aligned} \quad (7)$$

If fuel analysis is reported on a volumetric or molecular basis, it is simplest to calculate air requirements based on volume and, if necessary, convert to mass. The theoretical volume V_a of air required for stoichiometric combustion of a unit volume of gaseous fuels is

$$\begin{aligned} V_a &= 2.39CO + 2.39H_2 + 9.57CH_4 + 16.75C_2H_6 \\ &\quad + 23.95C_3H_8 + 31.14C_4H_{10} + 11.96C_2H_2 \\ &\quad + 14.38C_2H_4 + 7.18H_2S - 4.78O_2 \\ &\quad + 30.47 \text{ illuminants} \end{aligned} \quad (8)$$

where CO, H₂, and so forth are the volumetric fractions of each constituent in the fuel gas.

Illuminants include a variety of compounds not separated by usual gas analysis. In addition to ethylene (C₂H₄) and acetylene (C₂H₂), the principal illuminants included in Equation (8), and the dry air required for combustion, per unit volume of each gas, are as follows: propylene (C₃H₆), 21.44; butylene (C₄H₈), 28.58; pentene (C₅H₁₀), 35.73; benzene (C₆H₆), 35.73; toluene (C₇H₈), 42.88; and xylene (C₈H₁₀), 50.02. Because toluene and xylene are normally scrubbed from the gas before distribution, they can be disregarded in computing air required for combustion of gaseous fuels. The percentage of illuminants present in gaseous fuels is small, so the values can be lumped together, and an approximate value of 30 unit volumes of dry air per unit volume of gas can be used. If ethylene and acetylene are included as illuminants, a value of 20 unit volumes of dry air per unit volume of gaseous illuminants can be used.

For many combustion calculations, only approximate values of air requirements are necessary. If approximate values for theoretical air are sufficient, or if complete information on the fuel is not available, the values in Tables 9 and 10 can be used. Another value used for estimating air requirements is 0.9 ft³ of air for 100 Btu of fuel.

In addition to the amount theoretically required for combustion, **excess air** must be supplied to most practical combustion systems to ensure complete combustion:

$$\text{Excess air, \%} = \frac{\text{Air supplied} - \text{Theoretical air}}{\text{Theoretical air}} \quad (9)$$

The excess air level at which a combustion process operates significantly affects its overall efficiency. Too much excess air dilutes flue gas excessively, lowering its heat transfer temperature and increasing sensible flue gas loss. Conversely, too little excess air can

Table 9 Approximate Air Requirements for Stoichiometric Combustion of Fuels

Type of Fuel	Air Required		Approx. Precision, %	Exceptions
	lb/lb Fuel	ft ³ /Unit Fuel*		
Solid	Btu/lb × 0.00073	Btu/lb × 0.0097	3	Fuels containing more than 30% water
Liquid	Btu/lb × 0.00071	Btu/lb × 0.0094	3	Results low for gasoline and kerosene
Gas	Btu/lb × 0.00067	Btu/lb × 0.0089	5	300 Btu/ft ³ or less

*Unit fuel for solid and liquid fuels in lb, for gas in ft³.

Table 10 Approximate Air Requirements for Stoichiometric Combustion of Various Fuels

Type of Fuel	Theoretical Air Required for Combustion
Solid fuels	lb/lb fuel
Anthracite	9.6
Semibituminous	11.2
Bituminous	10.3
Lignite	6.2
Coke	11.2
Liquid fuels	lb/gal fuel
No. 1 fuel oil	103
No. 2 fuel oil	106
No. 5 fuel oil	112
No. 6 fuel oil	114
Gaseous fuels	ft ³ /ft ³ fuel
Natural gas	9.6
Butane	31.1
Propane	24.0

lead to incomplete combustion and loss of unburned combustible gases. Combustion efficiency is usually maximized when just enough excess air is supplied and properly mixed with combustible gases to ensure complete combustion. The general practice is to supply 5 to 50% excess air, depending on the type of fuel burned, combustion equipment, and other factors.

The amount of dry air supplied per unit mass of fuel burned can be obtained from the following equation, which is reasonably precise for most solid and liquid fuels:

$$\text{Dry air supplied} = \frac{C(3.04N_2)}{CO_2 + CO} \quad (10)$$

where

- Dry air supplied = unit mass per unit mass of fuel
- C = unit mass of carbon burned per unit mass of fuel, corrected for carbon in ash
- CO₂, CO, N₂ = percentages by volume from flue gas analysis

These values of dry air supplied and theoretical air can be used in Equation (9) to determine excess air.

Excess air can also be calculated from unit volumes of stoichiometric combustion products and air, and from volumetric analysis of the flue gas:

$$\text{Excess air, \%} = 100 \left(\frac{P}{A} \right) \left(\frac{U - CO_2}{CO_2} \right) \quad (11)$$

where

- U = ultimate carbon dioxide of flue gases resulting from stoichiometric combustion, %
- CO₂ = carbon dioxide content of flue gases, %
- P = dry products from stoichiometric combustion, unit volume per unit volume of gas burned
- A = air required for stoichiometric combustion, unit volume per unit volume of gas burned

Because the ratio P/A is approximately 0.9 for most natural gases, a value of 90 can be substituted for 100(P/A) in Equation (11) for rough calculation.

Because excess air calculations are almost invariably made from flue gas analysis results and theoretical air requirements are not always known, another convenient method of expressing Equation (9) is

$$\text{Excess air, \%} = \frac{100[O_2 - (CO/2)]}{0.264N_2 - [O_2 - (CO/2)]} \quad (12)$$

where O₂, CO, and N₂ are percentages by volume from the flue gas analysis, dry basis.

Table 11 Approximate Maximum Theoretical (Stoichiometric) CO₂ Values, and CO₂ Values of Various Fuels with Different Percentages of Excess Air

Type of Fuel	Theoretical or Maximum CO ₂ , %	Percent CO ₂ at Given Excess Air Values		
		20%	40%	60%
Gaseous Fuels				
Natural gas	12.1	9.9	8.4	7.3

Theoretical CO₂

The theoretical (or ultimate, stoichiometric, or maximum) CO₂ concentration attainable in the products from the combustion of a hydrocarbon fuel with air is obtained when the fuel is completely burned with the theoretical quantity of air and zero excess air. Theoretical CO₂ varies with the carbon/hydrogen ratio of the fuel. For combustion with excess air present, theoretical CO₂ values can be calculated from the flue gas analysis:

$$\text{Theoretical CO}_2, \% = U = \frac{CO_2}{1 - (O_2/20.95)} \quad (13)$$

where CO₂ and O₂ are percentages by volume from the flue gas analysis, dry basis.

Table 11 gives approximate theoretical CO₂ values for stoichiometric combustion of several common types of fuel, as well as CO₂ values attained with different amounts of excess air. In practice, desirable CO₂ values depend on the excess air, fuel, firing method, and other considerations.

Quantity of Flue Gas Produced

The mass of dry flue gas produced per mass of fuel burned is required in heat loss and efficiency calculations. This mass is equal to the sum of the mass of (1) fuel (minus ash retained in the furnace), (2) air theoretically required for combustion, and (3) excess air. For solid fuels, this mass, determined from the flue gas analysis, is

$$\text{Dry flue gas} = \frac{11CO_2 + 8O_2 + 7(CO + N_2)}{3(CO_2 + CO)} \quad (14)$$

where

- Dry flue gas = lb/lb of fuel
- C = lb of carbon burned per lb of fuel, corrected for carbon in ash
- CO₂, O₂, CO, N₂ = percentages by volume from flue gas analysis

The total dry gas volume of flue gases from combustion of one unit volume of gaseous fuels for various percentages of CO₂ is

$$\text{Dry flue gas} = \left(\frac{\text{Volume of CO}_2 \text{ produced}}{\text{Unit vol. of gas burned}} \right) \left(\frac{100}{CO_2} \right) \quad (15)$$

where

- Dry flue gas = unit volume per unit volume of gaseous fuel
- CO₂ = percentage by volume from the flue gas analysis

Fig. 3 Water Vapor and Dew Point of Flue Gas

Adapted from *Gas Engineers Handbook* (1965). Printed with permission of Industrial Press and American Gas Association.

Excess air quantity can be estimated by subtracting the quantity of dry flue gases resulting from stoichiometric combustion from the total volume of flue gas.

Water Vapor and Dew Point of Flue Gas

Water vapor in flue gas is the total of the water (1) contained in the fuel, (2) contained in the stoichiometric and excess air, and (3) produced from combustion of hydrogen or hydrocarbons in the fuel. The amount of water vapor in stoichiometric combustion products may be calculated from the fuel burned by using the water data in Table 1.

The dew point is the temperature at which condensation begins and can be determined using Figure 3. The volume fraction of water vapor P_{wv} in the flue gas can be determined as follows:

$$P_{wv} = \frac{V_w}{(100V_c/P_c) + V_w} \tag{16}$$

where

V_w = total water vapor volume (from fuel; stoichiometric, excess, and dilution air; and combustion)

V_c = unit volume of CO₂ produced per unit volume of gaseous fuel

P_c = percent CO₂ in flue gas

Using Figure 4, the dew points of solid, liquid, or gaseous fuels may be estimated. For example, to find the dew point of flue gas resulting from the combustion of a solid fuel with a weight ratio (hydrogen to carbon-plus-sulfur) of 0.088 and sufficient excess air to produce 11.4% oxygen in the flue gas, start with the weight ratio of 0.088. Proceed vertically to the intersection of the solid fuels curve and then to the theoretical dew point of 115°F on the dew-point scale (see dashed lines in Figure 4). Follow the curve fixed by this point (down and to the right) to 11.4% oxygen in the flue gas (on the abscissa). The actual dew point is 93°F and is found on the dew-point scale.

The dew point can be estimated for flue gas from natural gas having a higher heating value (HHV) of 1020 Btu/ft³ with 6.3% oxygen or 31.5% air. Start with 1020 Btu/ft³ and proceed vertically to the intersection of the gaseous fuels curve and then to the theoretical dew point of 139°F on the dew-point scale. Follow the curve fixed by this point to 6.3% oxygen or 31.5% air in the flue gas. The actual dew point is 127°F.

The presence of sulfur dioxide, and particularly sulfur trioxide, influences the vapor pressure of condensate in flue gas, and the dew point can be raised by as much as 25 to 75°F, as shown in Figure 5. To illustrate the use of Figure 5, for a manufactured gas with an

HHV of 550 Btu/ft³ containing 15 grains of sulfur per 100 ft³ being burned with 40% excess air, the proper curve in Figure 5 is determined as follows:

$$\frac{\text{Grains sulfur per } 100 \text{ ft}^3 \text{ of fuel}}{\text{Btu per ft}^3 \text{ of fuel}} \times 100 = \frac{15}{550} \times 100 = 2.73 \tag{17}$$

This curve lies between the 0 and 3 curves and is close to the 3 curve. The dew point for any percentage of excess air from zero to 100% can be determined on this curve. For this flue gas with 40% excess air, the dew point is about 160°F, instead of 127°F for zero sulfur at 40% excess air.

Sample Combustion Calculations

Example 2. Analysis of flue gases from burning a natural gas shows 10.0% CO₂, 3.1% O₂, and 86.9% N₂ by volume. Analysis of the fuel is 90% CH₄, 5% N₂, and 5% C₂H₆ by volume. Find U (maximum theoretical percent CO₂), and percentage of excess air.

Solution: From Equation (13),

$$U = \frac{10.0}{1 - (3.1/20.95)} = 11.74\% \text{ CO}_2$$

From Equation (11), using $100(P/A) = 90$,

$$\text{Excess air} = \frac{(11.74 - 10.0)90}{10} = 15.7\%$$

Example 3. For the same analysis as in Example 2, find, per cubic foot of fuel gas, the volume of dry air required for combustion, the volume of each constituent in the flue gases, and the total volume of dry and wet flue gases.

Solution: From Equation (8), the volume of dry air required for combustion is

$$9.57\text{CH}_4 + 16.75\text{C}_2\text{H}_6 = (9.57 \times 0.90) + (16.75 \times 0.05) = 9.45 \text{ ft}^3 \text{ per ft}^3 \text{ of fuel gas}$$

(The volume of dry air may also be calculated using Table 10.)

From Table 1, the cubic feet of flue gas constituents per cubic foot of fuel gas are as follows:

Nitrogen, N ₂	
From methane	(0.9CH ₄)(9.57 - 2.0) = 6.81
From ethane	(0.05C ₂ H ₆)(16.75 - 3.5) = 0.66
Nitrogen in fuel	= 0.05
Nitrogen in excess air	0.791 × 0.157 × 9.45 = 1.17
	Total nitrogen = 8.69 ft ³

Oxygen, O ₂	
In excess air	0.209 × 0.157 × 9.45 = 0.31 ft ³

Carbon dioxide, CO ₂	
From methane	(0.9CH ₄)(1.0) = 0.90
From ethane	(0.05C ₂ H ₆)(2.0) = 0.10
	Total carbon dioxide = 1.00 ft ³

Water vapor, H ₂ O (does not appear in some flue gas analyses)	
From methane	(0.9CH ₄)(2.0) = 1.8
From ethane	(0.05C ₂ H ₆)(3.0) = 0.15
	Total water vapor = 1.95 ft ³

Total volume of dry gas per cubic foot of fuel gas
 $8.69 + 0.31 + 1.00 = 10.0 \text{ ft}^3$

Total volume of wet gases per cubic foot of fuel gas (neglecting water vapor in combustion air)

$$10.0 + 1.95 = 11.95 \text{ ft}^3$$

The cubic feet of dry flue gas per cubic foot of fuel gas can also be computed from Equation (15):

$$(1.00)(100)/10.0 = 10.0 \text{ ft}^3$$

EFFICIENCY CALCULATIONS

In analyzing heating appliance efficiency, an energy balance is made that accounts (as much as possible) for disposition of all thermal energy released by combustion of the fuel quantity consumed. The various components of this balance are generally expressed in terms of Btu/lb of fuel burned or as a percentage of its higher heating value. The following are major components of an energy balance and their calculation methods:

1. Useful heat q_1 , or heat transferred to the heated medium; for convection heating equipment, this value is computed as the product of the mass rate of flow and enthalpy change.
2. Heat loss as sensible heat in the dry flue gases

$$q_2 = m_g c_{pg} (t_g - t_a) \tag{18}$$

where m_g (mass of dry flue gas per mass of fuel, lb/lb) is calculated as in Equation (14).

3. Heat loss in water vapor in products formed by combustion of hydrogen

$$q_3 = (9H_2/100)[(h)_{tg} - (h_f)_{ta}] \tag{19}$$

4. Heat loss in water vapor in the combustion air

$$q_4 = Mm_a[(h)_{tg} - (h_g)_{ta}] \tag{20}$$

where m_a is calculated as in Equations (6) and (7).

5. Heat loss from incomplete combustion of carbon

$$q_5 = 10,143C \left(\frac{CO}{CO_2 + CO} \right) \tag{21}$$

Fig. 5 Influence of Sulfur Oxides on Flue Gas Dew Point

6. Heat loss from unburned carbon in the ash or refuse

$$q_6 = 14,600[(C_u/100) - C] \tag{22}$$

7. Unaccounted-for heat losses, q_7

The following symbols are used in Equations (18) to (22):

- q_1 = useful heat, Btu/lb of fuel
- q_2 = heat loss in dry flue gases, Btu/lb of fuel

- q_3 = heat loss in water vapor from combustion of hydrogen, Btu/lb of fuel
 q_4 = heat loss in water vapor in combustion air, Btu/lb of fuel
 q_5 = heat loss from incomplete combustion of carbon, Btu/lb of fuel
 q_6 = heat loss from unburned carbon in ash, Btu/lb of fuel
 q_7 = unaccounted-for heat losses, Btu/lb of fuel
 c_{pg} = mean specific heat of flue gases at constant pressure (from 0.242 to 0.254 Btu/lb·°F for flue gas temperatures from 300 to 1000°F), Btu/lb·°F
 $(h_{fg})_{ig}$ = enthalpy of superheated steam at flue gas temperature and 14.696 psia, Btu/lb
 $(h_f)_{la}$ = enthalpy of saturated water liquid at air temperature, Btu/lb
 $(h_g)_{la}$ = enthalpy of saturated steam at combustion air temperature, Btu/lb
 m_a = mass of combustion air per mass of fuel used, lb/lb of fuel
 m_g = mass of dry flue gas per mass of fuel, lb/lb of fuel
 t_a = temperature of combustion air, °F
 t_g = temperature of flue gases at exit of heating device, °F
 H_2 = hydrogen in fuel, % by mass (from ultimate analysis of fuel)
 M = humidity ratio of combustion air, mass of water vapor per mass of dry air

CO, CO₂ = carbon monoxide and carbon dioxide in flue gases, % by volume

C = mass of carbon burned per unit of mass of fuel, corrected for carbon in ash, lb/lb of fuel

$$C = \frac{WC_u - W_a C_a}{100W} \quad (23)$$

where

- C_u = percentage of carbon in fuel by mass from ultimate analysis
 W_a = mass of ash and refuse
 C_a = percent of combustible in ash by mass (combustible in ash is usually considered to be carbon)
 W = mass of fuel used

Useful heat (item 1) is generally measured for a particular piece of combustion equipment.

Flue gas loss is the sum of items 2 to 6. However, for clean-burning gas- and oil-fired equipment, items 5 and 6 are usually negligible and flue gas loss is the sum of items 2, 3, and 4.

Flue gas losses (the sum of items 2, 3, and 4) can be determined with sufficient precision for most purposes from the curves in Figure 6, if O₂ content and flue gas temperature are known. Values of the losses were computed from typical ultimate analyses, assuming 1% water vapor (by mass) in the combustion air. Curves for medium-volatile bituminous coal can be used for high-volatile bituminous coal with no appreciable error.

Generally, item 5 is negligible for modern combustion equipment in good operating condition.

Item 6 is generally negligible for gas and oil firing, but should be determined for coal-firing applications.

Item 7 consists primarily of radiation and convection losses from combustion equipment surfaces and losses caused by incomplete combustion not included in items 5 and 6. Heat loss from incomplete combustion is determined by subtracting the sum of items 1 to 6 from the fuel heating value.

Radiation and convection losses are not usually determined by direct measurement, but if the heating appliance is located within the heated space, radiation and convection losses can be considered useful heat rather than lost heat and can be omitted from heat loss calculations or added to item 1.

If CO is present in flue gases, small amounts of unburned hydrogen and hydrocarbons may also be present. The small losses caused by incomplete combustion of these gases would be included in item 7, if item 7 was determined by subtracting items 1 to 6 from the fuel heating value.

The overall thermal efficiency of combustion equipment is defined as

$$\text{Thermal efficiency, \%} = 100 \times \frac{\text{Useful heat}}{\text{Heating value of fuel}} \quad (24)$$

Equation (25) can be used to estimate efficiency for equipment where item 7 is small or radiation and convection are useful heat:

Thermal efficiency, % =

$$100 \times \frac{\text{Heating value of fuel} - (q_2 + q_3 + q_4 + q_5 + q_6)}{\text{Heating value of fuel}} \quad (25)$$

Using heating values based on gas volume, a gas appliance's thermal efficiency can be computed with sufficient precision by the following equation:

$$\eta = \frac{100(Q_h - Q_{fl})}{Q_h} \quad (26)$$

where

- η = thermal efficiency, %
 Q_h = higher heating value of fuel gas per unit volume
 Q_{fl} = flue gas losses per unit volume of fuel gas

To produce heat efficiently by burning any common fuel, flue gas losses must be minimized by (1) providing adequate heat-absorbing surface in the appliance, (2) maintaining clean heat transfer surfaces on both fire and water or air sides, and (3) reducing excess air to the minimum level consistent with complete combustion and discharge of combustion products.

Seasonal Efficiency

The method just presented is useful for calculating the steady-state efficiency of a heating system or device. Unfortunately, the seasonal efficiency can be significantly different from the steady-state efficiency. The primary factor affecting seasonal efficiency is flue loss during the burner-off period. The warm stack that exists at the end of the firing period can cause airflow in the stack while the burner is off, which can remove heat from furnace and heat exchanger components, the structure itself, and pilot flames. Also, if combustion air is drawn from the heated space within the structure, the heated air lost must be at least partly replaced with cold infiltrated air. For further discussion of seasonal efficiency, see Chapters 9 and 32 of the 2008 *ASHRAE Handbook—HVAC Systems and Equipment* and Chapter 19 of this volume.

COMBUSTION CONSIDERATIONS

Air Pollution

Combustion processes constitute the largest single source of anthropogenic (human-caused) air pollution. Pollutants can be grouped into five categories:

- Products of incomplete fuel combustion
 - Combustible aerosols (solid and liquid), including smoke, soot, and organics, but excluding ash
 - Carbon monoxide CO
 - Gaseous hydrocarbons
- Carbon dioxide CO₂
- Oxides of nitrogen (collectively referred to as NO_x)
 - Nitric oxide NO
 - Nitrogen dioxide NO₂
- Emissions resulting from fuel contaminants
 - Sulfur oxides, primarily sulfur dioxide SO₂ and small quantities of sulfur trioxide SO₃
 - Ash
 - Trace metals
- Emissions resulting from additives

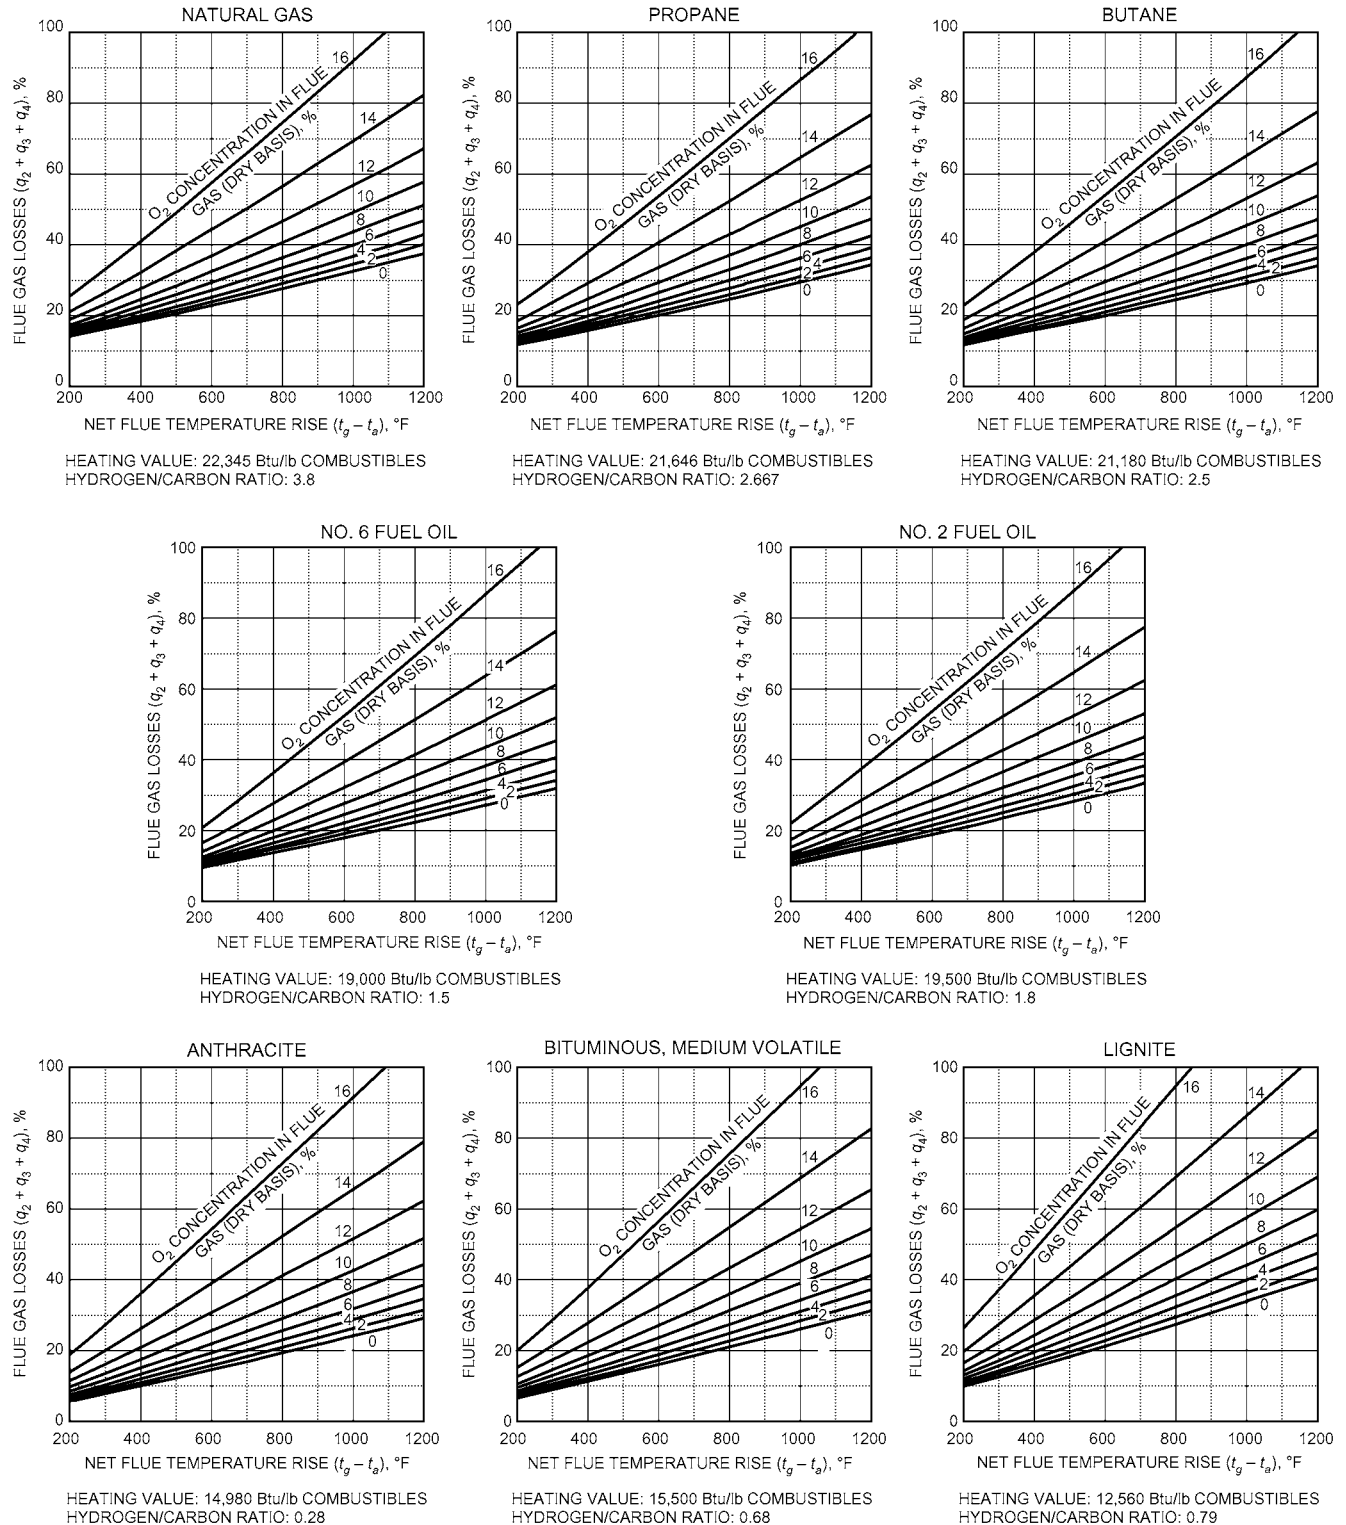

Fig. 6 Flue Gas Losses with Various Fuels
(Flue gas temperature rise shown. Loss based on 65°F room temperature.)

- Combustion-controlling additives
- Mercaptans
- Other additives

Emission levels of nitrogen oxides and products of incomplete combustion are directly related to the combustion process and can be

controlled, to some extent, by process modification. Emissions from fuel contaminants are related to fuel selection and are slightly affected by the combustion process. Emissions from additives must be considered in the overall evaluation of the merits of using additives.

Carbon dioxide as a pollutant has gained attention because of its suspected effect on global warming. Carbon dioxide is produced by

Table 12 NO_x Emission Factors for Combustion Sources Without Emission Controls

Source	NO _x Emission Factor, lb/10 ⁶ Btu of Heat Input
Gas-fired equipment	
Small industrial boilers	0.14
Commercial boilers	0.10
Residential furnaces	0.09
Distillate-oil-fired small industrial boilers, commercial boilers, and residential furnaces	0.14
Residual-oil-fired small industrial boilers and commercial boilers	0.37

HVAC&R equipment (either directly or as a result of generating the electric power to operate the HVAC&R equipment), transportation, industry, and other sources. Carbon dioxide emissions can be minimized by increasing appliance operating efficiencies and using fuels with higher hydrogen content.

Nitrogen oxides are produced during combustion, either (1) by thermal fixation (reaction of nitrogen and oxygen at high combustion temperatures), or (2) from fuel nitrogen (oxidation of organic nitrogen in fuel molecules). Unfortunately, high excess air and high flame temperature techniques, which ensure complete fuel combustion, tend to promote NO_x formation. NO levels in flames where the reactants are premixed tend to peak with excess air levels around 10%. Higher excess air levels generally reduce the amount of NO_x and flame temperatures.

Table 12 lists NO_x emission factors for uncontrolled fuel-burning equipment (i.e., equipment that does not have exhaust gas recirculation, low-NO_x burners, or other emission controls). Differences in emissions are caused by flame temperature and different levels of fuel nitrogen. The data in Table 12 are adapted from EPA (1995), which lists emission factors of a wide variety of equipment, as well as emission reduction options.

Carbon monoxide emissions depend less on fuel type and typically range from 0.03 to 0.04 lb/10⁶ Btu of heat input. For gas-fired commercial and industrial boilers, particulate emissions range from 0.005 to 0.006 lb/10⁶ Btu. For distillate-oil-fired commercial and industrial boilers, particulates are typically 0.014 lb/10⁶ Btu. For residential oil-fired equipment, particulate emission factors are 0.003 lb/10⁶ Btu. For residual-oil-fired equipment, particulate emissions depend on the sulfur content and, to a lesser extent, the mineral content. For a sulfur content of 1%, the particulate emission rate is typically 0.083 lb/10⁶ Btu.

Emission levels of products of incomplete fuel combustion can be reduced by reducing burner cycling, ensuring adequate excess air, improving mixing of air and fuel (by increasing turbulence, improving distribution, and improving liquid fuel atomization), increasing residence time in the hot combustion zone (possibly by decreasing the firing rate), increasing combustion zone temperatures (to speed reactions), and avoiding quenching the flame before reactions are completed.

Relative humidity of combustion air affects the amount of NO_x produced and must be considered when specifying acceptable NO_x emission rates and measuring NO_x production during appliance tests.

The relative contribution of each of these mechanisms to the total NO_x emissions depends on the amount of organic nitrogen in the fuel. Natural gas normally contains very little nitrogen. Virtually all NO_x emissions with gas firing are due to the thermal mechanism. Nitrogen content of distillate oil varies, but an average of 20 ppm of fuel NO_x is produced (about 20 to 30% of the total NO_x). Levels in residual oil can be significantly higher, with fuel NO_x contributing heavily to the total emissions.

Thermal fixation depends strongly on flame maximum temperature. For example, increasing the flame temperature from 2600 to

2800°F increases thermal NO_x tenfold. Therefore, methods to control thermal NO_x are based on methods to reduce the maximum flame temperature. Flue gas recirculation is perhaps the most effective method for commercial and industrial boilers. In gas-fired boilers, NO_x can be reduced 70% with 15 to 20% recirculation of flue gas into the flame. The NO_x reduction decreases with increasing fuel nitrogen content. With distillate-oil firing, reductions of 60 to 70% can be achieved. In residual-oil-fired boilers, flue gas recirculation can reduce NO_x emissions by 15 to 30%. The maximum rate of flue gas recirculation is limited by combustion instability and CO production.

Two-stage firing is the only technique that reduces NO_x produced both by thermal fixation and fuel nitrogen in industrial and utility applications. The fuel-rich or air-deficient primary combustion zone retards NO_x formation early in combustion (when NO_x forms most readily from fuel nitrogen), and avoids peak temperatures, reducing thermal NO_x. Retrofit low-NO_x burners that control air distribution and fuel air mixing in the flame zone can be used to achieve staged combustion. With oil firing, NO_x reductions of 20 to 50% can be obtained with low-NO_x burners. Application of flue gas recirculation and other control methods to residential, oil-fired heating systems was reviewed by Butcher et al. (1994).

The following are some methods of reducing NO_x emissions from gas-fired appliances (Murphy and Putnam 1985):

- Burner adjustment
- Flame inserts (radiation screens or rods)
- Staged combustion and delayed mixing
- Secondary air baffling
- Catalytic and radiant burners
- Total premix
- Pulse

Radiation screens or rods (flame inserts) surrounding or inserted into the flame absorb radiation to reduce flame temperature and retard NO_x formation. Proprietary appliance burners with no flame inserts have been produced to comply with the very strict NO_x emission limitations of California's Air Quality Management Districts.

The U.S. EPA sets limits on air pollutant emissions (Source Performance Standards) from boilers larger than 10 million Btu/h of heat input. In addition, states set emission regulations that are at least as strict at the federal limits and may apply to smaller equipment.

The EPA's automobile emission standard is 1.0 g of NO₂ per mile, which is equivalent to 750 ng/J of NO_x emission. California's maximum is 0.4 g/mile, equivalent to 300 ng/J. California's Air Quality Management Districts for the South Coast (Los Angeles) and the San Francisco Bay Area limit NO_x emission to 40 ng/J of useful heat for some natural gas-fired central furnaces.

For further discussion of air pollution aspects of fuel combustion, see EPA (1971a, 1971b).

Condensation and Corrosion

Fuel-burning systems that cycle on and off to meet demand cool down during the *off* cycle. When the appliance starts again, condensate forms briefly on surfaces until they are heated above the dew-point temperature. Low-temperature corrosion occurs in system components (heat exchangers, flues, vents, chimneys) when their surfaces remain below the dew-point temperature of flue gas constituents (water vapor, sulfides, chlorides, fluorides, etc.) long enough to cause condensation. Corrosion increases as condensate dwell time increases.

Acids in flue gas condensate are the principal substances responsible for low-temperature corrosion in fuel-fired systems. Sulfuric, hydrochloric, and other acids are formed when acidic compounds in fuel and air combustion products combine with condensed moisture in appliance heat exchangers, flues, or vents. Corrosion can be avoided by maintaining these surfaces above the flue gas dew point.

In high-efficiency, condensing-type appliances and economizers, flue gas temperatures are intentionally reduced below the flue gas dew-point temperatures to achieve efficiencies approaching 100%. In these systems, surfaces subjected to condensate must be made of corrosion-resistant materials. The most corrosive conditions exist at the leading edge of the condensing region, especially areas that experience evaporation during each cycle (Stickford et al. 1988). Draining condensate retards the concentration of acids on system surfaces; regions from which condensate partially or completely drains away before evaporation are less severely attacked than regions from which condensate does not drain before evaporation.

The metals most resistant to condensate corrosion are stainless-steel alloys with high chromium and molybdenum content, and nickel-chromium alloys with high molybdenum content (Stickford et al. 1988). Aluminum experiences general corrosion rather than pitting when exposed to flue gas condensate. If applied in sufficiently thick cross section to allow for metal loss, aluminum can be used in condensing regions. Most ceramic and high-temperature polymer materials resist the corrosive effects of flue gas condensate. These materials may have application in the condensing regions, if they can meet the structural and temperature requirements of a particular application.

In coal-fired power plants, the rate of corrosion for carbon steel condensing surfaces by mixed acids (primarily sulfuric and hydrochloric) is reported to be maximum at about $122 \pm 18^\circ\text{F}$ (Davis 1987). Mitigation techniques include (1) acid neutralization with a base such as NH_3 or $\text{Ca}(\text{OH})_2$; (2) use of protective linings of glass-filled polyester or coal-tar epoxy; and (3) replacement of steel with molybdenum-bearing stainless steels, nickel alloys, polymers, or other corrosion-resistant materials. Other elements in residual fuel oils and coals that contribute to high-temperature corrosion include sodium, potassium, and vanadium. Each fuel-burning system component should be evaluated during installation, or when modified, to determine the potential for corrosion and the means to retard corrosion (Paul et al. 1988).

If fuel-burning appliances accumulate condensate that does not evaporate, the condensate must be routed into a trapped drainage system. Because the condensate may be acidic, the drainage system must be suitable and environmentally acceptable. Condensate freezing must be considered in cold climates.

Abnormal Combustion Noise in Gas Appliances

During development of a new boiler, furnace, or other gas-fired appliance, tonal noise can be an unacceptable problem. Because the frequency of the tone is equal to a resonance frequency of the system, this problem is often called a *combustion resonance*, but this term is misleading: changing the appliance's resonance frequency merely changes the frequency of the tone without much effect on the amplitude.

The proper term is **combustion-driven oscillation**, which is caused by feedback instability. Pressure oscillations in the combustion chamber (which manifest themselves as objectionable noise) also interact with the flame, modulating the instantaneous rate of combustion, which, in turn, causes more pressure oscillations (Putnam 1971). This feedback involves the acoustic response of the combustion chamber and of the fuel-air supply system, as well as that of the flame. For some combinations of response properties, the feedback loop is unstable.

Predicting instability in a design is generally not practical for domestic or small commercial appliances because there is not enough information to predict the acoustic response of some of the components, particularly the flame.

A model of the feedback loop (Baade 1978) is very useful, however, for solving existing oscillation problems, where the only concern is the particular frequency at which the oscillation occurs. Reducing the response of the flame, fuel/air mixture supply, or combustion chamber at that frequency should be the focus. This concept

can be easily demonstrated with a small brazing torch in a tube of variable length (Baade 1987, 2004).

In some systems, the flame can be modified to reduce its response at the oscillation frequency. Often, this involves simply changing the fuel/air ratio further away from the stoichiometric ratio (Elsari and Cummings 2003; Goldschmidt et al. 1978), thus lengthening the flame, which can also be done by increasing the size of burner ports (Matsui 1981; Schimmer 1979). Other possibilities for reducing flame response are using a suitable mix of differently sized burner ports (Kagiya 2000) and modifying the heat transfer characteristics of the burner matrix (Schreel et al. 2002).

The fuel supply system response can be reduced by avoiding resonance at or near the frequency of oscillation (Kilham et al. 1964) or by tuning the supply system to an antiresonance at that frequency (Neumann 1974). Designs for this can be evaluated by modeling the mixture supply system using transmission matrices (Munjal 1987) and computer programs for matrix multiplication, which are widely available (Baade and Tomarchio 2008).

For the combustion chamber, changing the resonance frequency is generally futile, but increasing the damping always works, provided that the system can increase damping sufficiently. Any damping less than the critical amount will have very little effect.

In some systems, the oscillation frequency may be a function of the flue pipe length. In such cases, investigate changing the length as well as adding damping.

For large systems, combustion oscillations may possibly be eliminated by using active feedback (Sattinger et al. 2000). Active feedback is not likely to be cost-effective for residential and small commercial systems.

Soot

Soot deposits on flue surfaces of a boiler or heater act as an insulating layer over the surface, reducing heat transfer to the water or air. Soot can also clog flues, reduce draft and available air, and prevent proper combustion. Proper burner adjustment can minimize soot accumulation. Using off-specification fuel can contribute to soot generation.

CHAPTER 29

REFRIGERANTS

<i>Refrigerant Properties</i>	29.1
<i>Refrigerant Performance</i>	29.6
<i>Safety</i>	29.6
<i>Leak Detection</i>	29.6
<i>Effect on Construction Materials</i>	29.9

REFRIGERANTS are the working fluids in refrigeration, air conditioning, and heat-pumping systems. They absorb heat from one area, such as an air-conditioned space, and reject it into another, such as outdoors, usually through evaporation and condensation, respectively. These phase changes occur both in absorption and mechanical vapor compression systems, but not in systems operating on a gas cycle using a fluid such as air. (See Chapter 2 for more information on refrigeration cycles.) The design of the refrigeration equipment depends strongly on the selected refrigerant's properties. Tables 1 and 2 list standard refrigerant designations, some properties, and safety classifications from ASHRAE *Standard 34*.

Refrigerant selection involves compromises between conflicting desirable thermophysical properties. A refrigerant must satisfy many requirements, some of which do not directly relate to its ability to transfer heat. Chemical stability under conditions of use is an essential characteristic. Safety codes may require a nonflammable refrigerant of low toxicity for some applications. Environmental consequences of refrigerant leaks must also be considered. Cost, availability, efficiency, and compatibility with compressor lubricants and equipment materials are other concerns.

Latent heat of vaporization is another important property. On a molar basis, fluids with similar boiling points have almost the same latent heat. Because compressor displacement is defined on a volumetric basis, refrigerants with similar boiling points produce similar refrigeration effect with a given compressor. On a mass basis, latent heat varies widely among fluids. Efficiency of a theoretical vapor compression cycle is maximized by fluids with low vapor heat capacity. This property is associated with fluids having a simple molecular structure and low molecular mass.

Transport properties (e.g., thermal conductivity and viscosity) affect performance of heat exchangers and piping. High thermal conductivity and low viscosity are desirable.

No single fluid satisfies all the attributes desired of a refrigerant; consequently, various refrigerants are used. This chapter describes the basic characteristics of various refrigerants, and Chapter 30 lists thermophysical properties.

REFRIGERANT PROPERTIES

Global Environmental Properties

Chlorofluorocarbons (CFCs) and hydrochlorofluorocarbons (HCFCs) can affect both stratospheric ozone and climate change, whereas hydrofluorocarbons (HFCs) can affect climate change. Minimizing all refrigerant releases from systems is important not only because of environmental impacts, but also because charge losses lead to insufficient system charge levels, which in turn results in suboptimal operation and lowered efficiency.

Stratospheric Ozone Depletion. The stratospheric ozone layer filters out the UV-B portion of the sun's ultraviolet (UV) radiation. Overexposure to this radiation increases the risk of skin cancer,

cataracts, and impaired immune systems. It also can damage sensitive crops, reduce crop yields, and stress marine phytoplankton (and thus human food supplies from the oceans). In addition, exposure to UV radiation degrades plastics and wood.

Stratospheric ozone depletion has been linked to the presence of chlorine and bromine in the stratosphere. Chemicals with long atmospheric lifetimes can migrate to the stratosphere, where the molecules break down from interaction with ultraviolet light or through chemical reaction. Chemicals such as CFCs and HCFCs release chlorine, which reacts with stratospheric ozone.

Ozone-depleting substances, including CFCs and HCFCs, are to be phased out of production under the Montreal Protocol (UNEP 2003, 2006). U.S. regulations for CFC and HCFC refrigerants, including phaseout schedules, may be found at <http://www.epa.gov/ozone/strathome.html>. The Alliance for Responsible Atmospheric Policy (<http://www.arap.org/regs/>) also briefly summarizes regulations for several countries. Reclaimed CFC and HCFC refrigerants that meet the requirements of ARI *Standard 700* can continue to be used for servicing existing systems.

Global Climate Change. The average global temperature is determined by the balance of energy from the sun heating the earth and its atmosphere and of energy radiated from the earth and the atmosphere to space. **Greenhouse gases (GHGs)**, such as carbon dioxide (CO₂) and water vapor, as well as small particles trap heat at and near the surface, maintaining the average temperature of the Earth's surface about 61°F warmer than would be the case if these gases and particles were not present (the **greenhouse effect**).

Global warming (also called **global climate change**) is a concern because of an increase in the greenhouse effect from increasing concentrations of GHGs attributed to human activities. The major GHG of concern is CO₂ released to the atmosphere when fossil fuels (coal, oil, and natural gas) are burned for energy. Methane (CH₄), nitrous oxide (N₂O), CFCs, HCFCs, HFCs, perfluorocarbons (PFCs), and sulfur hexafluoride (SF₆) are also GHGs.

In 1988, the United Nations Environment Programme (UNEP) and the World Meteorological Organization (WMO) established the Intergovernmental Panel on Climate Change (IPCC) to provide an objective source of information about the causes of climate change, its potential environmental and socioeconomic consequences, and the adaptation and mitigation options to respond to it. According to IPCC (2007a), atmospheric concentration of carbon dioxide has increased by more than 35% over the past 250 years, primarily from burning fossil fuels, with some contribution from deforestation. Concentration of methane has increased by over 145%, and nitrous oxide by about 18%. IPCC (2007a) deems atmospheric concentrations of fluorochemicals, including fluorocarbon gases (CFCs, HCFCs, and HFCs) and sulfur hexafluoride, to be a smaller contributor to global climate change. On whether observed warming is attributable to human influence, IPCC (2007b) concludes that "Most of the observed increase in global averaged temperatures since the mid-twentieth century [about 1.2°F] is very likely [90% confident] due to the observed increase in anthropogenic greenhouse gas concentrations."

The preparation of this chapter is assigned to TC 3.1, Refrigerants and Secondary Coolants.

Table 1 Refrigerant Data and Safety Classifications

Refrigerant Number	Chemical Name ^{a,b}	Chemical Formula ^a	Molecular Mass ^a	Normal Boiling Point, ^a °F	Safety Group
Methane Series					
11	Trichlorofluoromethane	CCl ₃ F	137.4	75	A1
12	Dichlorodifluoromethane	CCl ₂ F ₂	120.9	-20	A1
12B1	Bromochlorodifluoromethane	CBrClF ₂	165.4	25	
13	Chlorotrifluoromethane	CClF ₃	104.5	-115	A1

^aMolecular mass and normal boiling point are not part of this standard.

^bAzeotropic refrigerants exhibit some segregation of components at conditions of temperature and pressure other than those at which they were formulated. Extent of segregation depends on the particular azeotrope and hardware system configuration.

^cExact composition of this azeotrope is in question, and additional experimental studies are needed.

^dR-507, R-508, and R-509 are allowed designations for R-507A, R-508A, and R-509A because of a change in designations after assignment of R-500 through R-509. Corresponding changes were not made for R-500 through R-506.

Global Environmental Characteristics of Refrigerants. Atmospheric release of CFC and HCFC refrigerants such as R-11, R-12, R-22, and R-502 contributes to depletion of the ozone layer. The measure of a material's ability to deplete stratospheric ozone is its **ozone depletion potential (ODP)**, a value relative to that of R-11 which is 1.0.

Halocarbons (CFCs, HCFCs, and HFCs) and many nonhalocarbons (e.g., hydrocarbons, carbon dioxide) are also greenhouse gases. The **global warming potential (GWP)** of a GHG is an index describing its relative ability to trap radiant energy compared to CO₂ (R-744), which has a very long atmospheric lifetime. GWP may be calculated for any particular **integration time horizon (ITH)**. Typically, a 100 year ITH is used for regulatory purposes, and may be designated as GWP₁₀₀.

The energy refrigeration appliances consume is often produced from fossil fuels, which results in emission of CO₂, a contributor to global warming. This indirect effect associated with energy consumption is frequently much larger than the direct effect of refrigerant emissions. The **total equivalent warming impact (TEWI)** of an HVAC&R system is the sum of direct refrigerant emissions expressed in terms of CO₂ equivalents, and indirect emissions of CO₂ from the system's energy use over its service life. Another measure is **life-cycle climate performance (LCCP)**, which includes TEWI and adds direct and indirect emissions effects associated with manufacturing the refrigerant.

Ammonia (R-717), hydrocarbons, HCFCs, and most HFCs have shorter atmospheric lifetimes than CFCs because they are largely destroyed in the lower atmosphere by reactions with OH radicals. A shorter atmospheric lifetime generally results in lower ODP and GWP₁₀₀ values. Environmentally preferred refrigerants (1) have

low or zero ODP, (2) have relatively short atmospheric lifetimes, (3) have low GWP₁₀₀, (4) provide good system efficiency, (5) have appropriate safety properties, and (6) yield a low TEWI or LCCP in system applications (i.e., leaks are minimized or prevented, and performance is optimized).

Table 3 shows atmospheric lifetime, ODP, and GWP₁₀₀ of refrigerants being phased out under the Montreal Protocol and of refrigerants being used to replace them, alone or as components of blends. Because HFCs do not contain chlorine or bromine, their ODP values are negligible (Ravishankara et al. 1994) and thus are shown as 0 in Table 3. Nonhalocarbon refrigerants listed have zero ODP and very low GWP₁₀₀.

There are some differences between the values stipulated for reporting under the Montreal and Kyoto protocols and the latest scientific values. These are not of sufficient magnitude to significantly alter design decisions based on the numbers in the table. All these values have rather wide error bands and may change with each assessment of the science. Changes in GWP assessments are largely dominated by changes in understanding of CO₂, which is the reference chemical.

Table 4 shows the calculated ODPs and GWP₁₀₀s for refrigerant blends, using the latest scientific assessment values as reported in Calm and Hourahan (2007).

Physical Properties

Table 5 lists some physical properties of commonly used refrigerants, a few very-low-boiling-point cryogenic fluids, some newer refrigerants, and some older refrigerants of historical interest. These refrigerants are arranged in increasing order of atmospheric boiling point.

Table 5 also includes the freezing point, critical properties, and refractive index. Of these properties, normal boiling point is most important because it is a direct indicator of the temperature at which a refrigerant can be used. The freezing point must be lower than any contemplated usage. The critical properties describe a material at the

Fig. 2 Specific Heat of Aqueous Lithium Bromide Solutions

point where the distinction between liquid and gas is lost. At higher temperatures, no separate liquid phase is possible for pure fluids. In refrigeration cycles involving condensation, a refrigerant must be chosen that allows this change of state to occur at a temperature somewhat below the critical. Cycles that reject heat at supercritical temperatures (such as cycles using carbon dioxide) are also possible.

Lithium Bromide/Water and Ammonia/Water Solutions.

These are the most commonly used working fluids in absorption refrigeration systems. Figure 1 shows gravity, Figure 2 shows specific heat, and Figure 3 shows viscosity of lithium bromide/water solutions. Chapter 30 has an enthalpy-concentration diagram and a vapor pressure diagram for lithium bromide/water solutions. Chapter 30 also has equilibrium properties of water/ammonia solutions.

Electrical Properties

Tables 6 and 7 list the electrical characteristics of refrigerants that are especially important in hermetic systems.

Sound Velocity

The practical velocity of a gas in piping or through openings is limited by the velocity of sound in the gas.

Table 8 gives examples of the velocity of sound in the vapor phase of various refrigerants. Chapter 30 has sound velocity data for many refrigerants. The velocity increases when temperature is increased and decreases when pressure is increased. The velocity of sound can be calculated from the equation

$$V_a = \sqrt{g_c (dp/d\rho)_S} = \sqrt{\gamma g_c (dp/d\rho)_T} \quad (1)$$

where

- V_a = sound velocity, ft/s
- g_c = gravitational constant = 32.1740 lb_m·ft/lb_f·s²
- p = pressure, lb_f/ft²
- ρ = density, lb_m/ft³
- γ = c_p/c_v = ratio of specific heats
- S = entropy, Btu/lb·°R
- T = temperature, °R

Sound velocity can be estimated from tables of thermodynamic properties. Change in pressure with a change in density ($dp/d\rho$) can be estimated at either constant entropy or constant temperature. It is simpler to estimate at constant temperature, but the ratio of specific heats must also be known.

REFRIGERANT PERFORMANCE

Chapter 2 describes several methods of calculating refrigerant performance, and Chapter 30 includes tables of thermodynamic properties of refrigerants.

Table 9 shows the theoretical calculated performance of a number of refrigerants for a standard cycle of 5°F evaporation and 86°F condensation. In most cases, suction vapor is assumed to be saturated, and compression is assumed adiabatic or at constant entropy. For R-113 and R-114, for example, these assumptions cause some liquid in the discharge vapor. In these cases, it is assumed that discharge vapor is saturated and that suction vapor is slightly superheated. Note that actual operating conditions and performance differ somewhat from numbers in the table because of additional factors such as compressor efficiency and transport properties.

SAFETY

Tables 1 and 2 summarize toxicity and flammability characteristics of many refrigerants. In ASHRAE *Standard* 34, refrigerants are classified according to the hazard involved in their use. The toxicity and flammability classifications yield six safety groups (A1, A2, A3, B1, B2, and B3) for refrigerants. Group A1 refrigerants are the least hazardous, Group B3 the most hazardous.

The safety classification in ASHRAE *Standard* 34 consists of a capital letter and a numeral. The capital letter designates a toxicity class based on allowable exposure:

- Class A: Toxicity has not been identified at concentrations less than or equal to 400 ppm by volume, based on data used to determine threshold limit value/time-weighted average (TLV/TWA) or consistent indices.
- Class B: There is evidence of toxicity at concentrations below 400 ppm by volume, based on data used to determine TLV/TWA or consistent indices.

The numeral denotes flammability:

- Class 1: No flame propagation in air at 70°F and 14.7 psia
- Class 2: Lower flammability limit (LFL) greater than 0.00625 lb/ft³ at 70°F and 14.7 psia and heat of combustion less than 8174 Btu/lb
- Class 3: Highly flammable as defined by LFL less than or equal to 0.00625 lb/ft³ at 70°F and 14.7 psia or heat of combustion greater than or equal to 8174 Btu/lb

LEAK DETECTION

Leak detection in refrigeration equipment is of major importance for manufacturers and service engineers.

Electronic Detection

Electronic detectors are widely used in manufacture and assembly of refrigeration equipment. Instrument operation depends on the variation in current flow caused by ionization of decomposed refrigerant between two oppositely charged platinum electrodes. This instrument can detect any of the halogenated refrigerants except R-14; however, it is not recommended for use in atmospheres that contain explosive or flammable vapors. Other vapors, such as alcohol and carbon monoxide, may interfere with the test.

The electronic detector is the most sensitive of the various leak detection methods, reportedly capable of sensing a leak of 1/100 oz of R-12 per year. A portable model is available for field testing. Other models are available with automatic balancing systems that correct for refrigerant vapors that might be present in the atmosphere around the test area.

Bubble Method

The object to be tested is pressurized with air or nitrogen. A pressure corresponding to operating conditions is generally used. If possible, the object is immersed in water, and any leaks are detected by observing bubbles in the liquid. Adding a detergent to the water decreases surface tension, prevents escaping gas from clinging to the side of the object, and promotes formation of a regular stream of small bubbles. Kerosene or other organic liquids are sometimes used for the same reason. A solution of soap or detergent can be brushed or poured onto joints or other spots where leakage is suspected. Leaking gas forms soap bubbles that can be readily detected.

Leaks can also be determined by pressurizing or evacuating and observing the change in pressure or vacuum over a period of time. This is effective in checking system tightness but does not locate the point of leakage.

UV Dye Method

A stable UV-fluorescent dye is introduced into the system to be tested. Operating the system mixes the UV dye uniformly in the

*Superheat required.

oil/refrigerant system. The dye, which usually prefers oil, shows up at the leak's location, and can be detected using an appropriate UV lamp. Ensure that the dye is compatible with system components and that no one is exposed to UV radiation from the lamp. This method is often more effective for liquid leaks than for vapor.

Another, more expensive method is to use dispersive and nondispersive infrared analyzers. Although these analyzers are expensive, they can not only find the refrigerant leak but also identify the refrigerant.

Ammonia Leaks

Ammonia can be detected by any of the previously described methods, or by bringing a solution of hydrochloric acid near the object. If ammonia vapor is present, a white cloud or smoke of ammonium chloride forms. Ammonia can also be detected with indicator paper that changes color in the presence of a base.

EFFECT ON CONSTRUCTION MATERIALS

Metals

Halogenated refrigerants can be used satisfactorily under normal conditions with most common metals, such as steel, cast iron, brass, copper, tin, lead, and aluminum. Under more severe conditions, various metals affect properties such as hydrolysis and thermal decomposition in varying degrees. The tendency of metals to promote thermal decomposition of halogenated compounds is in the following order:

(least decomposition) Inconel < 18-8 stainless steel < nickel < copper < 1040 steel < aluminum < bronze < brass < zinc < silver (most decomposition)

This order is only approximate, and there may be exceptions for individual compounds or for special use conditions. The effect of metals on hydrolysis is probably similar.

Magnesium alloys and aluminum containing more than 2% magnesium are not recommended for use with halogenated compounds

Table 10 Swelling of Elastomers in Liquid Refrigerants at Room Temperature, % Linear Swell

Refrigerant Number	Polyiso- prene (Sulfur Cure)	Poly- chloro- prene	Butyl Rubber	Styrene		
				Buta- diene Rubber	Nitrile Rubber	Fluoro- elastomer

152a	4.2	3.0	1.7	2.8	8.8	3.91

where even trace amounts of water may be present. Zinc is not recommended for use with CFC-113. Experience with zinc and other fluorinated compounds has been limited, but no unusual reactivity has been observed under normal conditions of use in dry systems.

Ammonia should never be used with copper, brass, or other alloys containing copper. Further discussion of the compatibility of refrigerants and lubricants with construction materials may be found in Chapter 5 of the 2006 *ASHRAE Handbook—Refrigeration*.

Elastomers

Linear swelling of some elastomers in the liquid phase of HCFC and HFC refrigerants is shown in Table 10. Swelling data can be used to a limited extent in comparing the effect of refrigerants on elastomers. However, other factors, such as the amount of extraction, tensile strength, and degree of hardness of the exposed elastomer, must be considered. When other fluids (e.g., lubricants) are present in addition to the refrigerant, the combined effect on elastomers should be determined. Extensive test data for compatibility of elastomers and gasketing materials with refrigerants and lubricants are reported by Hammel et al. (1994). Diffusion of fluids through elastomers is another consideration; Table 11 shows the diffusion rate of water and R-22 through elastomers.

Table 11 Diffusion of Water and R-22 Through Elastomers

Elastomer	Diffusion Rate	
	Water ^a	R-22 ^b
Polychloroprene	0.717	1.31
Nitrile rubber	0.109	19.7
Chlorosulfonated polyethylene	0.457	0.52
Butyl rubber	0.043	0.30
Fluoroelastomer	—	3.61
Polyethylene	0.123	—
Natural	1.428	—

Adapted from Eiseman (1955).

^a0.003 in. film, 100% rh at 100°F. Water diffusion rate is in pounds per hour per 1000 ft² of elastomer.

^bFilm thickness = 0.001 in.; temperature = 77°F. Gas at 1 atm and 32°F. Diffusion rate per day in cubic feet of gas per square foot of elastomer.

Plastics

The effect of a refrigerant on a plastic material should be thoroughly examined under conditions of intended use, including the presence of lubricants. Plastics are often mixtures of two or more basic types, and it is difficult to predict the refrigerant's effect. Swelling data can be used as a general guide of effect, but, as with elastomers, the effect on properties of the plastic should also be examined. Extensive test data for compatibility of plastics with refrigerants and lubricants are reported by Cavestri (1993), including 23 plastics, 10 refrigerants, 7 lubricants, and 17 refrigerant/lubricant combinations. Refrigerants and lubricants had little effect on most of the plastics. Three plastics (acrylonitrile-butadiene-styrene, polyphenylene oxide, and polycarbonate) were affected enough to be considered incompatible. In a separate study by DuPont Fluoroproducts, two additional plastics (acrylic and polystyrene plastics) were determined to have questionable compatibility with HCFC and HFC refrigerants.

CHAPTER 30

THERMOPHYSICAL PROPERTIES OF REFRIGERANTS

THIS chapter presents data for thermodynamic and transport properties of refrigerants, arranged for the occasional user. The refrigerants have a thermodynamic property chart on pressure-enthalpy coordinates with an abbreviated set of tabular data for saturated liquid and vapor on the facing page. In addition, tabular data in the superheated vapor region are given for R-134a to assist students working on compression cycle examples.

For each cryogenic fluid, a second table of properties is provided for vapor at a pressure of one standard atmosphere; these data are needed when such gases are used in heat transfer or purge gas applications. For zeotropic blends, including R-729 (air), tables are incremented in pressure, with properties given for liquid on the bubble line and vapor on the dew line. This arrangement is used because pressure is more commonly measured in the field while servicing equipment; it also highlights the difference between bubble and dew-point temperatures (the “temperature glide” experienced with blends).

Most CFC refrigerants have been deleted. Tables for R-11, R-13, R-113, R-114, R-141b, R-142b, R-500, R-502, R-503, and R-720 (neon) may be found in the 1997 *ASHRAE Handbook—Fundamentals*. R-12 has been retained to assist in making comparisons. Revised formulations have been used for many refrigerants; these conform to international standards, where applicable. Thermodynamic properties of R-12, R-22, R-32, R-123, R-125, R-134a, R-143a, R-152a, R-717 (ammonia), and R-744 (carbon dioxide) and refrigerant blends R-404A, R-407C, R-410A, and R-507 conform to ISO/DIS *Draft Standard 17584, Refrigerant Properties*.

Reference states used for most refrigerants correspond to the American convention of 0 Btu/lb for enthalpy and 0 Btu/lb·°F for entropy for saturated liquid at –40°F. Exceptions are water and fluids with very low critical temperatures (e.g., ethylene, cryogen).

These data are intended to help engineers make preliminary comparisons among unfamiliar fluids. For greater detail and a wider range of data, see the sources in the References.

CHAPTER 31

PHYSICAL PROPERTIES OF SECONDARY COOLANTS (BRINES)

Brines	31.1
Inhibited Glycols	31.4
Halocarbons	31.12
Nonhalocarbon, Nonaqueous Fluids	31.13

In many refrigeration applications, heat is transferred to a **secondary coolant**, which can be any liquid cooled by the refrigerant and used to transfer heat without changing state. These liquids are also known as **heat transfer fluids**, **brines**, or **secondary refrigerants**.

Other ASHRAE Handbook volumes describe various applications for secondary coolants. In the 2006 *ASHRAE Handbook—Refrigeration*, refrigeration systems are discussed in Chapter 4, their uses in food processing in Chapters 14 to 29, and ice rinks in Chapter 35. In the 2007 *ASHRAE Handbook—HVAC Applications*, solar energy use is discussed in Chapter 33, thermal storage in Chapter 34, and snow melting and freeze protection in Chapter 50.

This chapter describes physical properties of several secondary coolants and provides information on their use. Additional, less widely used secondary coolants such as ethyl alcohol or potassium formate are not included in this chapter, but their physical properties are summarized in Melinder (2007). The chapter also includes

information on corrosion protection. Additional information on corrosion inhibition can be found in Chapter 48 of the 2007 *ASHRAE Handbook—HVAC Applications* and Chapter 4 of the 2006 *ASHRAE Handbook—Refrigeration*.

BRINES

Physical Properties

Water solutions of calcium chloride and sodium chloride are the most common refrigeration brines. Tables 1 and 2 list the properties of pure calcium chloride brine and sodium chloride brine. For commercial grades, use the formulas in the footnotes to these tables. For calcium chloride brines, Figure 1 shows specific heat, Figure 2 shows the ratio of mass of solution to that of water, Figure 3 shows viscosity, and Figure 4 shows thermal conductivity. Figures 5 to 8 show the same properties for sodium chloride brines.

Fig. 5 Specific Heat of Sodium Chloride Brines (adapted from Carrier 1959)

Fig. 6 Specific Gravity of Sodium Chloride Brines (adapted from Carrier 1959)

Brine applications in refrigeration are mainly in industrial machinery and in skating rinks. Corrosion is the principal problem for calcium chloride brines, especially in ice-making tanks where galvanized iron cans are immersed.

Ordinary salt (sodium chloride) is used where contact with calcium chloride is intolerable (e.g., the brine fog method of freezing fish and other foods). It is used as a spray to air-cool unit coolers to prevent frost formation on coils. In most refrigerating work, the lower freezing point of calcium chloride solution makes it more convenient to use.

Commercial calcium chloride, available as Type 1 (77% minimum) and Type 2 (94% minimum), is marketed in flake, solid, and solution forms; flake form is used most extensively. Commercial sodium chloride is available both in crude (rock salt) and refined grades. Because magnesium salts tend to form sludge, their presence in sodium or calcium chloride is undesirable.

Corrosion Inhibition

All brine systems must be treated to control corrosion and deposits. Historically, chloride-based brines were maintained at neutral

Fig. 7 Viscosity of Sodium Chloride Brines
(adapted from Carrier 1959)

Fig. 8 Thermal Conductivity of Sodium Chloride Brines
(adapted from Carrier 1959)

pH and treated with sodium chromate. However, using chromate as a corrosion inhibitor is no longer deemed acceptable because of its environmental effect. Instead, most brines use a sodium-nitrite-based inhibitor ranging from approximately 3000 ppm in calcium brines to 4000 ppm in sodium brines. Other, proprietary organic inhibitors are also available to mitigate the inherent corrosiveness of brines.

Before using any inhibitor package, review federal, state, and local regulations concerning the use and disposal of the spent fluids. If the regulations prove too restrictive, an alternative inhibition system should be considered.

INHIBITED GLYCOLS

Ethylene glycol and propylene glycol, when properly inhibited for corrosion control, are used as aqueous-freezing-point depressants (antifreeze) and heat transfer media. Their chief attributes are their ability to efficiently lower the freezing point of water, their low volatility, and their relatively low corrosivity when properly inhibited. Inhibited ethylene glycol solutions have better thermophysical properties than propylene glycol solutions, especially at lower temperatures. However, the less toxic propylene glycol is preferred for applications involving possible human contact or where mandated by regulations.

Physical Properties

Ethylene glycol and propylene glycol are colorless, practically odorless liquids that are miscible with water and many organic compounds. Table 3 shows properties of the pure materials.

The freezing and boiling points of aqueous solutions of ethylene glycol and propylene glycol are given in Tables 4 and 5. Note that increasing the concentration of ethylene glycol above 60% by mass causes the freezing point of the solution to increase. Propylene glycol solutions above 60% by mass do not have freezing points. Instead of freezing, propylene glycol solutions supercool and become a glass (a liquid with extremely high viscosity and the appearance and properties of a noncrystalline amorphous solid). On the dilute side of the eutectic (the mixture at which freezing produces a solid phase of the same composition), ice forms on freezing; on the concentrated side, solid glycol separates from solution on freezing. The

(Dow Chemical 2001b)

Fig. 10 Specific Heat of Aqueous Solutions of Industrially Inhibited Ethylene Glycol (vol. %)
(Dow Chemical 2001b)

freezing rate of such solutions is often quite slow, but, in time, they set to a hard, solid mass.

Physical properties (i.e., density, specific heat, thermal conductivity, and viscosity) for aqueous solutions of ethylene glycol can be found in Tables 6 to 9 and Figures 9 to 12; similar data for aqueous solutions of propylene glycol are in Tables 10 to 13 and Figures 13 to 16. Densities are for aqueous solutions of industrially inhibited glycols, and are somewhat higher than those for pure glycol and water alone. Typical corrosion inhibitor packages do not significantly affect other physical properties. Physical properties for the two fluids are similar, except for viscosity. At the same concentration, aqueous solutions of propylene glycol are more viscous than solutions of ethylene glycol. This higher viscosity accounts for the majority of the performance difference between the two fluids.

The choice of glycol concentration depends on the type of protection required by the application. If the fluid is being used to prevent equipment damage during idle periods in cold weather, such as winterizing coils in an HVAC system, 30% by volume ethylene glycol or 35% by volume propylene glycol is sufficient. These

concentrations allow the fluid to freeze. As the fluid freezes, it forms a slush that expands and flows into any available space. Therefore, expansion volume must be included with this type of protection. If the application requires that the fluid remain entirely liquid, use a concentration with a freezing point 5°F below the lowest expected temperature. Avoid excessive glycol concentration because it increases initial cost and adversely affects the fluid's physical properties.

Additional physical property data are available from suppliers of industrially inhibited ethylene and propylene glycol.

Corrosion Inhibition

Interestingly, ethylene glycol and propylene glycol, when not diluted with water, are actually less corrosive than water is with common construction metals. However, once diluted with water (as is typical), all aqueous glycol solutions are more corrosive than the water from which they are prepared. This is because uninhibited glycols oxidize with use to form acidic degradation products, and become increasingly more corrosive if not properly inhibited. The amount of oxidation is influenced by temperature, degree of aeration, and type of metal components to which the glycol solution is exposed. It is therefore necessary to use not only corrosion

Fig. 16 Viscosity of Aqueous Solutions of Industrially Inhibited Propylene Glycol (vol. %)
(Dow Chemical 2001a)

inhibitors that are effective for water-based fluids, but also additional additives to buffer or neutralize the acidic glycol degradation products that form during use. Corrosion inhibitors form a surface barrier that protects metal from attack, but their effectiveness is highly dependent on solution pH. Failure to compensate for glycol degradation leads to a downward shift in solution pH, which negates the usefulness of the corrosion inhibitor at protecting iron-based alloys (particularly cast iron and carbon steels, but also solders). Properly inhibited glycol products are available from several suppliers.

Service Considerations

Design Considerations. Inhibited glycols can be used at temperatures as high as 350°F. However, maximum-use temperatures vary from fluid to fluid, so the manufacturer's suggested temperature-use ranges should be followed. In systems with a high degree of aeration, the bulk fluid temperature should not exceed 150°F; however, temperatures up to 350°F are permissible in a pressurized system if air intake is eliminated. Maximum film temperatures should not exceed 50°F above the bulk temperature. Nitrogen blanketing minimizes oxidation when the system operates at elevated temperatures for extended periods.

Minimum operating temperatures for a recirculating fluid are typically -20°F for ethylene glycol solutions and 0°F for propylene glycol solutions. Operation below these temperatures is generally impractical, because the fluids' viscosity builds dramatically, thus increasing pumping horsepower requirements and reducing heat transfer film coefficients.

Standard materials can be used with most inhibited glycol solutions, except galvanized metals, which form insoluble zinc salts with the corrosion inhibitors. This depletes corrosion inhibitors below effective limits, and can cause excessive insoluble salt (sludge) formation.

Because removal of sludge and other contaminants is critical, install suitable filters. If inhibitors are rapidly and completely adsorbed by such contamination, the fluid is ineffective for corrosion inhibition. Consider such adsorption when selecting filters.

Storage and Handling. Inhibited glycol concentrates are stable, relatively noncorrosive materials with high flash points. These fluids can be stored in mild steel, stainless steel, or aluminum vessels. However, aluminum should be used only when the fluid temperature is below 150°F. Corrosion in the vapor space of vessels may be a problem, because the fluid's inhibitor package cannot reach these surfaces to protect them. A protective coating may be necessary (e.g., novolac-based vinyl ester resins, high-bake phenolic resins, polypropylene, polyvinylidene fluoride). To ensure the coating is suitable for

a particular application and temperature, consult the manufacturer. Because the chemical properties of an inhibited glycol concentrate differ from those of its dilutions, the effect of the concentrate on different containers should be known when selecting storage.

Choose transfer pumps only after considering temperature/viscosity data. Centrifugal pumps with electric motor drives are often used. Materials compatible with ethylene or propylene glycol should be used for pump packing material. Mechanical seals are also satisfactory. Bypass or inline filters are recommended to remove suspended particles, which can abrade seal surfaces. Welded mild steel transfer piping with a minimum diameter is normally used in conjunction with the piping, although flanged and gasketed joints are also satisfactory.

Preparation Before Application. Before an inhibited glycol is charged into a system, remove residual contaminants such as sludge, rust, brine deposits, and oil so the newly installed fluid functions properly. Avoid strong acid cleaners; if they are required, consider inhibited acids. Completely remove the cleaning agent before charging with inhibited glycol.

Dilution Water. Use distilled, deionized, or condensate water, because water from some sources contains elements that reduce the effectiveness of the inhibited formulation. If water of this quality is unavailable, water containing less than 25 ppm chloride, less than 25 ppm sulfate, and less than 100 ppm of total hardness may be used.

Fluid Maintenance. Glycol concentrations can be determined by refractive index, gas chromatography, or Karl Fischer analysis for water (assuming that the concentration of other fluid components, such as inhibitor, is known). Using density to determine glycol concentration is unsatisfactory because (1) density measurements are temperature-sensitive, (2) inhibitor concentrations can change density, (3) values for propylene glycol are close to those of water, and (4) propylene glycol values exhibit a maximum at 70 to 75% concentration.

An effective inhibitor monitoring and maintenance schedule is essential to keep a glycol solution relatively noncorrosive for a long period. Inspection immediately after installation, and annually thereafter, is normally an effective practice. Visual inspection of solution and filter residue can often detect potential system problems.

Many manufacturers of inhibited glycol-based heat transfer fluids provide analytical service to ensure that their product remains in good condition. This analysis may include some or all of the following: percent of ethylene and/or propylene glycol, freezing point, pH, reserve alkalinity, corrosion inhibitor evaluation, contaminants, total hardness, metal content, and degradation products. If maintenance on the fluid is required, recommendations may be given along with the analysis results.

Properly inhibited and maintained glycol solutions provide better corrosion protection than brine solutions in most systems. A long, though not indefinite, service life can be expected. Avoid indiscriminate mixing of inhibited formulations.

HALOCARBONS

Many common refrigerants are used as secondary coolants as well as primary refrigerants. Their favorable properties as heat transfer fluids include low freezing points, low viscosities, nonflammability, and good stability. Chapters 29 and 30 present physical and thermodynamic properties for common refrigerants.

Tables 1 and 2 in Chapter 29 summarizes comparative safety characteristics for halocarbons. ACGIH has more information on halocarbon toxicity threshold limit values and biological exposure indices (see the Bibliography).

Construction materials and stability factors in halocarbon use are discussed in Chapter 29 of this volume and Chapter 5 of the 2006 *ASHRAE Handbook—Refrigeration*.

NONHALOCARBON, NONAQUEOUS FLUIDS

Numerous additional secondary refrigerants, used primarily by the chemical processing and pharmaceutical industries, have been used rarely in the HVAC and allied industries because of their cost and relative novelty. Before choosing these types of fluids, consider electrical classifications, disposal, potential worker exposure, process containment, and other relevant issues.

Tables 14 to 16 list physical properties for a mixture of dimethylsiloxane polymers of various relative molecular masses (Dow Corning 1989) and d-limonene. Information on d-limonene is limited; it is based on measurements made over small data temperature

ranges or simply on standard physical property estimation techniques. The compound (molecular formula C₁₀H₁₆) is derived as an extract from orange and lemon oils.

The mixture of dimethylsiloxane polymers can be used with most standard construction materials; d-limonene, however, can be quite corrosive, easily autooxidizing at ambient temperatures. This fact should be understood and considered before using d-limonene in a system.

CHAPTER 32

SORBENTS AND DESICCANTS

<i>Desiccant Applications</i>	32.1
<i>Desiccant Cycle</i>	32.1
<i>Types of Desiccants</i>	32.3
<i>Desiccant Isotherms</i>	32.5
<i>Desiccant Life</i>	32.5
<i>Cosorption of Water Vapor and Indoor Air Contaminants</i>	32.5

SORPTION refers to the binding of one substance to another. **Sorbents** are materials that have an ability to attract and hold other gases or liquids. They can be used to attract gases or liquids other than water vapor, which makes them very useful in chemical separation processes. **Desiccants** are a subset of sorbents; they have a particular affinity for water.

Virtually all materials are desiccants; that is, they attract and hold water vapor. Wood, natural fibers, clays, and many synthetic materials attract and release moisture as commercial desiccants do, but they lack holding capacity. For example, woolen carpet fibers attract up to 23% of their dry weight in water vapor, and nylon can take up almost 6% of its weight in water. In contrast, a commercial desiccant takes up between 10 and 1100% of its dry weight in water vapor, depending on its type and on the moisture available in the environment. Furthermore, commercial desiccants continue to attract moisture even when the surrounding air is quite dry, a characteristic that other materials do not share.

All desiccants behave in a similar way: they attract moisture until they reach equilibrium with the surrounding air. Moisture is usually removed from the desiccant by heating it to temperatures between 120 and 500°F and exposing it to a scavenger airstream. After the desiccant dries, it must be cooled so that it can attract moisture once again. Sorption always generates sensible heat equal to the latent heat of the water vapor taken up by the desiccant plus an additional heat of sorption that varies between 5 and 25% of the latent heat of the water vapor. This heat is transferred to the desiccant and to the surrounding air.

The process of attracting and holding moisture is described as either adsorption or absorption, depending on whether the desiccant undergoes a chemical change as it takes on moisture. **Adsorption** does not change the desiccant, except by addition of the weight of water vapor; it is similar in some ways to a sponge soaking up water. **Absorption**, on the other hand, changes the desiccant. An example of an absorbent is table salt, which changes from a solid to a liquid as it absorbs moisture.

DESICCANT APPLICATIONS

Desiccants can dry either liquids or gases, including ambient air, and are used in many air-conditioning applications, particularly when the

- Latent load is large in comparison to the sensible load
- Energy cost to regenerate the desiccant is low compared to the cost of energy to dehumidify the air by chilling it below its dew point and reheating it
- Moisture control level for the space would require chilling the air to subfreezing dew points if compression refrigeration alone were used to dehumidify the air

The preparation of this chapter is assigned to TC 8.12, Desiccant Dehumidification Equipment and Components.

- Temperature control level for the space or process requires continuous delivery of air at subfreezing temperatures

In any of these situations, the cost of running a vapor compression cooling system can be very high. A desiccant process may offer considerable advantages in energy, initial cost of equipment, and maintenance.

Because desiccants can attract and hold more than simply water vapor, they can remove contaminants from airstreams to improve indoor air quality. Desiccants have been used to remove organic vapors and, in special circumstances, to control microbiological contaminants (Battelle 1971; Buffalo Testing Laboratory 1974). Hines et al. (1991) also confirmed their usefulness in removing vapors that can degrade indoor air quality. Desiccant materials can adsorb hydrocarbon vapors while they are collecting moisture from air. These cosorption phenomena show promise of improving indoor air quality in typical building HVAC systems.

Desiccants are also used in drying compressed air to low dew points. In this application, moisture can be removed from the desiccant without heat. Desorption is accomplished using differences in vapor pressures compared to the total pressures of the compressed and ambient pressure airstreams.

Finally, desiccants are used to dry the refrigerant circulating in air-conditioning and refrigeration systems. This reduces corrosion in refrigerant piping and prevents valves and capillaries from becoming clogged with ice crystals. In this application, the desiccant is not regenerated; it is discarded when it has adsorbed its limit of water vapor.

This chapter discusses the water sorption characteristics of desiccant materials and explains some of the implications of those characteristics in ambient pressure air-conditioning applications. Information on other applications for desiccants can be found in Chapter 36 of this volume; Chapters 6, 26, 35, 41, and 45 of the 2006 *ASHRAE Handbook—Refrigeration*; Chapters 1, 2, 5, 9, 16, 18, 21, 28, and 45 of the 2007 *ASHRAE Handbook—HVAC Applications*; and Chapters 23 and 25 of the 2008 *ASHRAE Handbook—HVAC Systems and Equipment*.

DESICCANT CYCLE

Practically speaking, all desiccants function by the same way: by moisture transfer caused by a difference between water vapor pressures at their surface and of the surrounding air. When the vapor pressure at the desiccant surface is lower than that of the air, the desiccant attracts moisture. When the surface vapor pressure is higher than that of the surrounding air, the desiccant releases moisture.

Figure 1 shows the moisture content relationship between a desiccant and its surface vapor pressure. As the moisture content of the desiccant rises, so does the water vapor pressure at its surface. At some point, the vapor pressure at the desiccant surface is the same as that of the air: the two are in equilibrium. Then, moisture cannot move in either direction until some external force changes the vapor pressure at the desiccant or in the air.

Fig. 1 Desiccant Water Vapor Pressure as Function of Moisture Content
(Harriman 2003)

Fig. 2 Desiccant Water Vapor Pressure as Function of Desiccant Moisture Content and Temperature
(Harriman 2003)

Figure 2 shows the effect of temperature on vapor pressure at the desiccant surface. Both higher temperature and increased moisture content increase surface vapor pressure. When surface vapor pressure exceeds that of the surrounding air, moisture leaves the desiccant (**reactivation** or **regeneration**). After the desiccant is dried (reactivated) by the heat, its vapor pressure remains high, so it has very little ability to absorb moisture. **Cooling** the desiccant reduces its surface vapor pressure so that it can absorb moisture again. The complete cycle is illustrated in Figure 3.

The economics of desiccant operation depend on the energy cost of moving a given material through this cycle. Dehumidification of air (loading the desiccant with water vapor) generally proceeds without energy input other than fan and pump costs. The major portion of energy is invested in regenerating the desiccant (moving from point 2 to point 3) and cooling the desiccant (point 3 to point 1).

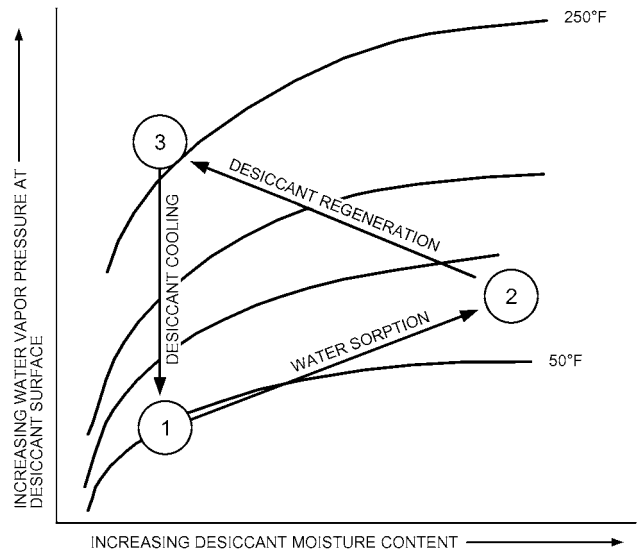

Fig. 3 Desiccant Cycle
(Harriman 2003)

Table 1 Vapor Pressures of Different Relative Humidities at 70°F

Relative Humidity at 70°F, %	Dew Point, °F	Vapor Pressure, in. Hg
10	12	0.07
20	28	0.15
30	37	0.22
40	45	0.30
50	51	0.37
60	55	0.44
70	60	0.52
80	64	0.59
90	67	0.67
100	70	0.74

Regeneration energy is equal to the sum of the heat

- Necessary to raise the desiccant to a temperature high enough to make its surface vapor pressure higher than that of the surrounding air
- Necessary to vaporize the moisture it contains (about 1060 Btu/lb)
- From desorption of water from the desiccant (a small amount)

The **cooling energy** is proportional to the (1) desiccant mass and (2) difference between its temperature after regeneration and the lower temperature that allows the desiccant to remove water from the airstream again.

The cycle is similar when desiccants are regenerated using pressure differences in a compressed air application. The desiccant is saturated in a high-pressure chamber (i.e., that of the compressed air). Then valves open, isolating the compressed air from the material, and the desiccant is exposed to air at ambient pressure. The saturated desiccant's vapor pressure is much higher than ambient air at normal pressures; thus, moisture leaves the desiccant for the surrounding air. An alternative desorption strategy returns a small portion of dried air to the moist desiccant bed to reabsorb moisture, then vents that moist air to the atmosphere.

Table 1 shows the range of vapor pressures over which the desiccant must operate in space-conditioning applications. It converts the relative humidity at 70°F to dew point and the corresponding vapor pressure. The greater the difference between the air and desiccant surface vapor pressures, the greater the ability of the material to absorb moisture from the air at that moisture content.

The ideal desiccant for a particular application depends on the range of water vapor pressures likely to occur in the air, temperature of the regeneration heat source, and moisture sorption and desorption characteristics of the desiccant within those constraints. In commercial practice, however, most desiccants can be made to perform well in a wide variety of operating situations through careful engineering of the mechanical aspects of the dehumidification system. Some of these hardware issues are discussed in Chapter 23 of the 2008 *ASHRAE Handbook—HVAC Systems and Equipment*.

TYPES OF DESICCANTS

Desiccants can be liquids or solids and can hold moisture through absorption or adsorption, as described earlier. Most absorbents are liquids, and most adsorbents are solids.

Liquid Absorbents

Liquid absorption dehumidification can best be illustrated by comparison to air washer operation. When air passes through an air washer, its dew point approaches the temperature of the water supplied to the machine. Air that is more humid is dehumidified, and air that is less humid is humidified. In a similar manner, a liquid absorption dehumidifier brings air into contact with a liquid desiccant solution. The liquid’s vapor pressure is lower than water at the same temperature, and air passing over the solution approaches this reduced vapor pressure; it is dehumidified.

The vapor pressure of a liquid absorption solution is directly proportional to its temperature and inversely proportional to its concentration. Figure 4 illustrates the effect of increasing desiccant concentration on the water vapor pressure at its surface. The figure shows the vapor pressure of various solutions of water and triethylene glycol, a commercial liquid desiccant. As the mixture’s glycol content increases, its vapor pressure decreases. This lower pressure allows the glycol solution to absorb moisture from

the air whenever the air’s vapor pressure is greater than that of the solution.

Viewed another way, the vapor pressure of a given concentration of absorbent solution approximates the vapor pressure values of a fixed relative humidity line on a psychrometric chart. Higher solution concentrations give lower equilibrium relative humidities, which allow the absorbent to dry air to lower levels.

Figure 5 illustrates the effect of temperature on the vapor pressure of various solutions of water and lithium chloride (LiCl), another common liquid desiccant. A solution that is 25% lithium chloride has a vapor pressure of 0.37 in. Hg at a temperature of 70°F. If the same 25% solution is heated to 100°F, its vapor pressure more than doubles to 0.99 in. Hg. Expressed another way, the 70°F, 25% solution is in equilibrium with air at a 51°F dew point. The same 25% solution at 100°F is at equilibrium with an airstream at a 79°F dew point. The warmer the desiccant, the less moisture it can attract from the air.

In standard practice, behavior of a liquid desiccant is controlled by adjusting its temperature, concentration, or both. Desiccant temperature is controlled by simple heaters and coolers. Concentration is controlled by heating the desiccant to drive moisture out into a waste airstream or directly to the ambient.

Commercially available liquid desiccants have an especially high water-holding capacity. Each molecule of LiCl, for example, can hold two water molecules, even in the dry state. Above two water molecules per molecule of LiCl, the desiccant becomes a liquid and continues to absorb water. If the solution is in equilibrium with air at 90% rh, approximately 26 water molecules are attached to each molecule of LiCl. This represents a water absorption of more than 1000% on a dry-weight basis.

As a practical matter, however, the absorption process is limited by the exposed surface area of desiccant and by the contact time allowed for reaction. More surface area and more contact time allow the desiccant to approach its theoretical capacity. Commercial desiccant systems stretch these limits by flowing liquid desiccant onto an extended surface, much like in a cooling tower.

(from data of Dow 1981)

Fig. 5 Surface Vapor Pressure of Water/Lithium Chloride Solutions
(from data of Foote Mineral 1988)

Solid Adsorbents

Adsorbents are solid materials with a tremendous internal surface area per unit of mass; a single gram can have more than 50,000 ft² of surface area. Structurally, adsorbents resemble a rigid sponge, and the surface of the sponge in turn resembles the ocean coastline of a fjord. This analogy indicates the scale of the different surfaces in an adsorbent. The fjords can be compared to the **capillaries** in the adsorbent. The spaces between the grains of sand on the fjord beaches can be compared to the spaces between the individual molecules of adsorbent, all of which have the capacity to hold water molecules. The bulk of the adsorbed water is contained by condensation into the capillaries, and the majority of the surface area that attracts individual water molecules is in the crystalline structure of the material itself.

Adsorbents attract moisture because of the electrical field at the desiccant surface. The field is not uniform in either force or charge, so specific sites on the desiccant surface attract water molecules that have a net opposite charge. When the complete surface is covered, the adsorbent can hold still more moisture because vapor condenses into the first water layer and fills the capillaries throughout the material. As with liquid absorbents, the ability of an adsorbent to attract moisture depends on the difference in vapor pressure between its surface and the air.

The capacity of solid adsorbents is generally less than the capacity of liquid absorbents. For example, a typical molecular sieve adsorbent can hold 17% of its dry weight in water when the air is at 70°F and 20% rh. In contrast, LiCl can hold 130% of its mass at the same temperature and relative humidity. But solid adsorbents have several other favorable characteristics.

For example, molecular sieves continue to adsorb moisture even when they are quite hot, allowing dehumidification of very warm airstreams. Also, several solid adsorbents can be manufactured to precise tolerances, with pore diameters that can be closely controlled. This means they can be tailored to adsorb molecules of a specific diameter. Water, for example, has an effective molecular diameter of 3.2 Ångstrom. A molecular sieve adsorbent with an average pore diameter of 4.0 Ångstrom adsorbs water but has almost no capacity for larger molecules, such as organic solvents. This selective adsorption characteristic is useful in many applications. For example, several desiccants with different pore sizes can be combined in series to remove first water and then other specific contaminants from an airstream.

Adsorption Behavior. Adsorption behavior depends on (1) total surface area, (2) total volume of capillaries, and (3) range of capillary diameters. A large surface area gives the adsorbent a larger capacity at low relative humidities. Large capillaries provide a high capacity for condensed water, which gives the adsorbent a higher capacity at high relative humidities. A narrow range of capillary diameters makes an adsorbent more selective in the vapor molecules it can hold.

In designing a desiccant, some tradeoffs are necessary. For example, materials with large capillaries necessarily have a smaller surface area per unit of volume than those with smaller capillaries. As a result, adsorbents are sometimes combined to provide a high adsorption capacity across a wide range of operating conditions. Figure 6 illustrates this point using three noncommercial silica gel adsorbents prepared for use in laboratory research. Each has a different internal structure, but because they are all silicas, they have similar surface adsorption characteristics. Gel 1 has large capillaries, making its total volume large but its total surface area small. It has a large adsorption capacity at high relative humidities but adsorbs a small amount at low relative humidities.

In contrast, Gel 8 has a capillary volume one-seventh the size of Gel 1, but a total surface area almost twice as large. This gives it a higher capacity at low relative humidities but a lower capacity to hold the moisture that condenses at high relative humidities.

Silica gels and most other adsorbents can be manufactured to provide optimum performance in a specific application, balancing

capacity against strength, weight, and other favorable characteristics (Bry-Air 1986).

Types of Solid Adsorbents. General classes of solid adsorbents include

- Silica gels
- Zeolites
- Synthetic zeolites (molecular sieves)
- Activated aluminas
- Carbons
- Synthetic polymers

Silica gels are amorphous solid structures formed by condensing soluble silicates from solutions of water or other solvents. Advantages include relatively low cost and relative simplicity of structural customizing. They are available as large as spherical beads about 3/16 in. in diameter or as small as grains of a fine powder.

Zeolites are aluminosilicate minerals. They occur in nature and are mined rather than synthesized. Zeolites have a very open crystalline lattice that allows molecules like water vapor to be held inside the crystal itself like an object in a cage. Particular atoms of an aluminosilicate determine the size of the openings between the “bars” of the cage, which in turn governs the maximum size of the molecule that can be adsorbed into the structure.

Synthetic zeolites, also called **molecular sieves**, are crystalline aluminosilicates manufactured in a thermal process. Controlling the process temperature and the composition of the ingredient materials allows close control of the structure and surface characteristics of

Gel Number	Total Surface Area, m ² /g	Average Capillary Diameter, nm	Total Volume of Capillaries, mm ³ /g
1	315	21	1700
5	575	3.8	490
8	540	2.2	250

Fig. 6 Adsorption and Structural Characteristics of Some Experimental Silica Gels
(from data of Oscic and Cooper 1982)

the adsorbent. At a somewhat higher cost, this provides a much more uniform product than naturally occurring zeolites.

Activated aluminas are oxides and hydrides of aluminum that are manufactured in thermal processes. Their structural characteristics can be controlled by the gases used to produce them and by the temperature and duration of the thermal process.

Carbons are most frequently used for adsorption of gases other than water vapor because they have a greater affinity for the nonpolar molecules typical of organic solvents. Like other adsorbents, carbons have a large internal surface and especially large capillaries. This capillary volume gives them a high capacity to adsorb water vapor at relative humidities of 45 to 100%.

Synthetic polymers have potential for use as desiccants as well. Long molecules, like those found in polystyrenesulfonic acid sodium salt (PSSASS), are twisted together like strands of string. Each of the many sodium ions in the long PSSASS molecules has the potential to bind several water molecules, and the spaces between the packed strings can also contain condensed water, giving the polymer a capacity exceeding that of many other solid adsorbents.

DESICCANT ISOTHERMS

Figure 7 shows a rough comparison of the sorption characteristics of different desiccants. Large variations from these isotherms occur because manufacturers use different methods to optimize materials for different applications. The suitability of a given desiccant to a particular application is generally governed as

Sources for isotherms presented in the figure include
PSSASS: Czanderna (1988)
Lithium chloride: Munters Corporation; Cargocaire Division and Kathabar, Inc.
Triethylene glycol: Dow Chemical Corporation
Silica gel: Davison Chemical Division of W.R. Grace Co.
Activated carbon: Calgon Corporation
Activated alumina: LaRoche Industries Inc.
Molecular sieve: Davison Chemical Division of W.R. Grace Co.

Fig. 7 Sorption Isotherms of Various Desiccants

much by the engineering of the mechanical system that presents the material to the airstreams as by the characteristics of the material itself.

Several sources give details of desiccant equipment design and information about desiccant isotherm characteristics. Brunauer (1945) considers five basic isotherm shape types. Each isotherm shape is determined by the dominant sorption mechanisms of the desiccant, which give rise to its specific capacity characteristics at different vapor pressures. Isotherm shape can be important in designing the optimum desiccant for applications where a narrow range of operating conditions can be expected. Collier (1986, 1988) illustrates how an optimum isotherm shape can be used to ensure a maximum coefficient of performance in one particular air-conditioning desiccant application.

DESICCANT LIFE

The useful life of desiccant materials depends largely on the quantity and type of contamination in the airstreams they dry. In commercial equipment, desiccants last from 10,000 to 100,000 h or longer before they need replacement. Normally, two mechanisms cause the loss of desiccant capacity: (1) change in desiccant sorption characteristics through **chemical reactions** with contaminants and (2) loss of effective surface area through clogging or **hydrothermal degradation**.

Liquid adsorbents are more susceptible to chemical reaction with airstream contaminants other than water vapor than are solid adsorbents. For example, certain sulfur compounds can react with LiCl to form lithium sulfate, which is not a desiccant. If the concentration of sulfur compounds in the airstream were below 10 ppm and the desiccant were in use 24 h a day, capacity reduction would be approximately 10 to 20% after three years of operation. If the concentration were 30 ppm, this reduction would occur after one year. In contaminated environments, equipment manufacturers often arrange filters to remove these products of reaction, and provide devices to replenish desiccant so that capacity stays constant.

Solid adsorbents tend to be less chemically reactive and more sensitive to clogging, a function of the type and quantity of particulate material in the airstream. Also, certain types of silica gel can be sensitive to saturated airstreams or to liquid moisture carried over from cooling coils into the desiccant bed. In more challenging applications, thermally stabilized desiccants are used in place of less durable materials.

In air-conditioning applications, desiccant equipment is designed to minimize the need for desiccant replacement in much the same way that vapor compression cooling systems are designed to avoid the need for compressor replacement. Unlike filters, desiccants are seldom intended to be frequently replaced during normal service in an air-drying application.

COSORPTION OF WATER VAPOR AND INDOOR AIR CONTAMINANTS

Hines et al. (1991) confirmed that many desiccant materials can collect common indoor pollutants while they collect water vapor from ambient air. This characteristic promises to become useful in future air-conditioning systems where indoor air quality is especially important.

The behavior of different desiccant and vapor mixtures is complex, but in general, pollutant sorption reactions can be classified into five categories:

- Humidity-neutral sorption
- Humidity-reduced sorption
- Humidity-enhanced sorption
- Humidity-pollutant displacement
- Desiccant-catalyzed pollutant conversion

Humidity-reduced sorption is illustrated by the behavior of water vapor and chloroform on activated carbon. Sorption is humidity-neutral until relative humidity exceeds 45%, when the uptake of chloroform is reduced. The adsorbed water blocks sites that would otherwise attract and hold chloroform. In contrast, water and carbonyl chloride mixtures on activated carbon demonstrate humidity-enhanced sorption (i.e., sorption of the pollutant increases at high relative humidities). Hines et al. (1991) attribute this phenomenon to the high water solubility of carbonyl chloride.

CHAPTER 33

PHYSICAL PROPERTIES OF MATERIALS

VALUES in the following tables are in consistent units to assist the engineer looking for approximate values. For data on refrigerants, see Chapter 29; for secondary coolants, see Chapter 31. Chapter 26 gives more information on the values for materials used in building construction and insulation. Many

properties vary with temperature, material density, and composition. The references document the source of the values and provide more detail or values for materials not listed here. The preparation of this chapter is assigned to TC 1.3, Heat Transfer and Fluid Flow.

<i>U.S. Energy Use</i>	34.6
<i>U.S. Agencies and Associations</i>	34.8

BECAUSE energy used in buildings and facilities composes a significant amount of the total energy used for all purposes, and thus affects energy resources, ASHRAE recognizes the “effect of its technology on the environment and natural resources to protect the welfare of posterity” (ASHRAE 2003).

Many governmental agencies regulate energy conservation, often through the procedures to obtain building permits. Required efficiency values for building energy use strongly influence selection of HVAC&R systems and equipment and how they are applied.

More information on sustainable design is available in the *ASHRAE GreenGuide* (2006) and in Chapter 35.

CHARACTERISTICS OF ENERGY AND ENERGY RESOURCE FORMS

The HVAC&R industry deals with energy forms as they occur on or arrive at a building site. Generally, these forms are fossil fuels (natural gas, oil, and coal) and electricity. Solar and wind energy are also available at most sites, as is low-level geothermal energy (an energy source for heat pumps). Direct-use (high-temperature) geothermal energy is available at some locations.

Forms of On-Site Energy

Fossil fuels and electricity are commodities that are usually metered or measured for payment at the facility’s location. Solar or wind energy is freely available but does incur cost for the means to use it. High-temperature geothermal energy, which is not universally available, may or may not be a sold commodity, depending on the particular locale and local regulations. Chapter 32 of the 2007 *ASHRAE Handbook—HVAC Applications* has more information on geothermal energy.

Some on-site energy forms require further processing or conversion into more suitable forms for the particular systems and equipment in a building or facility. For instance, natural gas or oil is burned in a boiler to produce steam or hot water, which is then distributed to various use points (e.g., heating coils in air-handling systems, unit heaters, convectors, fin-tube elements, steam-powered cooling units, humidifiers, kitchen equipment) throughout the building. Although the methods and efficiencies of these processes fall within the scope of the HVAC&R designer, *how* an energy source arrives at a given facility site is not under direct control. On-site energy choices, if available, may be controlled by the designer based in part on the present and projected future availability of the resources.

The basic energy source for heating may be natural gas, oil, coal, or electricity. Cooling may be produced by electricity, thermal energy, or natural gas. If electricity is generated on site, the generator may be driven by an engine or fuel cell that consumes fossil fuels or hydrogen on site, or by a turbine using steam or gas directly.

The term **energy source** refers to on-site energy in the form in which it arrives at or occurs on a site (e.g., electricity, gas, oil, coal). **Energy resource** refers to the raw energy that (1) is extracted from the earth (wellhead or mine-mouth), (2) is used to generate the energy source delivered to a building site (e.g., coal used to generate electricity), or (3) occurs naturally and is available at a site (solar, wind, or geothermal energy).

Nonrenewable and Renewable Energy Resources

From the standpoint of energy conservation, energy resources can be classified as either (1) nonrenewable resources, which have definite, although sometimes unknown, limitations; or (2) renewable resources, which have the potential to regenerate in a reasonable period. Resources used most in industrialized countries are nonrenewable (ASHRAE 2003).

Note that *renewable* does not mean an infinite supply. For instance, hydropower is limited by rainfall and appropriate sites, usable geothermal energy is available only in limited areas, and crops are limited by the available farm area and competing nonenergy land uses. Other forms of renewable energy also have supply limitations.

Nonrenewable resources of energy include

- Coal
- Crude oil
- Natural gas
- Uranium or plutonium (nuclear energy)

Renewable resources of energy include

- Hydropower
- Solar
- Wind
- Earth heat (geothermal)
- Biomass (wood, wood wastes, and municipal solid waste, landfill methane, etc.)
- Tidal power
- Ocean thermal
- Atmosphere or large body of water (as used by the heat pump)
- Crops (for alcohol production or as boiler fuel)

Characteristics of Fossil Fuels and Electricity

Most on-site energy for buildings in developed countries involves electricity and fossil fuels as primary on-site energy sources. Both fossil fuels and electricity can be described by their energy content (Btu). This implies that energy forms are comparable and that an equivalence can be established. In reality, however, they are only comparable in energy terms when they are used to generate heat. Fossil fuels, for example, cannot directly drive motors or energize light bulbs. Conversely, electricity gives off heat as a byproduct regardless of whether it is used for running a motor or lighting a light bulb, and regardless of whether that heat is needed. Thus,

The preparation of this chapter is assigned to TC 2.8, Building Environmental Impacts and Sustainability.

electricity and fossil fuels have different characteristics, uses, and capabilities aside from any differences in their derivation.

Other differences between energy forms include methods of extraction, transformation, transportation, and delivery, and characteristics of the resource itself. Natural gas arrives at the site in virtually the same form in which it was extracted from the earth. Oil is processed (distilled) before arriving at the site; having been extracted as crude oil, it arrives at a given site as, for example, No. 2 oil or diesel fuel. Electricity is created (converted) from a different energy form, often a fossil fuel, which itself may first be converted to a thermal form. The total electricity conversion, or generation, process includes energy losses governed largely by the laws of thermodynamics.

Fuel cells, which are used only on a small scale, convert a fossil fuel to electricity by chemical means.

Fossil fuels undergo a conversion process by combustion (oxidation) and heat transfer to thermal energy in the form of steam or hot water. The conversion equipment is a boiler or a furnace in lieu of a generator, and conversion usually occurs on a project site rather than off-site. (District heating or cooling is an exception.) Inefficiencies of the fossil fuel conversion occur on site, whereas inefficiencies of most electricity generation occur off site, before the electricity arrives at the building site. (Cogeneration is an exception.)

Sustainability is an important consideration for energy use. The United Nations' Brundtland Report (UN 1987) stated that the development of the built environment is sustainable if it "meets the needs of the present without compromising the ability of future generations to meet their own needs." More information may be found in Chapter 35.

ON-SITE ENERGY/ENERGY RESOURCE RELATIONSHIPS

An HVAC&R designer must select one or more forms of energy. Most often, these are fossil fuels and electricity, although installations are sometimes designed using a single energy source (e.g., only a fossil fuel or only electricity).

Solar energy normally impinges on the site (and on the facilities to be put there), so it affects the facility's energy consumption. The designer must account for this effect and may have to decide whether to make active use of solar energy. Other naturally occurring and distributed renewable forms such as wind power and earth heat (if available) might also be considered.

The designer should be aware of the relationship between on-site energy sources and raw energy resources, including how these resources are used and what they are used for. The relationship between energy sources and energy resources involves two parts: (1) quantifying the energy resource units expended and (2) considering the societal effect of depletion of one energy resource (caused by on-site energy use) with respect to others.

Quantifiable Relationships

As on-site energy sources are consumed, a corresponding amount of resources are consumed to produce that on-site energy. For instance, for every volume of No. 2 oil consumed by a boiler at a building site, some greater volume of crude oil is extracted from the earth. On leaving the well, the crude oil is transported and processed into its final form, perhaps stored, and then transported to the site where it will be used.

Even though natural gas often requires no significant processing, it is transported, often over long distances, to reach its final destination, which causes some energy loss. Electricity may have as its raw energy resource a fossil fuel, uranium, or an elevated body of water (hydroelectric generating plant).

Data are available to help determine the amount of resource use per delivered on-site energy source unit. In the United States, data are available from entities within the U.S. Department of Energy and from the agencies and associations listed at the end of this chapter.

A **resource utilization factor (RUF)** is the ratio of resources consumed to energy delivered (for each form of energy) to a

building site. Specific RUFs may be determined for various energy sources normally consumed on site, including nonrenewable sources such as coal, gas, oil, and electricity, and renewable sources such as solar, geothermal, waste, and wood energy. With electricity, which may derive from several resources depending on the particular fuel mix of the generating stations in the region served, the overall RUF is the weighted combination of individual factors applicable to electricity and a particular energy resource. Grumman (1984) gives specific formulas for calculating RUFs.

There are great differences in the efficiency of equipment used in buildings. Although electricity incurs losses in its production, it is often much more efficient than direct fuel use at the building site, particularly for lighting or heat pump applications. Minimizing both energy cost and the amount of energy resources needed to accomplish a task effectively should be a major design goal, which requires consideration of both RUFs and end-use efficiency of building equipment.

Although a designer is usually not required to determine the amount of energy resources attributable to a given building or building site for its design or operation, this information may be helpful when assessing the long-range availability of energy for a building or the building's effect on energy resources. Fuel-quantity-to-energy resource ratios or factors are often used, which suggests that energy resources are of concern to the HVAC&R industry.

Intangible Relationships

Energy resources should not simply be converted into common energy units [e.g., quadrillion (10^{15}) Btu or quad] because the commonality gives a misleading picture of the equivalence of these resources. Other differences and limitations of each of the resources defy easy quantification. For instance, electricity that arrives and is used on a site can be generated from coal, oil, natural gas, uranium, or hydropower. The end result is the same: electricity at x kV, y Hz. However, the societal impact of a kilowatt-hour of electricity generated by hydropower may not equal that of a kilowatt-hour generated by coal, uranium, domestic oil, or imported oil.

Intangible factors such as safety, environmental acceptability, availability, and national interest also are affected in different ways by the consumption of each resource. Heiman (1984) proposes a procedure for weighting the following intangible factors:

National/Global Considerations

- Balance of trade
- Environmental impacts
- International policy
- Employment
- Minority employment
- Availability
- Alternative uses
- National defense
- Domestic policy
- Effect on capital markets

Local Considerations

- Exterior environmental impact
 - Air
 - Solid waste
 - Water resources
- Local employment
- Local balance of trade
- Use of distribution infrastructure
- Local energy independence
- Land use
- Exterior safety

Site Considerations

- Reliability of supply
- Indoor air quality

- Aesthetics
- Interior safety
- Anticipated changes in energy resource prices

SUMMARY

In HVAC&R system design, the need to address immediate issues such as economics, performance, and space constraints often prevents designers from fully considering the energy resources affected. Today's energy resources are less certain because of issues such as availability, safety, national interest, environmental concerns, and the world political situation. As a result, the reliability, economics, and continuity of many common energy resources over the potential life of a building being designed are unclear. For this reason, the designer of building energy systems must consider the energy resources on which the long-term operation of the building will depend. If the continued viability of those resources is reason for concern, the design should provide for, account for, or address such an eventuality.

ENERGY RESOURCE PLANNING

The energy supplier (or suppliers) in a particular jurisdiction must plan for that jurisdiction's future energy needs. For competitive energy markets where these decisions do not have high societal costs, these plans are made by energy suppliers and are not revealed to governmental authorities or the public more than is absolutely necessary, because of the advantage competitors could gain by this knowledge. For electricity (and, to a lesser extent, natural gas), significant societal issues are involved in energy resource planning decisions that cannot be made by energy suppliers without approval by many different groups. Issues include

- **Reliability**, which is affected by the diversity of supply sources available. For gas, this includes the number of geographic supply sources and pipelines; for electricity, it includes the percentage of generation from various fuel sources. Consider the projected future supply and reliability of energy resources, including the possibility of supply disruption by natural or political events, and the likelihood of future supply shortages, which could reduce reliability.
- **Reserve margins**, or the ratio of total supply sources to expected peak supply source needs. Reserve levels that are too high result in waste of resources, higher environmental costs, and possibly poor financial health of the energy suppliers. Reserves that are too low result in volatile and very high peak energy prices and reduced reliability.
- **Land use**. Energy production and transmission often require governmental cooperation to condemn private property for energy production and transmission facilities. Construction and maintenance are also regulated to protect wetlands, prevent toxic waste releases, and other environmental issues.

Note that some energy deregulation plans provide no guidance at all on energy supplies, through integrated resource planning (IRP) or other methods. Energy suppliers choose whether to expand their capacity, and what types of fuel those facilities use, based on their own assessment of the future profitability of that investment. In these markets, decisions are made with little societal input other than permitting and pollution control regulations, just as a decision might be made by a manufacturer in an industry such as steel or paper.

INTEGRATED RESOURCE PLANNING (IRP)

In regulated utility markets, integrated resource planning is commonly used for planning significant new energy facilities, especially for electricity. Steps include (1) forecasting the amount of new resources needed and (2) determining the type and provider of this resource. Traditionally, the local utility provider forecasts future needs of a given energy resource, then either builds the necessary facility with the approval of regulators or uses a standard offer bid

to determine what nonutility provider (or the utility itself) would provide the new energy resource.

Supplying new energy resources through either a standard bid process by a supplier or traditional utility regulation usually results in selection of the lowest-cost supply option, without regard for environmental costs or other societal needs. IRP allows a greater variety of resource options and allows environmental and other indirect societal costs to be given greater consideration.

IRP addresses a wider population of stakeholders than most other planning processes. Many regulatory agencies involve the public in the formulation and review of integrated resource plans. Customers, environmentalists, and other public interest groups are often prominent in these proceedings.

In deregulated energy markets, supplying markets with new energy resources is typically left up to competitive market forces. This has sometimes resulted in excessive reliance on one form of energy, such as natural gas generation. Another result has been highly volatile prices, when supply is not provided because of insufficient price signals, followed by much higher prices and energy shortages until new supply sources can be obtained (which may not be for several years because of the time required for construction and environmental approval processes). Energy efficiency and demand response programs are increasingly treated as an energy resource on a par with energy production options, with incentives and compensation provided for participants in these programs.

Demand-side management (DSM) is a common option for providing new energy resources, especially for electricity. These are actions taken to reduce the demand for energy, rather than increase the supply of energy. DSM is desirable because its environmental costs are almost always lower than those of building new energy facilities. However, the following factors have caused a decline in the number of DSM programs:

- Building and equipment codes and standards are a highly efficient form of DSM, reducing energy use with much lower administrative costs than programs that reward installation of more efficient equipment at a single site. However, they are more subtle than traditional DSM programs and may not always be recognized as a form of DSM.
- Opening markets to competing suppliers makes it more difficult to administer and implement DSM programs. However, they are still possible if regulators wish to continue them, and set appropriate rules and regulations for the market to allow implementation of DSM programs.

Many IRP participants may be interested in only one aspect of the process. For example, the energy industry's main interest may be cost minimization, whereas environmentalists may want to minimize pollutant emissions and prevent environmental damage from construction of energy facilities. Participation by all affected interest groups helps provide the best overall solution for society, including indirect costs and benefits from these energy resource decisions.

TRADABLE EMISSION CREDITS

Increasingly, quotas and limits apply to emissions of various pollutants. Often, a market-based system of tradable credits is used with these quotas. A company is given the right to produce a given level of emissions, and it earns a credit, which can be sold to others, if it produces fewer emissions than that level. If one company can reduce its emissions at a lower cost than another, it can do so and sell the emissions credit to the second company and earn a profit from its pollution control efforts. In the United States, emissions quota and trading programs currently include sulfur dioxide (SO₂) and nitrogen oxides (NO_x), with plans to implement carbon dioxide (CO₂) trading now under consideration, as well. In Europe, emissions trading for CO₂ began January 1, 2005. To date, this type of activity has largely involved large industrial plants, but it can also involve commercial

Fig. 1 Energy Production Trends: 1996-2005
(Basis: EIA 2007)

Fig. 2 World Primary Energy Production by Resource: 2005
(Basis: Table 2.9 in EIA 2007)

buildings with on-site emissions, such as generation equipment or gas engine-driven cooling.

Designers must be aware of any regulations concerning pollutant emissions; failure to comply with these regulations may result in civil or criminal penalties for designers or their clients. However, understand the options available under these regulations. The purchase or sale of emissions credits may allow reduced construction or building operations costs if the equipment can overcomply at a lower cost than the cost of another source of emissions to comply, or vice versa. In some cases, documentation of energy savings beyond what codes and regulations require can result in receiving emissions credits that may be sold later.

OVERVIEW OF GLOBAL ENERGY RESOURCES

WORLD ENERGY RESOURCES

Data in this section are from the U.S. Department of Energy's *International Energy Annual 2005* (EIA 2007).

Production

Energy production trends, by leading producers and world regions, from 1996 to 2005 are shown in Figure 1. World primary energy production, which essentially did not increase in the early 1990s, has risen about 2.4% per year from 1996 to 2005, as dramatic economic growth occurred in developing countries such as China. The largest total energy producers in 2005 were the United States (15%), China (14%), Russia (11%), and Saudi Arabia (6%). Together, they produce about 46% of the world's energy production. Total world energy production by resource type is shown in Figure 2.

Fig. 3 World Crude Oil Reserves: 2006
(Basis: Table 8.1 in EIA 2007)

Fig. 4 World Natural Gas Reserves: 2006
(Basis: Table 8.1 in EIA 2007)

Crude Oil. World crude oil production was 73.81 million barrels per day in 2005. The biggest crude oil producers in 2005 were the Middle East (31%), Russia (12%), Central/South America (9%), the United States (7%), and Europe (7%). Since 1996, oil production declined by 25% in the United States, and increased 35% in Russia.

Natural Gas. World production reached 101.5×10^{12} ft³ in 2005, up 64% from the 1996 level. The biggest producers in 2005 were Russia (22%), the United States (18%), Canada (6%), and Iran (4%). Natural gas production in Iran has increased 150% since 1996.

Coal. At 6.49×10^9 short tons in 2005, coal production was up 26.5% since 1996. Leading producers of coal were China (37%), the United States (17%), India (7%), and Australia (6%). Since 1996, China, India, and Australia each increased coal production by more than 50%, and the United States increased production by 6%.

Reserves

On January 1, 2006, estimated world reserves of crude oil and gas were distributed by world region as shown in Figures 3 and 4. Countries with the largest reported crude oil reserves are Saudi Arabia (21%), Canada (14%), Iran (10%), and Iraq (9%). Most of Canada's crude oil reserves are in the form of tar sands, which have only recently been included as proven reserves. The largest gas reserves are in Russia (27%), Iran (16%), and Qatar (15%).

World coal reserves as of January 1, 2006, are shown by region in Figure 5. The most plentiful reserves, as a percent of total, were in the United States (27%), Russia (17%), China (13%), India (9%), and Australia (9%).

An important factor is the relative amount of these energy resources that has not yet been consumed. A standard measure is called **proved energy reserves**, which is the remaining known deposits that could be recovered economically given current economic and operating conditions. Dividing proved reserves by the

Fig. 5 World Recoverable Coal Reserves: 2006
(Basis: Table 8.2 in EIA 2007)

Fig. 6 World Petroleum Consumption: 2005
[Basis: Table 11.9 (EIA 2001) and Table 2.1 (EIA 2007)]

current production rate gives the number of years of the resource remaining. Using this measure, the reserve-to-production ratio at the end of 2005 for crude oil was 48.0 years; for natural gas, 60.3 years; and for coal, more than 153.7 years.

This does not mean that these resources will be depleted in that length of time: additional resources may be discovered in new areas, and improved technology may increase the amount of a resource that may be economically extracted. Also, the future rate of production and consumption may be higher or lower than current levels, which would decrease or increase the remaining years of a resource. However, reserve-to-production ratios provide insights into the limited nature of nonrenewable energy resources and the need to find alternatives, especially for resources with fewer years of remaining reserves.

Also note that, particularly for nations with nationalized energy production, there are limited opportunities to verify energy reserve data, and very large upward or downward revisions have occurred. This is independent of upward revisions that occur when new resources are discovered, or downward revisions as energy reserves are depleted. In recent years, some energy industry sources in particular have questioned the oil reserves of Saudi Arabia (Simmons 2006.)

Consumption

Data on world energy consumption are available only by type of resource rather than by total energy consumed.

Petroleum. Consumption trends of the leading consumers from 1960 to 2005 are depicted in Figure 6. In 2005, the United States consumed far more petroleum than any other country: 24.9% of the world total. Other major petroleum-consuming countries were China (8.0%), Japan (6.4%), Russia (3.3%), and Germany (3.1%).

Fig. 7 World Natural Gas Consumption: 2005
(Basis: Table 1.3 in EIA 2007)

Fig. 8 World Coal Consumption: 2005
(Basis: Table 1.4 in EIA 2007)

Fig. 9 World Electricity Generation by Resource: 2004
(Basis: Table 6.3 in EIA 2007)

Natural Gas. In 2005, the two biggest natural gas producers (the United States and Russia) were also the two biggest consumers. Figure 7 depicts natural gas consumption by the leading consumer countries as a percentage of world consumption. Of the major consumers, the United States consumed more than it produced (123%), and Russia consumed less (71%), as did Canada (52%). Germany produced very little, and consumption in the United Kingdom was slightly more than production (108%). World consumption of natural gas increased 26.1% between 1996 and 2005. After the United States and Russia, no single country consumed more than 5% of the world total.

Coal. Here, the two largest coal producers (China and the United States) were also the two largest consumers. China is by far the largest coal consumer, with consumption approximately double the United States' in 2005. Figure 8 depicts the percentage of world consumption by the leading consumers during 2005. Since 1980, world coal consumption has increased 57%, mostly in the last five years because of extremely rapid growth in China. Over the same period, consumption by China increased 229%, the United States 60%, and India 290%. Significant drops occurred in Germany, Poland, and Russia.

Electricity. Figure 9 shows the world's electricity generation by energy resource in 2004. Figure 10 shows installed capacity for the same resources at the beginning of 2005. Both net generation and installed capacity were dominated by the United States (23% and 25%, respectively). Comparable figures for the next largest are

Fig. 10 World Installed Electricity Generation Capacity by Resource: 2005
(Basis: Table 6.4 in EIA 2007)

Fig. 11 Per Capita Energy Consumption by Selected Countries: 2005
(Basis: Tables B-1 and E-1 in EIA 2007)

China (14 and 11%, respectively), Japan (6% for both), and Russia (5 and 6%, respectively). In 2005, China had more than five times as much generating capacity as it had in 1980.

Hydroelectric generation increased in the world by 67% between 1980 and 2005, with the largest increases in Central and South America and China. The top countries for hydroelectric generation in 2005 were Canada, Brazil, the United States, and China, collectively accounting for 47% of the world total quantity of hydroelectric generation.

Total world electricity generation from nuclear resources increased 284% between 1980 and 2005, with higher-than-average increases occurring in Asia, Europe, and Africa. The top-generating countries in 2005 were the United States (30% of world total), France (16%), and Japan (11%).

Per Capita. Figure 11 compares the per capita energy consumption of selected countries for 2005. As is apparent, per capita energy consumption in cold-climate countries tends to be highest; also, the level in more developed countries is vastly different from that in less developed countries and differs considerably even among the more developed countries. Note that, although China's total energy use has grown very rapidly in recent years, on a per capita basis it is still far below the levels of more developed countries.

CARBON EMISSIONS

Worldwide carbon emissions from burning and flaring fossil fuels rose 25.1% from 1996 to 2005. Total carbon emissions were 28.193 billion metric tons of carbon dioxide in 2005, up from 22.531 billion metric tons in 1996. Figure 12 shows the changes in carbon emissions from burning fossil fuels from 1996 to 2005 for the total world and for selected countries. Russia, the United States, and Western Europe has small (under 10%) increases in carbon emissions. The developing countries and the Middle East show the largest increases, with extremely rapid carbon emissions growth in China in recent years. Note that although developing countries have the highest growth rates, their per capita carbon emissions are much less than in wealthier nations. A

A. PERCENT CHANGE IN CARBON EMISSIONS FROM FOSSIL FUELS BY COUNTRY/REGION: 1996-2005

B. WORLD CARBON DIOXIDE EMISSIONS BY COUNTRY/REGION

Fig. 12 World Carbon Emissions
(Basis: Table H-1 in EIA 2007)

graph of per capita carbon emissions would look very similar to Figure 11, which shows per capita energy consumption of selected countries.

U.S. ENERGY USE

Per Capita Energy Consumption

Figure 13, based on data from EIA (2006a), shows the growth in per capita energy use since 1950. The 1960s experienced a sharp increase in the per capita energy use growth rate, which leveled off during the 1970s because of higher energy prices and the emphasis on energy conservation. Since the early 1980s, however, per capita energy use growth has been relatively stable as energy efficiency increased. In recent years, per capita energy use has been slowly declining.

The *Annual Energy Outlook* is the basic source of data for projecting energy use in the United States (EIA 2006b). Figures 14 and 15 summarize data from this source.

EIA (2006b) forecasts energy trends based on macroeconomic growth scenarios, which include a variety of energy price and economic growth assumptions. Figures 14 and 15 (the baseline or reference case) assume average annual growth of the real gross domestic

Fig. 13 Per Capita U.S. Energy Consumption
(Basis: Table 1.5 in EIA 2006a)

Fig. 14 Projected Total U.S. Energy Consumption by End-Use Sector
(Basis: Table A-2 in EIA 2007)

product (GDP) at 2.4%, of the labor force at 0.9%, and of productivity at 1.9%. The forecast, in order to be policy-neutral, also assumes that all federal, state, and local laws and regulations in effect December 31, 2007, remain unchanged through 2030. Note that this forecast includes the effects of the EISA 2007 energy bill, which included significant energy efficiency and conservation requirements, such as increased use of biofuels and higher fuel economy standards for automobiles and other personal transportation vehicles.

Projected Overall Energy Consumption

Figure 14 shows energy use by major end-use sector (i.e., residential, commercial, industrial, and transportation). HVAC&R engineers are primarily concerned with the first three sectors. Figure 15 shows energy consumption by type of resource. Figure 14 shows less total energy consumption than Figure 15, primarily because it excludes the thermodynamic losses of electricity generation and the processing and delivery burdens of various energy forms.

The following observations apply to the overall picture of projected energy use in the United States over the next two decades (Figures 14 and 15):

- Although a major issue in energy markets is carbon emissions, no specific programs such as cap-and-trade or carbon taxes are reflected in these forecasts, because no specific policies for carbon reductions had been enacted in 2007.
- Carbon emissions from energy use are projected to increase by an average of 0.6% per year through 2030 because of rising energy demand, increasing population, improvements in efficiency, and slow growth in the use of renewable sources. The 2030 level of carbon emissions is projected to be almost 16% higher than the 2006 levels.
- Crude oil prices are expected to rise at an annual rate of 0.3% more than inflation. However, crude oil at any given time may fluctuate substantially because of short-term political or economic events affecting supplies.

Fig. 15 Projected Total U.S. Energy Consumption by Resource
(Basis: Table A-1 in EIA 2007)

- The wellhead price of natural gas was projected to rise at an annual rate of 0.3% more than inflation from 2006 through 2030. However, the U.S. Department of Energy (DOE) starts from a base price in 2006 that is well below actual market prices experienced in 2007 and 2008. This forecast assumes a long-term slow rise in price as lower-cost natural gas supply sources become less available. In recent years, U.S. natural gas markets have experienced extreme price volatility, making the outlook uncertain.
- The price of coal is expected to decline at an annual rate of 0.2% over the same period as a result of better productivity, more low-cost western coal production, and competitive labor pressures.
- Electricity prices are projected to show no change other than the effects of inflation from 2006 to 2030, because of improved technology and efficiency and the assumed very low increases in fuel costs.

Nuclear power generation is expected to grow at an annual rate of 0.6% per year, because of construction of new nuclear power plants along with life extensions for existing plants. A total of 17 GW of new nuclear generation units are projected to be completed by 2030, which equates to 11 to 15 new units, depending on facility size and design.

- Electricity generation using renewable sources (which includes cogenerators) will increase by 2.1% per year, but is projected to become the third largest source of electricity after coal and nuclear power by 2025, surpassing natural gas generation between 2020 and 2025.
- Petroleum consumption will grow by 0.4% annually, led by the transportation sector, which is where most of it (74%) is used.
- The share of petroleum consumption met by net imports is projected to be about 64% in 2030, only a fraction of a percent higher than current levels. Over this period, U.S. crude oil production is projected to increase at an annual rate of 0.5%, reversing a multidecade slow decline since the 1970s. Reasons include higher prices encouraging more drilling, enhanced oil recovery projects at existing fields, and production of oil from shale. The forecast is for U.S. oil production to peak in approximately 2020, with declining production through 2030, but with production in 2030 still about 11% above current levels.
- Natural gas consumption will increase by 0.2% per year in all sectors. Natural gas use for electric generation is projected to decline after 2010, and direct use by residential and commercial consumers to increase.
- Coal consumption will increase at an average annual rate of 1.2%. Most of it (90%) will be used for electricity generation.
- Consumption of nonhydroelectric renewable energy will increase by 4.4% per year. This includes ethanol used as a transportation fuel.
- Electricity consumption is projected to grow by 0.9% annually, with efficiency gains offset by increased use of electricity-using equipment and an increasing population.

- Total energy demand in the commercial and residential sectors will grow at 1.4% and 0.8% per year, respectively. This results from increasing population and greater use of computers, telecommunications, and other office appliances, but it is offset by somewhat improved building and equipment efficiencies.
- Energy use by the transportation sector will grow at an average of 0.7% per year, with variations from this average depending heavily on prevailing fuel prices. The growth rate for transportation energy use is much lower than in recent forecasts, reflecting new mandatory fuel economy standards to be implemented during the forecast period.
- Per capita energy use is projected to decline by 0.1% annually, as increases in efficiency more than offset population growth and new energy-consuming products.
- Total energy use per dollar of gross domestic product (energy intensity), however, will continue to fall at an average rate of about 2.4% per year through 2030.

Outlook Summary

In general, the following key issues will dominate energy matters in the next two decades:

- Continued dependency of the United States on imported oil
- Potential increases in use of nuclear power for electric generation
- Role of technology developments, including energy conservation and energy efficiency as alternatives to energy production
- Substantial increases in use of renewable energy, rising from 9.4% of total U.S. production in 2006 to 13.6% in 2030
- Continued growth in total worldwide carbon emissions, and debate over actions to deal with the issue
- Relative merits of various energy alternatives, including nuclear power and different renewable energy options
- Population growth, coupled with the shift of large population segments into retirement

CHAPTER 35

SUSTAINABILITY

<i>Definition</i>	35.1	<i>Primary HVAC&R Considerations in Sustainable Design</i>	35.2
<i>Characteristics of Sustainability</i>	35.1	<i>Factors Driving Sustainability into Design Practice</i>	35.3
<i>Factors Impacting Sustainability</i>	35.2	<i>Designing for Effective Energy Resource Use</i>	35.5

THE Brundtland Commission of the United Nations (UN 1987) stated that development of the built environment is sustainable "...if it meets the needs of the present without compromising the ability of future generations to meet their own needs." Given the profound impact of buildings on the environment, the work of HVAC&R design engineers is inextricably linked to sustainability. The engineering sector has seminal influence on building performance, and HVAC&R designers' work is inherently related to overall sustainability in buildings.

HVAC&R engineering design on projects concerned with performance and sustainability requires understanding of and involvement with more than just HVAC, including projected energy and water demands, stormwater runoff generation, waste generation, and air quality impacts. This chapter is intended to provide key information and identify reference sources for further resources on

- Defining the energy, water, and other resource-consuming aspects of projects
- Quantifying the relative environmental impacts of competing design alternatives

These aspects of sustainability are addressed with respect to energy and water conservation, greenhouse gas and air quality impacts, and other impacts of buildings, such as stormwater runoff and potable water use.

The need to address sustainability in the built environment is being accelerated by external pressures such as environmental and resource concerns, rising energy prices, indoor environmental quality, global warming, and energy security. While economies transition from carbon-based to other forms of more sustainable energy, engineers will be challenged to meet an ever-increasing tide of regulation and demand.

DEFINITION

Sustainability has been defined in the *ASHRAE GreenGuide* (ASHRAE 2006a), in general terms, as "providing for the needs of the present without detracting from the ability to fulfill the needs of the future," a definition very similar to that developed in 1987 by the United Nations' Brundtland Commission (UN 1987). Others have defined sustainability as "the concept of maximizing the effectiveness of resource use while minimizing the impact of that use on the environment" (ASHRAE 2006b) and an environment in which "... an equilibrium . . . exists between human society and stable ecosystems" (Townsend 2006).

Sustaining (i.e., keeping up or prolonging) those elements on which humankind's existence and that of the planet depend, such as energy, the environment, and health, are worthy goals.

The preparation of this chapter is assigned to TC 2.8, Building Environmental Impacts and Sustainability.

CHARACTERISTICS OF SUSTAINABILITY

Sustainability Addresses the Future

Sustainability is focused on the distant future (e.g., 30 to 50 years). Any actions taken under the name of sustainability must address the impact of present actions on conditions likely to prevail in that future time frame.

In designing the built environment, the emphasis has often been on the present or the near future, usually in the form of capital- or first-cost impact. As is apparent when life-cycle costing analysis is applied, capital cost assumes less importance the longer the future period under consideration.

This emphasis on the distant future can differentiate sustainable design from **green design**. Whereas green design addresses many of the same characteristics as sustainable design, it may also emphasize near-term impacts such as indoor environmental quality, operation and maintenance features, and meeting current client needs. Thus, green design may focus more on the immediate future (i.e., starting when the building is first constructed and then occupied). Sustainable design is of paramount importance to the global environment in the long-term while still incorporating features of green design that focus on the present and near future.

Sustainability Has Many Contributors

Sustainability is not just about energy, carbon emissions, pollution, waste disposal, or population growth. Although these are central ideas in thinking about sustainability, it is an oversimplification to think that addressing one factor, or even any one set of factors, can result in a sustainable future for the planet.

It is likewise a mistake to think that HVAC&R design practitioners, by themselves and just through activities within their purview, can create a sustainable result. To be sure, their activities can *contribute* to sustainability by creating a sustainable building, development, or other related project. But they cannot *by themselves* create global sustainability. Such an endeavor depends on many outside factors that cannot be controlled by HVAC&R engineers; however, they should make their fair-share contribution to sustainability in all their endeavors, and encourage other individuals and entities to do the same.

Sustainability Is Comprehensive

Sustainability has no borders or limits. A good faith effort to make a project sustainable does not mean that sustainability will be achieved globally. A superb design job on a building with sustainability as a goal will probably not contribute much to the global situation if a significant number of other buildings are not so designed, or if the transportation sector makes an inadequate contribution, or if only a few regions of the world do their fair share toward making the planet sustainable. A truly sustainable outcome thus depends on efforts in all sectors the world around.

Technology Plays Only a Partial Role

It may well be that in due time technology will have the theoretical *capability*, if diligently applied, to create a sustainable future for

the planet and humankind. Having the capability to apply technology, however, does not guarantee that it will be applied; that must come from attitude or mindset. As with all things related to comprehensive change, there must be the *will*.

For example, automobile companies have the technical capability to make cars that are much more efficient, to the extent that some developed countries now dependent on imported oil could be self-sufficient. But that is not the case, perhaps because there is a lack of demand or because car companies are not required to build them. The technology is available, but the will is not there; motivation is absent.

Similarly, HVAC&R designers know how to design buildings that are much more energy efficient than they have been in the past, but such buildings are still relatively rare. ASHRAE's long-standing guidance in designing energy efficient—and now green and sustainable—buildings, along with the motivation provided by the U.S. Green Building Council's (USGBC) Leadership in Energy and Environmental Design (LEED®) Green Building Rating System™ and the American Institute of Architects' (AIA) commitment to stringent energy efficiency goals, have pointed the way technologically for the built environment and related industries to make their fair-share contribution to sustainability.

There is little ASHRAE, within its technological purview, can do directly about other, nontechnological barriers. It can, however, set a good example in its area of expertise and can also encourage and inspire other sectors to do their part to move towards sustainability.

FACTORS IMPACTING SUSTAINABILITY

The major factors impacting global sustainability are the following:

- Population growth
- Food supply
- Disease control and amelioration
- Energy resource availability
- Material resource availability and management
- Fresh water supply, both potable and nonpotable
- Effective and efficient usage practices for energy resources and water
- Air and water pollution
- Solid and liquid waste disposal
- Land use

The preceding are only broad categories, yet they encompass many subsidiary factors that have received public attention recently. For instance, climate change/global warming, carbon emissions, acid rain, deforestation, transportation, and watershed management are important factors as well. However, each of these can be viewed as a subset of one or more of the listed major areas.

PRIMARY HVAC&R CONSIDERATIONS IN SUSTAINABLE DESIGN

The main areas falling within an HVAC&R designer's (and ASHRAE's) purview on most projects are those dealing with energy and water use, material resources, air and water pollution, and solid waste disposal. Although HVAC&R professionals' expertise may impact issues such as land use and food supply on certain specialized projects, these more typically fall under the purview of other professionals and their organizations.

Energy Resource Availability

Although conventional energy resources and their availability largely fall beyond the scope of HVAC&R designers' work, an understanding of these topics is often required for participation in project discussions or utility programs relating to projects. Chapter 34 has more information on energy resources.

Some **renewable** energy resources, in contrast with traditional energy and fuels, are ubiquitous by nature and are thus available on many building sites. **Wind** and **solar** energy are widely distributed (if not always continuously available) on almost any site for use in active or passive ways. High-level (high-temperature) **geothermal** energy is only present at limited sites, and may thus be unavailable as a direct energy source on a multitude of relevant projects. Low-level geothermal, on the other hand, is dependent on the nearly constant temperature of the near-surface earth and thus can be used on almost any project if other factors align in its favor.

Designers should be familiar with the characteristics of common traditional (nonrenewable) energy resources (natural gas, heating oil, electricity) from the standpoint of their use in the relevant application. Designers are typically very familiar with the relative per-unit cost as it affects the operating cost of the building being designed. Other energy characteristics traditionally taken into account by the designer might also include ease of handling and use, cleanliness, emissions produced, and local availability, because these also have a direct effect on design and installation. Until recently, designers have not had reason to consider an energy resource's characteristics beyond the site line of the project at hand.

However, recent public focus on the impacts of building energy use on the environment has changed that approach. Designers now must consider a resource's broader characteristics that may affect the regional, national and global environment, such as its origin (domestic or foreign), future availability, emissions characteristics, broad economics, and social acceptability. Though responsible designers may not be able to do much about such factors, they should be aware of them; indeed, that awareness may affect decisions within the designer's control.

For instance, familiarity with an energy resource's emissions characteristics, whether at the well head, mine mouth, or generating station, may influence the designer to make the building more energy efficient, or provide the designer with arguments to convince the owner that energy-saving features in the building would be worth additional capital cost. Furthermore, as owners and developers of buildings become more aware of sustainability factors, designers must stay informed of the latest information and impacts.

One way to reduce a project's use of nonrenewable energy, beyond energy-efficient design itself, is to replace such energy use with renewable energy. Designers should develop familiarity with how projects might incorporate and benefit from renewable energy. Many kinds of passive design features can take advantage of naturally occurring energy.

Increasingly common examples of nonpassive approaches are solar systems, whether photovoltaic (electricity-generating) or solar thermal (hot-fluid generating). Low-level geothermal systems take advantage of naturally occurring and widely distributed earth-embedded energy. Wind systems are increasingly applied to supplement electric power grids, and are also sometimes incorporated on a smaller scale into on-site or distributed generation approaches.

Some large power users, such as municipalities or large industries, require that a minimum percentage of power they purchase be from renewable sources. Also, renewable portfolio standards are being imposed on electric utility companies by regulators.

Fresh Water Supply

HVAC&R systems can impact potable and nonpotable water supplies both directly and indirectly. First, some building systems use potable water, for example in evaporative cooling towers. Second, some building systems can discharge treated water or other waste streams with contaminants of concern that can impact local watersheds and water supplies. Indirect impacts include the use of water by utilities for electricity generation.

Effective and Efficient Use of Energy Resources and Water

This area is where HVAC&R engineers can have a profound impact on achieving sustainability goals. Impacts of building consumption can be at least partially mitigated through overall system performance improvement, as well as through increased use of on-site renewable energy and certain off-site energy resources. See the section on Designing for Effective Energy Resource Use for more information on addressing energy efficiency in the design process.

Building systems' water use can be reduced by reusing clean water from on-site, such as condensate drain water, or by using less potable water. For example, hybrid cooling towers can operate as water-to-air heat exchangers when run dry, and can operate their water sprays for additional evaporative capacity only when conditions require. In process control and refrigeration systems, similar opportunities exist. For more information on water use, the USGBC's LEED rating systems each include a section on water efficiency and provide guidance on controlling water use in buildings.

Discharge from building systems can be reduced through careful design, proper sequences and control, choice of lower impact chemical treatment regimes, or nonchemical water treatment. These techniques may not eliminate chemical treatment in all applications, but it can be substantially reduced.

Material Resource Availability and Management

Designers do not typically focus on embodied impacts of their systems design. For example, within the LEED framework, building systems under the purview of HVAC&R designers are currently excluded from credits for locally procured building materials and resources. However, the same concepts can be applied in selection and procurement of HVAC&R system components. For example, recycled steel content in system components could be required to be stated in HVAC&R product submittals. In some areas, locally assembled or manufactured components may be available that can reduce transportation impacts.

Air, Noise, and Water Pollution

HVAC&R systems and equipment can interact with both local and global environments. On a local scale, HVAC&R systems interact with the environment in ways such as acoustical noise generated by heat rejecting equipment (e.g., condensing units, cooling tower). Occasionally, this may require the addition of special barriers to prevent sound migration from the site, as shown in Figure 1.

Local impacts of combustion from on-site heat or electricity generation can be mitigated to an extent through careful consideration of the location of sources (emitters) with respect to nearby receptors, including outdoor air intakes and residences or other buildings with operable windows.

On a larger scale, air and water pollution occurs indirectly through the consumption of energy to operate building systems. This occurs in generating the electricity (whether from fossil fuel, nuclear, or hydroelectric resources), steam, or hot water for building heating or cooling. In this sense, improved efficiency is an approach to partial mitigation.

Solid and Liquid Waste Disposal

The solid waste disposal burden from installation and operations of building systems can be substantially reduced. Competing alternatives can be assessed through life cycle analysis. For example, an air-cooled unitary system with a shorter service life than a costlier water-cooled alternative could, over the course of the building's life, increase the solid waste burden when it is discarded.

An example of an HVAC&R design impacting liquid waste disposal is using glycol to protect coils from freezing, where the glycol must be eliminated in summer to provide required capacity. Because

Fig. 1 Cooling Tower Noise Barrier
(Courtesy Neil Moiseev)

reusing glycol is not a common practice, such a design would likely result in an annual glycol discharge.

In many locations, water quality regulations and agencies essentially limit or prohibit liquid waste disposal. Other approaches to pursue in reducing liquid waste disposal are discussed in the section on Effective and Efficient Use of Energy Resources and Water.

FACTORS DRIVING SUSTAINABILITY INTO DESIGN PRACTICE

HVAC&R designers face many challenges as they assimilate sustainability into their engineering practices. These challenges include climate change, a fast-changing regulatory and legal environment, and evolving standards of care. New tools, technologies, and approaches are required for well-prepared HVAC&R engineers. The challenges and the responses are creating new opportunities, just as changing project processes are allowing or requiring engineers to participate in projects in new ways.

Climate Change

In addition to their causal role (IPCC 2007), energy systems are exposed to significant vulnerabilities resulting from climate change. Increased volatility in weather profoundly affects HVAC&R practice. Historical weather data and extremes may inadequately describe conditions faced by a project built today, even over a modest lifespan for a building.

In 2001, the United Nations Environment Programme (UNEP) and the World Meteorological Organization (WMO) established the Intergovernmental Panel on Climate Change (IPCC) (www.ipcc.ch) to study and report on the scientific issues, potential impacts and mitigation methods associated with climate change. A series of publications were produced that discuss the possible outcomes and interventions required to mitigate the impacts of anthropogenic emissions.

Responsible designers are concerned with two dimensions of climate change: not only *what* they can do to reduce their designs' contribution, but also *whether* and *how* their designs should anticipate the future. It is the first that is the focus of this chapter and a majority of the available information on sustainable design. Warming trends

currently occurring have been quantified with certainty. As a result, historical weather data may not be the best source for load calculations. Depending on the rate of change, anticipating future weather may become more significant in its impact on the climate control of building systems.

Regulatory Environment

The global community has responded to two major environmental issues during the past two decades. In the late 1980s, the Montreal Protocol (UNEP 2003) regulated the manufacture and trade of refrigerants which had been shown to damage the stratosphere and the troposphere by depleting atmospheric ozone. The effect on the HVAC&R industry was to require research and investment in alternative materials to those that had become the mainstays of the industry (Figure 2).

Next came the much more controversial issue of greenhouse gas emissions (and their potential for causing global warming) in the early 1990s. In response to these threats, many countries have signed and accepted the Kyoto Protocol (UNFCCC 1998), which places limits on these emissions.

Both the underlying science and the regulation of greenhouse gas emissions, primarily concerning (but not limited to) carbon dioxide (CO₂), have been embroiled in politics. A consensus has finally been expressed from within the scientific community, which has spurred political and regulatory action. The Fourth Assessment Report of the World Meteorological Organization's International Panel for Climate Change (IPCC 2007) cites widespread consensus from hundreds of scientists worldwide that rising CO₂ levels are primarily attributable to human factors as well as being responsible for warming of the lower atmosphere and associated major impact on the environment and societies.

An emissions trading program for CO₂ equivalents, already in place in the European Union, has started in the United States. Such a program will change the way of thinking for engineers and industry as new opportunities and challenges emerge. For example, a rigorous measurement and verification approach could quantify reduced building energy use and allow building owners to monetize the associated carbon reduction.

Evolving Standards of Care

Litigation relating to sustainability and global climate issues has increased. For example, a consortium of states successfully sued to force the U.S. Environmental Protection Agency (EPA) to consider CO₂ a pollutant that is harming the environment and thus take measures to regulate its emissions. This ruling is one of several developments in the continued and broadened response to CO₂ emissions by society at large. Building design and construction industries are already being impacted.

Fig. 2 Effect of Montreal Protocol on Global Chlorofluorocarbon (CFC) Production

In the United States, some states have adopted carbon legislation, such as California's Global Warming Solutions Act of 2006. There and elsewhere, environmental impact reports are increasingly addressing not only local and immediate pollutant impacts, such as stormwater run-off, but greenhouse gas emissions as well.

Changing Design Process

Even in jurisdictions without regulatory change, change is happening in the HVAC&R industry. Today's engineer can contribute value to projects that include sustainability goals, using some of the many resources and approaches cited in this chapter.

ASHRAE, in partnership with the Illuminating Engineering Society of North America (IESNA) and the USGBC, has begun developing *Standard 189* for high-performance green buildings, which intends to call for a determination of annual CO₂ equivalent emissions in addition to overall energy savings and other requirements. The component of such emissions from electricity use depends on the mix of fuels used to generate the electricity. In addition to regional variations, the overall fuel mix is projected to change, as shown in Figure 3.

Emissions considerations alone are not the only driver for design decision-making. Energy price pressures continue to mount. Examples of recent pressures include

- Antiquated electric transmission and distribution infrastructure
- Power plants being forced to become cleaner and more efficient, expediting closure of cheap, dirty generators
- Mandates imposed on utilities to provide more renewable energy to customers
- Influence of commodities trading markets on spot and future prices
- Constrained natural gas reserves and growth in demand continuing to increase volatility in the natural gas market
- Global warming, through environmental pressures to reduce carbon emissions in the face of increased demand for electricity, and infrastructure damage from more frequent storms

These and other pressures are changing project teams and their work, which are being asked to

- Incorporate sustainable design guidance and rating systems into their work
- Add a variety of new team members who bring additional expertise to address sustainability
- Gather quantitative data related to energy, water, greenhouse gas emissions, etc.
- Use new analysis tools to help maximize sustainability

Opportunities relating to sustainability for the well prepared engineer are growing. The increased focus on sustainability in the built

Fig. 3 Electricity Generation by Fuel, 1980–2030 (EIA 2008)

environment allows for more integrated, effective, and efficient ways to meet the nexus between environment, economy, and regulation. The challenge for the industry is how quickly it can adapt to these new opportunities and grow in an increasingly regulated environment. At the very least, the standard of care for engineers must be tracked and implemented to manage liability. Sustainability can provide an avenue for engineers and others to increase market share while exceeding current regulatory constraints and anticipating future regulations. More details on design considerations are provided in the section on Designing for Effective Energy Resource Use.

Integrating sustainability into HVAC&R system design can result in built environments that respect the greater environment and provide safe and comfortable indoor environments. The three occurrences of the letter *i* in *sustainability* can be thought of as representing key concepts in sustainable design: *interactive*, *iterative*, and *integrated*. Design processes that require greater interaction between team members and more iterative analysis to improve design solutions can be undertaken by teams through what has become known as integrated design.

Sustainability is inherently multidisciplinary. Recognizing this, teams often assemble a broad array of experts in a collaborative, interdisciplinary approach to achieve the highest levels of sustainability possible. This integrated design approach is addressed in Chapter 57 of the 2007 *ASHRAE Handbook—HVAC Applications*.

Other Opportunities

In addition to designing HVAC&R systems, engineers may increasingly be called upon to help address issues ranging from transportation to irrigation to on-site renewable energy. The approach to sustainable design alternatives opens the door for creativity and innovation in the design process. Rather than taking a “one-size-fits-all” approach to design, engineers can provide a range of available solutions and facilitate flexible implementation. Often, engineers will be asked to develop and evaluate measures based on economic and environmental performance. Success may require design iterations to achieve the desired performance.

DESIGNING FOR EFFECTIVE ENERGY RESOURCE USE

Most energy used in buildings is from nonrenewable resources, the cost of which historically has not considered replenishment or environmental impact. Thus, consideration of energy use in design has been based primarily on economic advantages, which are weighted to encourage more rather than less use.

As resources become less readily available and more exotic, and replenishable sources are investigated, the need to operate buildings effectively using less energy becomes paramount. Extensive study since the mid-1970s has shown that building energy use can be significantly reduced by applying the fundamental principles discussed in the following sections.

Energy Ethic: Resource Conservation Design Principles

The basic approach to energy-efficient design is reducing loads (power), improving transport systems, and providing efficient components and “intelligent” controls. Important design concepts include understanding the relationship between energy and power, maintaining simplicity, using self-imposed budgets, and applying energy-smart design practices.

Energy and Power

From an economic standpoint, more energy-efficient systems need not be more expensive than less efficient systems. Quite the opposite is true because of the simple relationship between energy and power, in which power is simply the time rate of energy use (or, conversely, energy is power times time). Power terms such as horsepower, ton of refrigeration, Btu per hour, or kilowatt are used in

expressing the size of a motor, chiller, boiler, or transformer, respectively. Generally, the smaller the equipment, the less it costs. Other things being equal, as smaller equipment operates over time, it consumes less energy. Thus, in designing for energy efficiency, the first objective is always to reduce the power required to the bare minimum necessary to provide the desired performance, starting with the building’s heating and cooling loads (a power term, in Btu/h and continuing with the various systems and subsystems).

Simplicity

Complex designs to save energy seldom function in the manner intended unless the systems are continually managed and operated by technically skilled individuals. Experience has shown that long-term, energy-efficient performance with a complex system is seldom achievable. Further, when complex systems are operated by minimally skilled individuals, both energy efficiency and performance suffer. Most techniques discussed in this chapter can be implemented with great simplicity.

Self-Imposed Budgets

Just as an engineer must work to a cost budget with most designs, self-imposed power budgets can be similarly helpful in achieving energy-efficient design. The series of Advanced Energy Design Guides from ASHRAE are a source for guidance on achievable design budgets. For example, the following are possible categories of power budgets for a mid-rise office building:

• Installed lighting (overall)	W/ft ²
• Space sensible cooling	Btu/h·ft ²
• Space heating load	Btu/h·ft ²
• Electric power (overall)	W/ft ²
• Thermal power (overall)	Btu/h·ft ²
• Hydronic system head	ft of water
• Water chiller (water-cooled)	kW/ton
• Chilled-water system auxiliaries	kW/ton
• Unitary air-conditioning systems	kW/ton
• Annual electric energy	kWh/ft ² ·yr
• Annual thermal energy	Btu/ft ² ·yr·°F·day

As the building and systems are designed, all decisions become interactive as each subsystem’s power or energy performance is continually compared to the budget.

Design Process for Energy-Efficient Projects

Consider energy efficiency at the beginning of the building design process, because energy-efficient features are most easily and effectively incorporated at that time. Seek the active participation of all members of the design team, including the owner, architect, engineer, and often the contractor, early in the design process. Consider building attributes such as building function, form, orientation, window/wall ratio, and HVAC system types early in the process, because each has major energy implications. Identify meaningful energy performance benchmarks suited to the project, and set project-specific goals. Energy benchmarks for a sample project are shown in Table 1. Consider energy resources, on-site energy sources, and use of renewable energy, credits, or carbon offsets to mitigate environmental impacts of energy use.

Address a building’s energy requirements in the following sequence:

1. **Minimize the impact of the building’s functional requirements** by analyzing how the building relates to its external environment. Advocate changes in building form, aspect ratio, and other attributes that reduce, redistribute, or delay (shift) loads. The load calculation should be interactive so that the effect of those factors can be seen immediately.
2. **Minimize loads** by analyzing external and internal loads imposed on the building energy-using subsystems, both for

peak- and part-load conditions. Design for efficient and effective operation off-peak, where the majority of operating hours and energy use typically occurs.

3. **Maximize subsystem efficiency** by analyzing the diversified energy and power requirements of each energy-using subsystem serving the building's functional requirements. Consider static and dynamic efficiencies of energy conversion and energy transport subsystems, and consider opportunities to reclaim, redistribute, and store energy for later use.
4. **Study alternative ways to integrate subsystems** into the building by considering both power and time components of energy use. Identify, evaluate, and design each of these components to control overall design energy consumption. Consider the following when integrating major building subsystems:

- Address more than one problem at a time when developing design solutions, and make maximum use of the building's advantageous features (e.g., windows, structural mass).
- Examine design solutions that consider time (i.e., when energy use occurs), because sufficient energy may already be present from the environment (e.g., solar heat, night cooling) or from internal equipment (e.g., lights, computers) but available at times different from when needed. Active (e.g., heat pumps with water tanks) and passive (e.g., building mass) storage techniques may need to be considered.
- Examine design solutions that consider the anticipated use of space. For example, in large but relatively unoccupied spaces, consider task or zone lighting. Consider transporting excess energy (light and heat) from locations of production and availability to locations of need instead of purchasing additional energy.
- Never reject waste energy at temperatures usable for space conditioning or other practical purposes without calculating the economic benefit of energy recovery or treatment for reuse.
- Consider or advocate design solutions that provide more comfortable surface temperatures or increase the availability of controlled daylight in buildings where human occupancy is a primary function.
- Use easily understood design solutions, because they have a greater probability of use by building operators and occupants.
- Where the functional requirements of a building are likely to change over time, design the installed environmental system to adapt to meet anticipated changes and to provide flexibility in meeting future changes in use, occupancy, or other functions.

- Develop energy performance benchmarks, metrics, and targets that will allow building owners and operators to better realize the design intent. Differentiate between peak loads for system design and selection and lower operating loads that determine actual energy use.

Building Energy Use Elements

Envelope.

Control thermal conductivity by using insulation (including movable insulation), thermal mass, and/or phase-change thermal storage at levels that minimize net heating and cooling loads on a time-integrated (annual) basis.

- Minimize unintentional or uncontrolled thermal bridges, and include them in energy-related calculations because they can radically alter building envelope conductivity. Examples include wall studs, balconies, ledges, and extensions of building slabs.
- Minimize infiltration so that it approaches zero. (An exception is when infiltration provides the sole means of ventilation, such as in small residential units.) This minimizes fan energy consumption in pressurized buildings during occupied periods and minimizes heat loss (or unwanted heat gain, in warm climates) during unoccupied periods. In warm, humid climates, a tight envelope also improves indoor air quality. Reduce infiltration through design details that enhance the fit and integrity of building envelope joints in ways that may be readily achieved during construction (e.g., caulking, weatherstripping, vestibule doors, and/or revolving doors), with construction meeting accepted specifications.
- Consider operable windows to allow occupant-controlled ventilation. This requires careful design of the building's mechanical system to minimize unnecessary HVAC energy consumption, and building operators and occupants should be cautioned about improper use of operable windows. CIBSE (2005) provides comprehensive design considerations for natural ventilation.
- Strive to maintain occupant radiant comfort regardless of whether the building envelope is designed to be a static or dynamic membrane. Design opaque surfaces so that average inside surface temperatures remain within 5°F of room temperature in the coldest anticipated weather (i.e., winter design conditions) and so that the coldest inside surface remains within 25°F of room temperature (but always above the indoor dew point). In a building with time-varying internal heat generation, consider thermal mass for controlling radiant comfort. In the perimeter zone, thermal mass is more effective when it is positioned inside the envelope's insulation.

Table 1 Example Benchmark and Energy Targets for University Research Laboratory

Building area, ft ²	Lit/		Electricity for In-Building Pumps	Electricity for Plug Loads	Electricity for Unidentified Loads	Total Electricity	Cogenerated Electricity	NGrid Electricity
	Gross	Conditioned						
	170,000	110,500						
Electric	Electricity for Lighting	Electricity for Ventilation (Fans)						
Design load, W/ft ² gross	0.52	0.50	0.60	0.97	—	2.60	—	
Peak demand, W/ft ² gross	0.42	0.50	0.42	0.73	0.00016	2.07	—	
Peak demand, kW (Projected submetered peak)	71	85	72	124	20	372	—	
Annual consumption, kWh/yr (Projected submetered reading)	218,154	346,598	191,245	891,503	175,200	1,823,000	966,000	857,000
Annual use index goal, kWh/yr	1.28	2.04	1.12	5.24	1.03	10.72		
Annual use index goal, site Btu/ft ² gross·yr	4378	6956	3838	17,893	3516	36,583		
Annual use index, kWh/ft ² gross·yr*	2.51 to 3.32	4.48 to 6.88	included elsewhere	4.39 to 5.67	NA	14.74 to 17.91		
Annual use index, site Btu/ft ² gross·yr*	8564	15,286	—	14,979	—	50,293 to 61,109		

*From Labs21 program of U.S. Environmental Protection Agency (EPA) and U.S. Department of Energy (DOE). See <http://www.epa.gov/lab21gov/index.htm>.

- Effective control of solar radiation is critical to energy-efficient design because of the high level of internal heat production already present in most commercial buildings. In some climates, lighting energy consumption savings from daylighting techniques can be greater than the heating and cooling energy penalties that result from additional glazed surface area required, if the building envelope is properly designed for daylighting and lighting controls are installed and used. (In other climates, there may not be net savings.) Daylighting designs are most effective if direct solar beam radiation is not allowed to cause glare in building spaces.
- Design transparent parts of the building envelope to prevent solar radiant gain above that necessary for effective daylighting and solar heating. On south-facing facades (in the northern hemisphere), using low shading coefficients is generally not as effective as external physical shading devices in achieving this balance. Consider low-emissivity, high-visible-transmittance glazings for effective control of radiant heat gains and losses. For shading control, judicious use of vegetation may block excess gain year-round or seasonally, depending on the plant species chosen.

Lighting.

Lighting is both a major energy end use in commercial buildings (especially office buildings) and a major contributor to internal loads by increasing cooling loads and decreasing heating loads. Design should meet both the lighting functional criteria of the space and minimize energy use. IESNA (2000) recommends illuminance levels for visual tasks and surrounding lighted areas. Principles of energy-conserving design within that context include the following:

- Energy use is determined by the lighting load (demand power) and its duration of use (time). Minimize actual demand load rather than just apparent connected load. Control the load rather than just area switching, if switching may adversely affect the quality of the luminous environment.
- Consider daylighting with proper controls to reduce costs of electric lighting. Design should be sensitive to window glare, sudden changes in luminances, and general user acceptance of daylighting controls. Carefully select window treatment (blinds, drapes, and shades) and glazing to control direct solar penetration and luminance extremes while maintaining the view and daylight penetration.
- Design the lighting system so that illumination required for tasks is primarily limited to the location of the task and comes from a direction that minimizes direct glare and veiling reflections on the task. When the design is based on nonuniform illuminance, walls should be a light to medium color or illuminated to provide visual comfort. In densely occupied work spaces, uniform distribution of general lighting may be most appropriate. Where necessary, provide supplementary task illumination. General ambient illumination should not be lower than a third of the luminance required for the task, to help maintain visually comfortable luminance ratios.
- Use local task lighting to accommodate needs for higher lighting levels because of task visual difficulty, glare, intermittently changing requirements, or individual visual differences (poor or aging eyesight).
- Group similar activities so that high illuminance or special lighting for particular tasks can be localized in certain rooms or areas, and so that less-efficient fixtures required for critical glare control do not have to be installed uniformly when they are only required sparsely.
- Use lighting controls throughout so lighting is available when and where it is needed, but not wasted when tasks are less critical or spaces are not fully occupied. Also consider user acceptance of control strategies to maximize energy saving.
- Limit use of lower-efficiency lamps (e.g., incandescent) to applications where their color, lumens, or distribution characteristics cannot be duplicated by other sources. Limit use of extended-service incandescent lamps to applications where fixtures are difficult to reach and/or maintenance costs for replacing lamps would be excessive.
- Carry lighting design through the rest of the building's interior design. Reduced light absorption may be achieved by using lighter finishes, particularly on ceilings, walls, and partitions.

Other Loads.

- Minimize thermal impact of equipment and appliances on HVAC systems by using hoods, radiation shields, or other confining techniques, and by using controls to turn off equipment when not needed. Where practical, locate major heat-generating equipment where it can balance other heat losses. Computer centers or kitchen areas usually have separate, dedicated HVAC equipment. In addition, consider heat recovery for this equipment.
- Use storage techniques to level or distribute loads that vary on a time or spatial basis to allow operation of a device at maximum (often full-load) efficiency.

HVAC System Design.

- Consider separate HVAC systems to serve areas expected to operate on widely differing operating schedules or design conditions. For instance, systems serving office areas should generally be separate from those serving retail areas.
- Arrange systems so that spaces with relatively constant, weather-independent loads are served by systems separate from those serving perimeter spaces. Areas with special temperature or humidity requirements (e.g., computer rooms) should be served by systems separate from those serving areas that require comfort heating and cooling only. Alternatively, provide these areas with supplementary or auxiliary systems.
- Sequence the supply of zone cooling and heating to prevent simultaneous operation of heating and cooling systems for the same space, to the extent possible. Where this is not possible because of ventilation, humidity control, or air circulation requirements, reduce air quantities as much as possible before incorporating reheating, recooling, or mixing hot and cold airstreams. For example, if reheat is needed to dehumidify and prevent overcooling, *only* ventilation air needs to be treated, not the entire recirculated air quantity. Finally, reset supply air temperature up to the extent possible to reduce reheating, recooling, or mixing losses.
- Provide controls to allow operation in occupied and unoccupied modes. In the occupied mode, controls may provide for a gradually changing control point as system demands change from cooling to heating. In the unoccupied mode, ventilation and exhaust systems should be shut off if possible, and comfort heating and cooling systems should be shut off except to maintain space conditions ready for the next occupancy cycle.
- In geographical areas where diurnal temperature swings and humidity levels permit, consider judicious coupling of air distribution and building structural mass to allow nighttime cooling to reduce the requirement for daytime mechanical cooling.
- High ventilation rates, where required for special applications, can impose enormous heating and cooling loads on HVAC equipment. In these cases, consider recirculating filtered and cleaned air to the extent possible, rather than 100% outside air. Also, consider preheating outside air with reclaimed heat from other sources.

HVAC Equipment Selection.

- To allow HVAC equipment operation at the highest efficiencies, match conversion devices to load increments, and sequence the operation of modules. Oversized or large-scale systems should never serve small seasonal loads (e.g., a large heating boiler serving a summer-service water-heated load). Include specific low-load units and auxiliaries where prolonged use at minimal capacities is expected.

- Select the most efficient (or highest-COP) equipment practical at both design and reduced capacity (part-load) operating conditions.
- When selecting large-power devices such as chillers (including their auxiliary energy burdens), economic analysis of the complete life-cycle costs should be used. See Chapter 36 of the 2007 *ASHRAE Handbook—HVAC Applications* for more information on detailed economic analysis.
- Keep fluid temperatures for heating equipment devices as low as practical and for cooling equipment as high as practical, while still meeting loads and minimizing flow quantities.

Energy Transport Systems.

Energy should be transported as efficiently as possible. The following options are listed in order of efficiency, from the lowest energy transport burden (most efficient) to the highest (least efficient):

1. Electric wire or fuel pipe
2. Two-phase fluid pipe (steam or refrigerant)
3. Single-phase liquid/fluid pipe (water, glycol, etc.)
4. Air duct

Select a distribution system that complements other parameters such as control strategies, storage capabilities, conversion efficiency, and utilization efficiency.

The following specific design techniques may be applied to thermal energy transport systems:

Steam Systems.

- Include provisions for seasonal or non-use shutdown.
- Minimize venting of steam and ingestion of air, with design directed toward full-vapor performance.
- Avoid subcooling, if practical.
- Return condensate to boilers or source devices at the highest possible temperature.

Hydronic Systems.

- Minimize flow quantity by designing for the maximum practical temperature range.
- Vary flow quantity with load where possible.
- Design for the lowest practical pressure rise (or drop).
- Provide *operating* and *idle* control modes.
- When locating equipment, identify the critical pressure path and size runs for the minimum reasonable pressure drop.

Air Systems.

- Minimize airflow by careful load analysis and an effective distribution system. If the application allows, supply air quantity should vary with sensible load (i.e., VAV systems). Hold the fan pressure requirement to the lowest practical value and avoid using fan pressure as a source for control power.
- Provide *normal* and *idle* control modes for fan and psychrometric systems.
- Keep duct runs as short as possible, and keep runs on the critical pressure path sized for minimum practical pressure drop.

Power Distribution.

- Size transformers and generating units as closely as possible to the actual anticipated load (i.e., avoid oversizing to minimize fixed thermal losses).
- Consider distribution of electric power at the highest practical voltage and load selection at the maximum power factor consistent with safety.
- Consider tenant submetering in commercial and multifamily buildings as a cost-effective energy conservation measure. (A

large portion of energy use in tenant facilities occurs simply because there is no economic incentive to conserve.)

Domestic Hot-Water Systems.

- Choose shower heads that provide and maintain user comfort and energy savings. They should not have removable flow-restricting inserts to meet flow limitation requirements.
- Consider point-of-use water heaters where their use will reduce energy consumption and annual energy cost.
- Consider using storage to facilitate heat recovery when the heat to be recovered is out of phase with the demand for hot water or when energy use for water heating can be shifted to take advantage of off-peak rates.

Controls.

Well-designed digital control provides information to managers and operators as well as to the data processor that serves as the intelligent controller. Include the energy-saving concepts discussed previously throughout the operating sequences and control logic. However, energy conservation should not be sought at the expense of inadequate performance; in a well-designed system, these two parameters are compatible. See Chapter 7 of this volume and Chapter 46 of the 2007 *ASHRAE Handbook—HVAC Applications* for more information on controls.

HVAC engineers and technicians require instruments for both laboratory work and fieldwork. Precision is more essential in the laboratory, where research and development are undertaken, than in the field, where acceptance and adjustment tests are conducted. This chapter describes the characteristics and uses of some of these instruments.

TERMINOLOGY

The following definitions are generally accepted.

Accuracy. Capability of an instrument to indicate the true value of measured quantity. This is often confused with inaccuracy, which is the departure from the true value to which all causes of error (e.g., hysteresis, nonlinearity, drift, temperature effect, and other sources) contribute.

Amplitude. Magnitude of variation from its zero value in an alternating quantity.

Average. Sum of a number of values divided by the number of values.

Bandwidth. Range of frequencies over which a given device is designed to operate within specified limits.

Bias. Tendency of an estimate to deviate in one direction from a true value (a systematic error).

Calibration. (1) Process of comparing a set of discrete magnitudes or the characteristic curve of a continuously varying magnitude with another set or curve previously established as a standard. Deviation between indicated values and their corresponding standard values constitutes the correction (or calibration curve) for inferring true magnitude from indicated magnitude thereafter; (2) process of adjusting an instrument to fix, reduce, or eliminate the deviation defined in (1). Calibration reduces bias (systematic) errors.

Calibration curve. (1) Path or locus of a point that moves so that its graphed coordinates correspond to values of input signals and output deflections; (2) plot of error versus input (or output).

Confidence. Degree to which a statement (measurement) is believed to be true.

Deadband. Range of values of the measured variable to which an instrument will not effectively respond. The effect of deadband is similar to hysteresis, as shown in Figure 1.

Deviate. Any item of a statistical distribution that differs from the selected measure of control tendency (average, median, mode).

Deviation. Difference between a single measured value and the mean (average) value of a population or sample.

Deviation, standard. Square root of the average of the squares of the deviations from the mean (root mean square deviation). A measure of dispersion of a population.

Distortion. Unwanted change in wave form. Principal forms of distortion are inherent nonlinearity of the device, nonuniform response at different frequencies, and lack of constant proportionality between phase-shift and frequency. (A wanted or intentional change might be identical, but it is called **modulation**.)

Drift. Gradual, undesired change in output over a period of time that is unrelated to input, environment, or load. Drift is gradual; if variation is rapid and recurrent, with elements of both increasing and decreasing output, the fluctuation is referred to as **cycling**.

Dynamic error band. Spread or band of output-amplitude deviation incurred by a constant-amplitude sine wave as its frequency is varied over a specified portion of the frequency spectrum (see *Static error band*).

Emissivity. Ratio of the amount of radiation emitted by a real surface to that of an ideal (blackbody) emitter at the same temperature.

Error. Difference between the true or actual value to be measured (input signal) and the indicated value (output) from the measuring system. Errors can be systematic or random.

Error, accuracy. See *Error, systematic*.

Error, fixed. See *Error, systematic*.

Error, instrument. Error of an instrument's measured value that includes random or systematic errors.

Error, precision. See *Error, random*.

Error, probable. Error with a 50% or higher chance of occurrence. A statement of probable error is of little value.

Error, random. Statistical error caused by chance and not recurring. This term is a general category for errors that can take values on either side of an average value. To describe a random error, its distribution must be known.

Error, root mean square (RMS). Accuracy statement of a system comprising several items. For example, a laboratory potentiometer, volt box, null detector, and reference voltage source have individual accuracy statements assigned to them. These errors are generally independent of one another, so a system of these units displays an accuracy given by the square root of the sum of the squares of the individual limits of error. For example, four individual errors of 0.1% could yield a calibrated error of 0.4% but an RMS error of only 0.2%.

Error, systematic. Persistent error not due to chance; systematic errors are causal. It is likely to have the same magnitude and sign for every instrument constructed with the same components and

The preparation of this chapter is assigned to TC 1.2, Instruments and Measurements.

Fig. 1 Measurement and Instrument Terminology

procedures. Errors in calibrating equipment cause systematic errors because all instruments calibrated are biased in the direction of the calibrating equipment error. Voltage and resistance drifts over time are generally in one direction and are classed as systematic errors.

Frequency response (flat). Portion of the frequency spectrum over which the measuring system has a constant value of amplitude response and a constant value of time lag. Input signals that have frequency components within this range are indicated by the measuring system (without distortion).

Hydraulic diameter D_h . Defined as $4A_c/P_{wet}$, where A_c is flow cross-sectional area and P_{wet} is the wetted perimeter (perimeter in contact with the flowing fluid). For a rectangular duct with dimensions $W \times H$, the hydraulic diameter is $D_h = LW/(L + W)$. The related quantity *effective diameter* is defined as the diameter of a circular tube having the same cross-sectional area as the actual flow channel. For a rectangular flow channel, the effective diameter is $D_{eff} = \sqrt{4LW/\pi}$.

Hysteresis. Summation of all effects, under constant environmental conditions, that cause an instrument's output to assume

different values at a given stimulus point when that point is approached with increasing or decreasing stimulus. Hysteresis includes backlash. It is usually measured as a percent of full scale when input varies over the full increasing and decreasing range. In instrumentation, hysteresis and deadband exhibit similar output error behavior in relation to input, as shown in Figure 1.

Linearity. The straight-lineness of the transfer curve between an input and an output (e.g., the ideal line in Figure 1); that condition prevailing when output is directly proportional to input (see *Nonlinearity*). Note that the generic term *linearity* does not consider any parallel offset of the straight-line calibration curve.

Loading error. Loss of output signal from a device caused by a current drawn from its output. It increases the voltage drop across the internal impedance, where no voltage drop is desired.

Mean. See *Average*.

Median. Middle value in a distribution, above and below which lie an equal number of values.

Mode. Value in a distribution that occurs most frequently.

Noise. Any unwanted disturbance or spurious signal that modifies the transmission, measurement, or recording of desired data.

Nonlinearity. Prevailing condition (and the extent of its measurement) under which the input/output relationship (known as the input/output curve, transfer characteristic, calibration curve, or response curve) fails to be a straight line. Nonlinearity is measured and reported in several ways, and the way, along with the magnitude, must be stated in any specification.

Minimum-deviation-based nonlinearity: maximum departure between the calibration curve and a straight line drawn to give the greatest accuracy; expressed as a percent of full-scale deflection.

Slope-based nonlinearity: ratio of maximum slope error anywhere on the calibration curve to the slope of the nominal sensitivity line; usually expressed as a percent of nominal slope.

Most other variations result from the many ways in which the straight line can be arbitrarily drawn. All are valid as long as construction of the straight line is explicit.

Population. Group of individual persons, objects, or items from which samples may be taken for statistical measurement.

Precision. Repeatability of measurements of the same quantity under the same conditions; not a measure of absolute accuracy. It describes the relative tightness of the distribution of measurements of a quantity about their mean value. Therefore, precision of a measurement is associated more with its repeatability than its accuracy. It combines uncertainty caused by random differences in a number of identical measurements and the smallest readable increment of the scale or chart. Precision is given in terms of deviation from a mean value.

Primary calibration. Calibration procedure in which the instrument output is observed and recorded while the input stimulus is applied under precise conditions, usually from a primary external standard traceable directly to the National Institute of Standards and Technology (NIST).

Range. Statement of upper and lower limits between which an instrument's input can be received and for which the instrument is calibrated.

Reliability. Probability that an instrument's precision and accuracy will continue to fall within specified limits.

Repeatability. See *Precision*.

Reproducibility. In instrumentation, the closeness of agreement among repeated measurements of the output for the same value of input made under the same operating conditions over a period of time, approaching from both directions; it is usually measured as a nonreproducibility and expressed as reproducibility in percent of span for a specified time period. Normally, this implies a long period of time, but under certain conditions, the period may be a short time so that drift is not included. Reproducibility includes hysteresis, dead band, drift, and repeatability. Between repeated

measurements, the input may vary over the range, and operating conditions may vary within normal limits.

Resolution. Smallest change in input that produces a detectable change in instrument output. Resolution, unlike precision, is a psychophysical term referring to the smallest increment of humanly perceptible output (rated in terms of the corresponding increment of input). The precision, resolution, or both may be better than the accuracy. An ordinary six-digit instrument has a resolution of one part per million (ppm) of full scale; however, it is possible that the accuracy is no better than 25 ppm (0.0025%). Note that the practical resolution of an instrument cannot be any better than the resolution of the indicator or detector, whether internal or external.

Sensitivity. Slope of a calibration curve relating input signal to output, as shown in Figure 1. For linear instruments, sensitivity represents the change in output for a unit change in the input.

Sensitivity error. Maximum error in sensitivity displayed as a result of the changes in the calibration curve resulting from accumulated effects of systematic and random errors.

Stability. (1) Independence or freedom from changes in one quantity as the result of a change in another; (2) absence of drift.

Static error band. (1) Spread of error present if the indicator (pen, needle) stopped at some value (e.g., at one-half of full scale), normally reported as a percent of full scale; (2) specification or rating of maximum departure from the point where the indicator must be when an on-scale signal is stopped and held at a given signal level. This definition stipulates that the stopped position can be approached from either direction in following any random waveform. Therefore, it is a quantity that includes hysteresis and nonlinearity but excludes items such as chart paper accuracy or electrical drift (see *Dynamic error band*).

Step-function response. Characteristic curve or output plotted against time resulting from the input application of a step function (a function that is zero for all values of time before a certain instant, and a constant for all values of time thereafter).

Threshold. Smallest stimulus or signal that results in a detectable output.

Time constant. Time required for an exponential quantity to change by an amount equal to 0.632 times the total change required to reach steady state for first-order systems.

Transducer. Device for translating the changing magnitude of one kind of quantity into corresponding changes of another kind of quantity. The second quantity often has dimensions different from the first and serves as the source of a useful signal. The first quantity may be considered an input and the second an output. Significant energy may or may not transfer from the transducer's input to output.

Uncertainty. An estimated value for the bound on the error (i.e., what an error might be if it were measured by calibration). Although uncertainty may be the result of both systematic and precision errors, only precision error can be treated by statistical methods. Uncertainty may be either **absolute** (expressed in the units of the measured variable) or **relative** (absolute uncertainty divided by the measured value; commonly expressed in percent).

Zero shift. Drift in the zero indication of an instrument without any change in the measured variable.

UNCERTAINTY ANALYSIS

Uncertainty Sources

Measurement generally consists of a sequence of operations or steps. Virtually every step introduces a conceivable source of uncertainty, the effect of which must be assessed. The following list is representative of the most common, but not all, sources of uncertainty.

- Inaccuracy in the mathematical model that describes the physical quantity

- Inherent stochastic variability of the measurement process
- Uncertainties in measurement standards and calibrated instrumentation
- Time-dependent instabilities caused by gradual changes in standards and instrumentation
- Effects of environmental factors such as temperature, humidity, and pressure
- Values of constants and other parameters obtained from outside sources
- Uncertainties arising from interferences, impurities, inhomogeneity, inadequate resolution, and incomplete discrimination
- Computational uncertainties and data analysis
- Incorrect specifications and procedural errors
- Laboratory practice, including handling techniques, cleanliness, and operator techniques, etc.
- Uncertainty in corrections made for known effects, such as installation effect corrections

Uncertainty of a Measured Variable

For a measured variable X , the total error is caused by both **precision (random)** and **systematic (bias) errors**. This relationship is shown in Figure 2. The possible measurement values of the variable are scattered in a distribution around the parent population mean μ (Figure 2A). The curve (**normal** or **Gaussian distribution**) is the theoretical distribution function for the infinite population of measurements that generated X . The parent population mean differs from $(X)_{true}$ by an amount called the systematic (or bias) error β (Figure 2B). The quantity β is the total fixed error that remains after all calibration corrections have been made. In general, there are several sources of bias error, such as errors in calibration standard, data acquisition, data reduction, and test technique. There is usually no direct way to measure these errors. These errors are unknown and are assumed to be zero; otherwise, an additional correction would be applied to reduce them to as close to zero as possible. Figure 2B shows how the resulting deviation δ can be different for different random errors ϵ .

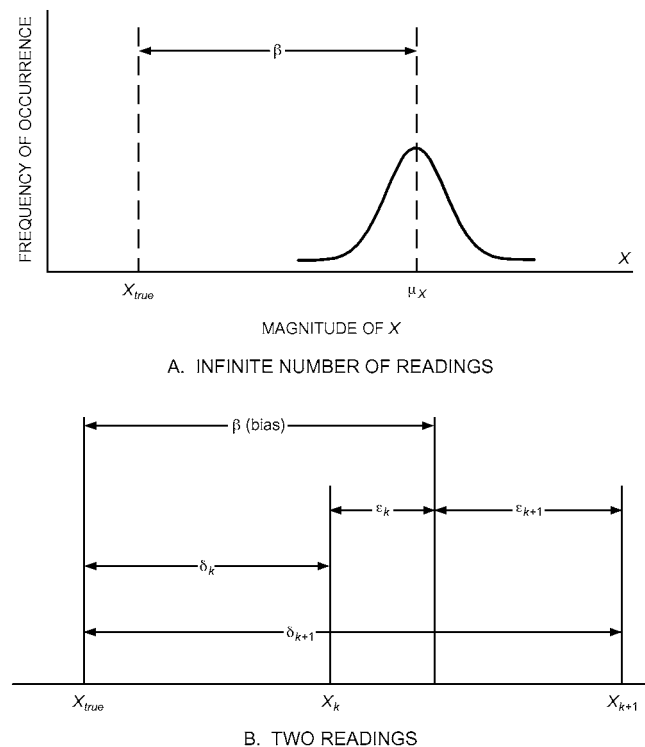

Fig. 2 Errors in Measurement of Variable X

The **precision uncertainty** for a variable, which is an estimate of the possible error associated with the repeatability of a particular measurement, is determined from the sample standard deviation, or the estimate of the error associated with the repeatability of a particular measurement. Unlike systematic error, precision error varies from reading to reading. As the number of readings of a particular variable tends to infinity, the distribution of these possible errors becomes Gaussian.

For each bias error source, the experimenter must estimate a **systematic uncertainty**. Systematic uncertainties are usually estimated from previous experience, calibration data, analytical models, and engineering judgment. The resultant uncertainty is the square root of the sum of the squares of the bias and precision uncertainties; see Coleman and Steele (1989).

For further information on measurement uncertainty, see ASME *Standards* MFC-2M and PTC 19.1, Abernethy et al. (1985), Brown et al. (1998), and Coleman and Steele (1995).

TEMPERATURE MEASUREMENT

Instruments for measuring temperature are listed in Table 1. Temperature sensor output must be related to an accepted temperature scale by manufacturing the instrument according to certain specifications or by calibrating it against a temperature standard. To help users conform to standard temperatures and temperature measurements, the International Committee of Weights and Measures (CIPM) adopted the International Temperature Scale of 1990 (ITS90).

The unit of temperature of the ITS-90 is the kelvin (K) and has a size equal to the fraction 1/273.16 of the thermodynamic temperature of the triple point of water.

In the United States, ITS-90 is maintained by the National Institute of Standards and Technology (NIST), which provides calibrations based on this scale for laboratories.

Benedict (1984), Considine (1985), DeWitt and Nutter (1988), Quinn (1990), and Schooley (1986, 1992) cover temperature measurement in more detail.

Sampling and Averaging

Although temperature is usually measured within, and is associated with, a relatively small volume (depending on the size of the thermometer), it can also be associated with an area (e.g., on a surface or in a flowing stream). To determine average stream temperature, the cross section must be divided into smaller areas and the temperature of each area measured. The temperatures measured are then combined into a weighted mass flow average by using either (1) equal areas and multiplying each temperature by the fraction of total mass flow in its area or (2) areas of size inversely proportional to mass flow and taking a simple arithmetic average of the temperatures in each. Mixing or selective sampling may be preferable to these cumbersome procedures. Although mixing can occur from turbulence alone, **transposition** is much more effective. In transposition, the stream is divided into parts determined by the type of stratification, and alternate parts pass through one another.

Table 1 Common Temperature Measurement Techniques

Measurement Means	Application	Approximate Range, °F	Uncertainty, °F	Limitations
Liquid-in-glass thermometers				
Mercury-in-glass	Temperature of gases and liquids by contact	−36/1000	0.05 to 3.6	In gases, accuracy affected by radiation
Organic fluid	Temperature of gases and liquids by contact	−330/400	0.05 to 3.6	In gases, accuracy affected by radiation
Resistance thermometers				
Platinum	Precision; remote readings; temperature of fluids or solids by contact	−430/1800	Less than 0.0002 to 0.2	High cost; accuracy affected by radiation in gases
Rhodium/iron	Transfer standard for cryogenic applications	−460/−400	0.0002 to 0.2	High cost
Nickel	Remote readings; temperature by contact	−420/400	0.02 to 2	Accuracy affected by radiation in gases
Germanium	Remote readings; temperature by contact	−460/−400	0.0002 to 0.2	
Thermistors	Remote readings; temperature by contact	Up to 400	0.0002 to 0.2	
Thermocouples				
Pt-Rh/Pt (type S)	Standard for thermocouples on IPTS-68, not on ITS-90	32/2650	0.2 to 5	High cost
Au/Pt	Highly accurate reference thermometer for laboratory applications	−60/1800	0.1 to 2	High cost
Types K and N	General testing of high temperature; remote rapid readings by direct contact	Up to 2300	0.2 to 18	Less accurate than Pt-Rh/Pt or Au/Pt thermocouples
Iron/Constantan (type J)	Same as above	Up to 1400	0.2 to 10	Subject to oxidation
Copper/Constantan (type T)	Same as above; especially suited for low temperature	Up to 660	0.2 to 5	
Ni-Cr/Constantan (type E)	Same as above; especially suited for low temperature	Up to 1650	0.2 to 13	
Bimetallic thermometers	For approximate temperature	−4/1200	2, usually much more	Time lag; unsuitable for remote use
Pressure-bulb thermometers				
Gas-filled bulb	Remote reading	−100/1200	4	Use caution to ensure installation is correct
Vapor-filled bulb	Remote testing	−25/500	4	Use caution to ensure installation is correct
Liquid-filled bulb	Remote testing	−60/2100	4	Use caution to ensure installation is correct
Optical pyrometers	For intensity of narrow spectral band of high-temperature radiation (remote)	1500 and up	30	Generally requires knowledge of surface emissivity
Infrared (IR) radiometers	For intensity of total high-temperature radiation (remote)	Any range		
IR thermography	Infrared imaging	Any range		Generally requires knowledge of surface emissivity
Seeger cones (fusion pyrometers)	Approximate temperature (within temperature source)	1200/3600	90	

Static Temperature Versus Total Temperature

When a fluid stream impinges on a temperature-sensing element such as a thermometer or thermocouple, the element is at a temperature greater than the true stream temperature. The difference is a fraction of the temperature equivalent of the stream velocity t_e .

$$t_e = \frac{3600V^2}{2g_c J c_p} \quad (1)$$

where

- t_e = temperature equivalent of stream velocity, °F
- V = stream velocity, fpm
- g_c = gravitational constant = 32.174 lb_m·ft/lb_f·s²
- J = mechanical equivalent of heat = 778.3 ft·lb_f/Btu
- c_p = specific heat of stream at constant pressure, Btu/lb_m·°F

This fraction of the temperature equivalent of the velocity is the **recovery factor**, which varies from 0.6 to 0.8°F for bare thermometers to 1.0°F for aerodynamically shielded thermocouples. For precise temperature measurement, each temperature sensor must be calibrated to determine its recovery factor. However, for most applications with air velocities below 2000 fpm, the recovery factor can be omitted.

Various sensors are available for temperature measurement in fluid streams. The principal ones are the **static temperature thermometer**, which indicates true stream temperature but is cumbersome, and the **thermistor**, used for accurate temperature measurement within a limited range.

LIQUID-IN-GLASS THERMOMETERS

Any device that changes monotonically with temperature is a thermometer; however, the term usually signifies an ordinary liquid-in-glass temperature-indicating device. Mercury-filled thermometers have a useful range from -37.8°F, the freezing point of mercury, to about 1000°F, near which the glass usually softens. Lower temperatures can be measured with organic-liquid-filled thermometers (e.g., alcohol-filled), with ranges of -330 to 400°F. During manufacture, thermometers are roughly calibrated for at least two temperatures, often the freezing and boiling points of water; space between the calibration points is divided into desired scale divisions. Thermometers that are intended for precise measurement applications have scales etched into the glass that forms their stems. The probable error for as-manufactured, etched-stem thermometers is ±1 scale division. The highest-quality mercury thermometers may have uncertainties of ±0.06 to 4°F if they have been calibrated by comparison against primary reference standards.

Liquid-in-glass thermometers are used for many HVAC applications, including local temperature indication of process fluids (e.g., cooling and heating fluids and air).

Mercury-in-glass thermometers are fairly common as temperature measurement standards because of their relatively high accuracy and low cost. If used as references, they must be calibrated on the ITS-90 by comparison in a uniform bath with a standard platinum resistance thermometer that has been calibrated either by the appropriate standards agency or by a laboratory that has direct traceability to the standards agency and the ITS-90. This calibration is necessary to determine the proper corrections to be applied to the scale readings. For application and calibration of liquid-in-glass thermometers, refer to NIST (1976, 1986).

Liquid-in-glass thermometers are calibrated by the manufacturer for total or partial stem immersion. If a thermometer calibrated for total immersion is used at partial immersion (i.e., with part of the liquid column at a temperature different from that of the bath), an emergent stem correction must be made, as follows:

$$\text{Stem correction} = Kn(t_b - t_s) \quad (2)$$

where

- K = differential expansion coefficient of mercury or other liquid in glass. K is 0.00009 for Fahrenheit mercury thermometers. For K values for other liquids and specific glasses, refer to Schooley (1992).
- n = number of degrees that liquid column emerges from bath
- t_b = temperature of bath, °F
- t_s = average temperature of emergent liquid column of n degrees, °F

Because the true temperature of the bath is not known, this stem correction is only approximate.

Sources of Thermometer Errors

A thermometer measuring gas temperatures can be affected by radiation from surrounding surfaces. If the gas temperature is approximately the same as that of the surrounding surfaces, radiation effects can be ignored. If the temperature differs considerably from that of the surroundings, radiation effects should be minimized by shielding or aspiration (ASME *Standard* PTC 19.3). **Shielding** may be provided by highly reflective surfaces placed between the thermometer bulb and the surrounding surfaces such that air movement around the bulb is not appreciably restricted (Parmelee and Huebscher 1946). Improper shielding can increase errors. **Aspiration** involves passing a high-velocity stream of air or gas over the thermometer bulb.

When a **thermometer well** within a container or pipe under pressure is required, the thermometer should fit snugly and be surrounded with a high-thermal-conductivity material (oil, water, or mercury, if suitable). Liquid in a long, thin-walled well is advantageous for rapid response to temperature changes. The surface of the pipe or container around the well should be insulated to eliminate heat transfer to or from the well.

Industrial thermometers are available for permanent installation in pipes or ducts. These instruments are fitted with metal guards to prevent breakage. However, the considerable heat capacity and conductance of the guards or shields can cause errors.

Allowing ample time for the thermometer to attain temperature equilibrium with the surrounding fluid prevents excessive errors in temperature measurements. When reading a liquid-in-glass thermometer, keep the eye at the same level as the top of the liquid column to avoid parallax.

RESISTANCE THERMOMETERS

Resistance thermometers depend on a change of the electrical resistance of a sensing element (usually metal) with a change in temperature; resistance increases with increasing temperature. Use of resistance thermometers largely parallels that of thermocouples, although readings are usually unstable above about 1000°F. Two-lead temperature elements are not recommended because they do not allow correction for lead resistance. Three leads to each resistor are necessary for consistent readings, and four leads are preferred. Wheatstone bridge circuits or 6-1/2-digit multimeters can be used for measurements.

A typical circuit used by several manufacturers is shown in Figure 3. This design uses a differential galvanometer in which coils L and H exert opposing forces on the indicating needle. Coil L is in series with the thermometer resistance AB, and coil H is in series with the constant resistance R. As the temperature falls, the resistance of AB decreases, allowing more current to flow through coil L than through coil H. This increases the force exerted by coil L, pulling the needle down to a lower reading. Likewise, as the temperature rises, the resistance of AB increases, causing less current to flow through coil L than through coil H and forcing the indicating needle to a higher reading. Rheostat S must be adjusted occasionally to maintain constant current.

The resistance thermometer is more costly to make and likely to have considerably longer response times than thermocouples. It gives best results when used to measure steady or slowly changing temperature.

Resistance Temperature Devices

Resistance temperature devices (RTDs) are typically constructed from platinum, rhodium/iron, nickel, nickel/iron, tungsten, or copper. These devices are further characterized by their simple circuit designs, high degree of linearity, good sensitivity, and excellent stability. The choice of materials for an RTD usually depends on the intended application; selection criteria include temperature range, corrosion protection, mechanical stability, and cost.

Presently, for HVAC applications, RTDs constructed of platinum are the most widely used. Platinum is extremely stable and resistant to corrosion. Platinum RTDs are highly malleable and can thus be drawn into fine wires; they can also be manufactured inexpensively as thin films. They have a high melting point and can be refined to high purity, thus attaining highly reproducible results. Because of

these properties, platinum RTDs are used to define the ITS-90 for the range of 13.8033 K (triple point of equilibrium hydrogen) to 1234.93 K (freezing point of silver).

Platinum resistance temperature devices can measure the widest range of temperatures and are the most accurate and stable temperature sensors. Their resistance/temperature relationship is one of the most linear. The higher the purity of the platinum, the more stable and accurate the sensor. With high-purity platinum, primary-grade platinum RTDs can achieve reproducibility of $\pm 0.00002^\circ\text{F}$, whereas the minimum uncertainty of a recently calibrated thermocouple is $\pm 0.4^\circ\text{F}$.

The most widely used RTD is designed with a resistance of $100\ \Omega$ at 32°F ($R_0 = 100\ \Omega$). Other RTDs are available that use lower resistances at temperatures above 1100°F . The lower the resistance value, the faster the response time for sensors of the same size.

Thin-Film RTDs. Thin-film $1000\ \Omega$ platinum RTDs are readily available. They have the excellent linear properties of lower-resistance platinum RTDs and are more cost-effective because they are mass produced and have lower platinum purity. However, many platinum RTDs with R_0 values of greater than $100\ \Omega$ are difficult to provide with transmitters or electronic interface boards from sources other than the RTD manufacturer. In addition to a nonstandard interface, higher- R_0 -value platinum RTDs may have higher self-heating losses if the excitation current is not controlled properly.

Thin-film RTDs have the advantages of lower cost and smaller sensor size. They are specifically adapted to surface mounting. Thin-film sensors tend to have an accuracy limitation of $\pm 0.1\%$ or $\pm 0.2^\circ\text{F}$. This may be adequate for most HVAC applications; only in tightly controlled facilities may users wish to install the standard wire-wound platinum RTDs with accuracies of 0.01% or $\pm 0.02^\circ\text{F}$ (available on special request for certain temperature ranges).

Assembly and Construction. Regardless of the R_0 value, RTD assembly and construction are relatively simple. Electrical connections come in three basic types, depending on the number of wires to be connected to the resistance measurement circuitry. Two, three, or four wires are used for electrical connection using a Wheatstone bridge or a variation (Figure 4).

In the basic two-wire configuration, the RTD's resistance is measured through the two connecting wires. Because the connecting wires extend from the site of the temperature measurement, any additional changes in resistivity caused by a change in temperature may affect the measured resistance. Three- and four-wire assemblies are built to compensate for the connecting lead resistance

Fig. 3 Typical Resistance Thermometer Circuit

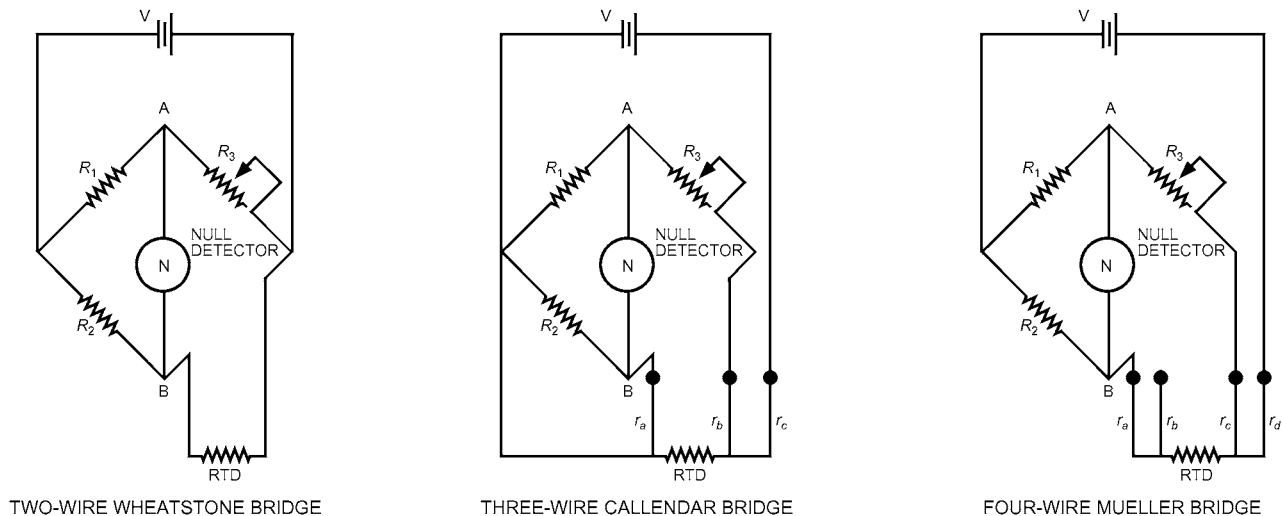

Fig. 4 Typical Resistance Temperature Device (RTD) Bridge Circuits

values. The original three-wire circuit improved resistance measurement by adding a compensating wire to the voltage side of the circuit. This helps reduce part of the connecting wire resistance. When more accurate measurements (better than $\pm 0.2^\circ\text{F}$) are required, the four-wire bridge, which eliminates all connecting wire resistance errors, is recommended.

All bridges discussed here are direct current (dc) circuits and were used extensively until the advent of precision alternating current (ac) circuits using microprocessor-controlled ratio transformers, dedicated analog-to-digital converters, and other solid-state devices that measure resistance with uncertainties of less than 1 ppm. Resistance measurement technology now allows more portable thermometers, lower cost, ease of use, and high-precision temperature measurement in industrial uses.

Thermistors

Certain semiconductor compounds (usually sintered metallic oxides) exhibit large changes in resistance with temperature, usually decreasing as the temperature increases. For use, the thermistor element may be connected by lead wires into a galvanometer bridge circuit and calibrated. Alternatively, a 6-1/2-digit multimeter and a constant-current source with a means for reversing the current to eliminate thermal electromotive force (emf) effects may also be used. This method is easier and faster, and may be more precise and accurate. Thermistors are usually applied to electronic temperature compensation circuits, such as thermocouple reference junction compensation, or to other applications where high resolution and limited operating temperature ranges exist. Figure 5 illustrates a typical thermistor circuit.

Semiconductor Devices

In addition to positive-resistance-coefficient RTDs and negative-resistance-coefficient thermistors, there are two other types of devices that vary resistance or impedance with temperature. Although the principle of their operation has long been known, their reliability was questioned because of imprecise manufacturing techniques. Improved silicon microelectronics manufacturing techniques have brought semiconductors to the point where low-cost, precise temperature sensors are commercially available.

Elemental Semiconductors. Because of controlled doping of impurities into elemental germanium, a germanium semiconductor

is a reliable temperature sensor for cryogenic temperature measurement in the range of 1.8 to 150°R.

Junction Semiconductors. The first simple junction semiconductor device consisted of a single diode or transistor, in which the forward-connected base emitter voltage was very sensitive to temperature. Today, the more common form is a pair of diode-connected transistors, which make the device suitable for ambient temperature measurement. Applications include thermocouple reference junction compensation.

The primary advantages of silicon transistor temperature sensors are their extreme linearity and exact R_0 value, as well as the incorporation of signal conditioning circuitry into the same device as the sensor element. As with thermocouples, these semiconductors require highly precise manufacturing techniques, extremely precise voltage measurements, multiple-point calibration, and temperature compensation to achieve an accuracy as high as $\pm 0.02^\circ\text{F}$, but with a much higher cost. Lower-cost devices achieve accuracies of $\pm 0.2^\circ\text{F}$ using mass-manufacturing techniques and single-point calibration. A mass-produced silicon temperature sensor can be interchanged easily. If one device fails, only the sensor element need be changed. Electronic circuitry can be used to recalibrate the new device.

Winding Temperature. The winding temperature of electrical operating equipment is usually determined from the resistance change of these windings in operation. With copper windings, the relation between these parameters is

$$\frac{R_1}{R_2} = \frac{148 + t_1}{148 + t_2} \tag{3}$$

where

- R_1 = winding resistance at temperature t_1, Ω
- R_2 = winding resistance at temperature t_2, Ω
- t_1, t_2 = winding temperatures, °F

The classical method of determining winding temperature is to measure the equipment when it is inoperative and temperature-stabilized at room temperature. After the equipment has operated sufficiently to stabilize temperature under load conditions, the winding resistance should be measured again by taking resistance measurements at known, short time intervals after shutdown. These values may be extrapolated to zero time to indicate the winding resistance at the time of shutdown. The obvious disadvantage of this method is that the device must be shut down to determine winding temperature. A circuit described by Seely (1955), however, makes it possible to measure resistances while the device is operating.

THERMOCOUPLES

When two wires of dissimilar metals are joined by soldering, welding, or twisting, they form a thermocouple junction or **thermojunction**. An emf that depends on the wire materials and the junction temperature exists between the wires. This is known as the **Seebeck voltage**.

Thermocouples for temperature measurement yield less precise results than platinum resistance thermometers, but, except for glass thermometers, thermocouples are the most common instruments of temperature measurement for the range of 32 to 1800°F. Because of their low cost, moderate reliability, and ease of use, thermocouples are widely accepted.

The most commonly used thermocouples in industrial applications are assigned letter designations. Tolerances of such commercially available thermocouples are given in Table 2.

Because the measured emf is a function of the difference in temperature and the type of dissimilar metals used, a known temperature at one junction is required; the remaining junction temperature may be calculated. It is common to call the one with known temperature the (cold) **reference junction** and the one with unknown temperature the (hot) **measured junction**. The reference junction is

Fig. 5 Basic Thermistor Circuit

Table 2 Thermocouple Tolerances on Initial Values of Electromotive Force Versus Temperature

Thermocouple Type	Material Identification	Temperature Range, °F	Reference Junction Tolerance at 32°F ^a	
			Standard Tolerance (whichever is greater)	Special Tolerance (whichever is greater)
T	Copper versus Constantan	32 to 700	±1.8°F or ±0.75%	±0.9°F or ±0.4%
J	Iron versus Constantan	32 to 1400	±4°F or ±0.75%	±2°F or ±0.4%
E	Nickel/10% Chromium versus Constantan	32 to 1600	±3.1°F or ±0.5%	±1.8°F or ±0.4%
K	Nickel/10% Chromium versus 5% Aluminum, Silicon	32 to 2300	±4°F or ±0.75%	±2°F or ±0.4%
N	Nickel/14% Chromium, 1.5% Silicon versus Nickel/4.5% Silicon, 0.1% Magnesium	32 to 2300	±4°F or ±0.75%	±2°F or ±0.4%
R	Platinum/13% Rhodium versus Platinum	32 to 2700	±2.7°F or ±0.25%	±1.1°F or ±0.1%
S	Platinum/10% Rhodium versus Platinum	32 to 2700	±2.7°F or ±0.25%	±1.1°F or ±0.1%
B	Platinum/30% Rhodium versus Platinum/6% Rhodium	1600 to 3100	±0.5%	±0.25%
T ^b	Copper versus Constantan	−328 to 32	±1.8°F or ±1.5%	c
E ^b	Nickel/10% Chromium versus Constantan	−328 to 32	±3.1°F or ±1%	c
K ^b	Nickel/10% Chromium versus 5% Aluminum, Silicon	−328 to 32	±4°F or ±2%	c

Source: ASTM Standard E230, Temperature-Electromotive Force (EMF) Tables for Standardized Thermocouples.

^aTolerances in this table apply to new thermocouple wire, normally in the size range of 0.01 to 0.1 in. diameter and used at temperatures not exceeding the recommended limits. Thermocouple wire is available in two grades: standard and special.

^bThermocouples and thermocouple materials are normally supplied to meet the tolerance specified in the table for temperatures above 32°F. The same materials, however, may not fall within the tolerances given in the second section of the table when operated below freezing (32°F). If materials are required to meet tolerances at subfreezing temperatures, the purchase order must state so.

^cLittle information is available to justify establishing special tolerances for below-freezing temperatures. Limited experience suggests the following special tolerances for types E and T thermocouples:

Type E −328 to 32°F; ±2°F or ±0.5% (whichever is greater)

Type T −328 to 32°F; ±1°F or ±0.8% (whichever is greater)

These tolerances are given only as a guide for discussion between purchaser and supplier.

typically kept at a reproducible temperature, such as the ice point of water.

Various systems are used to maintain the reference junction temperature (e.g., mixed ice and water in an insulated flask, or commercially available thermoelectric coolers to maintain the ice-point temperature automatically in a reference chamber). When these systems cannot be used in an application, measuring instruments with automatic reference junction temperature compensation may be used.

As previously described, the principle for measuring temperature with a thermocouple is based on accurate measurement of the Seebeck voltage. Acceptable dc voltage measurement methods are (1) millivoltmeter, (2) millivolt potentiometer, and (3) high-input impedance digital voltmeter. Many digital voltmeters include built-in software routines for direct calculation and display of temperature. Regardless of the method selected, there are many ways to simplify measurement.

Solid-state digital readout devices in combination with a millior microvoltmeter, as well as packaged thermocouple readouts with built-in cold junction and linearization circuits, are available. The latter requires a proper thermocouple to provide direct meter reading of temperature. Accuracy approaching or surpassing that of potentiometers can be attained, depending on the instrument quality. This method is popular because it eliminates the null balancing requirement and reads temperature directly in a digital readout.

Wire Diameter and Composition

Thermocouple wire is selected by considering the temperature to be measured, the corrosion protection afforded to the thermocouple, and the precision and service life required. Type T thermocouples are suitable for temperatures up to 700°F; type J, up to 1400°F; and types K and N, up to 2300°F. Higher temperatures require noble metal thermocouples (type S, R, or B), which have a higher initial cost and do not develop as high an emf as the base metal thermocouples. Thermocouple wires of the same type have small compositional variation from lot to lot from the same manufacturer, and especially among different manufacturers. Consequently, calibrating samples from each wire spool is essential for precision. Calibration data on wire may be obtained from the manufacturer.

Computer-friendly reference functions are available for relating temperature and emf of letter-designated thermocouple types. The

functions depend on thermocouple type and temperature range; they are used to generate reference tables of emf as a function of temperature, but are not well suited for calculating temperatures directly from values of emf. Approximate inverse functions are available, however, for calculating temperature and are of the form

$$t = \sum_{i=0}^n a_i E^i \quad (4)$$

where t = temperature, a_i = thermocouple constant coefficients, and E = voltage. Burns et al. (1992) give reference functions and approximate inverses for all letter-designated thermocouples.

The emf of a thermocouple, as measured with a high-input impedance device, is independent of the diameters of its constituent wires. Thermocouples with small-diameter wires respond faster to temperature changes and are less affected by radiation than larger ones. Large-diameter wire thermocouples, however, are necessary for high-temperature work when wire corrosion is a problem. For use in heated air or gases, thermocouples are often shielded and sometimes aspirated. One way to avoid error caused by radiation is using several thermocouples of different wire sizes and estimating the true temperature by extrapolating readings to zero diameter.

With thermocouples, temperatures can be indicated or recorded remotely on conveniently located instruments. Because thermocouples can be made of small-diameter wire, they can be used to measure temperatures within thin materials, within narrow spaces, or in otherwise inaccessible locations.

Multiple Thermocouples

Thermocouples in series, with alternate junctions maintained at a common temperature, produce an emf that, when divided by the number of thermocouples, gives the average emf corresponding to the temperature difference between two sets of junctions. This series arrangement of thermocouples, often called a **thermopile**, is used to increase sensitivity and is often used for measuring small temperature changes and differences.

Connecting several thermocouples of the same type in parallel with a common reference junction is useful for obtaining an average temperature of an object or volume. In such measurements, however,

it is important that the electrical resistances of the individual thermocouples be the same. Use of thermocouples in series and parallel arrangements is discussed in *ASTM Manual 12*.

Surface Temperature Measurement

The thermocouple is useful in determining surface temperature. It can be attached to a metal surface in several ways. For permanent installations, soldering, brazing, or peening (i.e., driving the thermocouple measuring junction into a small drilled hole) is suggested. For temporary arrangements, thermocouples can be attached by tape, adhesive, or putty-like material. For boiler or furnace surfaces, use furnace cement. To minimize the possibility of error caused by heat conduction along wires, a surface thermocouple should be made of fine wires placed in close contact with the surface being measured for about an inch from the junction to ensure good thermal contact. Wires must be insulated electrically from each other and from the metal surface (except at the junction).

Thermocouple Construction

Thermocouple wires are typically insulated with fibrous glass, fluorocarbon resin, or ceramic insulators. In another form of thermocouple, the wires are insulated with compacted ceramic insulation inside a metal sheath, providing both mechanical protection and protection from stray electromagnetic fields. The measuring junction may be exposed or enclosed within the metal sheath. An enclosed junction may be either grounded or ungrounded to the metal sheath.

An exposed junction is in direct contact with the process stream; it is therefore subject to corrosion or contamination, but provides a fast temperature response. A grounded enclosed junction, in which the wires are welded to the metal sheath, provides electrical grounding, as well as mechanical and corrosion protection, but has a slower response time. Response time is even slower for ungrounded enclosed junctions, but the thermocouple wires are isolated electrically and are less susceptible to some forms of mechanical strain than those with grounded construction.

OPTICAL PYROMETRY

Optical pyrometry determines a surface's temperature from the color of the radiation it emits. As the temperature of a surface increases, it becomes deep red in color, then orange, and eventually white. This behavior follows from Wein's law, which indicates that the wavelength corresponding to the maximum intensity of emitted radiation is inversely proportional to the absolute temperature of the emitting surface. Thus, as temperature increases, the wavelength decreases.

To determine the unknown surface temperature, the color of the radiation from the surface is optically compared to the color of a heated filament. By adjusting the current in the filament, the color of the filament is made to match the color of radiation from the source surface. When in balance, the filament virtually disappears into the background image of the surface color. Filament calibration is required to relate the filament current to the unknown surface temperature. For further information, see Holman (2001).

INFRARED RADIATION THERMOMETERS

Infrared radiation (IR) thermometers, also known as *remote temperature sensors* (Hudson 1969) or *pyrometers*, allow noncontact measurement of surface temperature over a wide range. In these instruments, radiant flux from the observed object is focused by an optical system onto an infrared detector that generates an output signal proportional to the incident radiation that can be read from a meter or display unit. Both point and scanning radiometers are available; the latter can display the temperature variation in the field of view.

IR thermometers are usually classified according to the detector used: either thermal or photon. In **thermal detectors**, a change in

electrical property is caused by the heating effect of the incident radiation. Examples of thermal detectors are the thermocouple, thermopile, and metallic and semiconductor bolometers. Typical response times are one-quarter to one-half second. In **photon detectors**, a change in electrical property is caused by the surface absorption of incident photons. Because these detectors do not require an increase in temperature for activation, their response time is much shorter than that of thermal detectors. Scanning radiometers usually use photon detectors.

An IR thermometer only measures the power level of radiation incident on the detector, a combination of thermal radiation emitted by the object and surrounding background radiation reflected from the object's surface. Very accurate measurement of temperature, therefore, requires knowledge of the long-wavelength emissivity of the object as well as the effective temperature of the thermal radiation field surrounding the object. Calibration against an internal or external source of known temperature and emissivity may be needed to obtain true surface temperature from the radiation measurements.

In other cases, using published emissivity factors for common materials may suffice. Many IR thermometers have an emissivity adjustment feature that automatically calculates the effect of emissivity on temperature once the emissivity factor is entered. Thermometers that do not have an emissivity adjustment are usually preset to calculate emissivity at 0.95, a good estimate of the emissivity of most organic substances, including paint. Moreover, IR thermometers are frequently used for relative, rather than absolute, measurement; in these cases, adjustment for emissivity may be unnecessary. The most significant practical problem is measuring shiny, polished objects. Placing electrical tape or painting the measurement area with flat black paint and allowing the temperature of the tape or paint to equilibrate can mitigate this problem.

A key factor in measurement quality can be the optical resolution or spot size of the IR thermometer, because this specification determines the instrument's measurement area from a particular distance and, thus, whether a user is actually measuring the desired area. Optical resolution is expressed as distance to spot size ($D:S$) at the focal. Part of the $D:S$ specification is a description of the amount of target infrared energy encircled by the spot; typically it is 95%, but may be 90%.

Temperature resolution of an IR thermometer decreases as object temperature decreases. For example, a radiometer that can resolve a temperature difference of 0.5°F on an object near 70°F may only resolve a difference of 2°F on an object at 32°F.

INFRARED THERMOGRAPHY

Infrared thermography acquires and analyzes thermal information using images from an infrared imaging system. An infrared imaging system consists of (1) an infrared television camera and (2) a display unit. The infrared camera scans a surface and senses the self-emitted and reflected radiation viewed from the surface. The display unit contains either a cathode-ray tube (CRT) that displays a gray-tone or color-coded thermal image of the surface or a color liquid crystal display (LCD) screen. A photograph of the image on the CRT is called a *thermogram*. Introductions to infrared thermography are given by Madding (1989) and Paljak and Pettersson (1972).

Thermography has been used to detect missing insulation and air infiltration paths in building envelopes (Burch and Hunt 1978). Standard practices for conducting thermographic inspections of buildings are given in *ASTM Standard C1060*. A technique for quantitatively mapping heat loss in building envelopes is given by Mack (1986).

Aerial infrared thermography of buildings is effective in identifying regions of an individual built-up roof that have wet insulation (Tobiasson and Korhonen 1985), but it is ineffective in ranking a

Table 3 Humidity Sensor Properties

Type of Sensor	Sensor Category	Method of Operation	Approximate Range	Some Uses	Approximate Accuracy
Psychrometer	Evaporative cooling	Temperature measurement of wet bulb	32 to 180°F	Measurement, standard	±3 to 7% rh
Adiabatic saturation psychrometer	Evaporative cooling	Temperature measurement of thermodynamic wet bulb	40 to 85°F	Measurement, standard	±0.2 to 2% rh
Chilled mirror	Dew point	Optical determination of moisture formation	-110 to 200°F dp	Measurement, control, meteorology	±0.4 to 4°F
Heated saturated salt solution	Water vapor pressure	Vapor pressure depression in salt solution	-20 to 160°F dp	Measurement, control, meteorology	±3°F
Hair	Mechanical	Dimensional change	5 to 100% rh	Measurement, control	±5% rh
Nylon	Mechanical	Dimensional change	5 to 100% rh	Measurement, control	±5% rh
Dacron thread	Mechanical	Dimensional change	5 to 100% rh	Measurement	±7% rh
Goldbeater's skin	Mechanical	Dimensional change	5 to 100% rh	Measurement	±7% rh
Cellulosic materials	Mechanical	Dimensional change	5 to 100% rh	Measurement, control	±5% rh
Carbon	Mechanical	Dimensional change	5 to 100% rh	Measurement	±5% rh
Dunmore type	Electrical	Impedance	7 to 98% rh at 40 to 140°F	Measurement, control	±1.5% rh
Polymer film electronic hygrometer	Electrical	Impedance or capacitance	10 to 100% rh		±2 to 3% rh
Ion exchange resin	Electrical	Impedance or capacitance	10 to 100% rh at -40 to 190°F	Measurement, control	±5% rh
Porous ceramic	Electrical	Impedance or capacitance	Up to 400°F	Measurement, control	±1 to 1.5% rh
Aluminum oxide	Electrical	Capacitance	-110 to 140°F dp	Trace moisture measurement, control	±2°F dp
Electrolytic hygrometer	Electrolytic cell	Electrolyzes due to adsorbed moisture	1 to 1000 ppm	Measurement	
Infrared laser diode	Electrical	Optical diodes	0.1 to 100 ppm	Trace moisture measurement	±0.1 ppm
Surface acoustic wave	Electrical	SAW attenuation	85 to 98% rh	Measurement, control	±1% rh
Piezoelectric	Mass sensitive	Mass changes due to adsorbed moisture	-100 to 0°F	Trace moisture measurement, control	±2 to 10°F dp
Radiation absorption	Moisture absorption	Moisture absorption of UV or IR radiation	0 to 180°F dp	Measurement, control, meteorology	±4°F dp, ±5% rh
Gravimetric	Direct measurement of mixing ratio	Comparison of sample gas with dry airstream	120 to 20,000 ppm mixing ratio	Primary standard, research and laboratory	±0.13% of reading
Color change	Physical	Color changes	10 to 80% rh	Warning device	±10% rh

Notes:

1. This table does not include all available technology for humidity measurement.
 2. Approximate range for device types listed is based on surveys of device manufacturers.

3. Approximate accuracy is based on manufacturers' data.
 4. Presently, NIST only certifies instruments with operating ranges within -103 to 212°F dp.

group of roofs according to their thermal resistance (Burch 1980; Goldstein 1978). In this latter application, the emittances of the separate roofs and outdoor climate (i.e., temperature and wind speed) throughout the microclimate often produce changes in the thermal image that may be incorrectly attributed to differences in thermal resistance.

Industrial applications include locating defective or missing pipe insulation in buried heat distribution systems, surveys of manufacturing plants to quantify energy loss from equipment, and locating defects in coatings (Bentz and Martin 1987). Madding (1989) discusses applications to electrical power systems and electronics.

HUMIDITY MEASUREMENT

Any instrument that can measure the humidity or psychrometric state of air is a hygrometer, and many are available. The indication sensors used on the instruments respond to different moisture property contents. These responses are related to factors such as wet-bulb temperature, relative humidity, humidity (mixing) ratio, dew point, and frost point.

Table 3 lists instruments for measuring humidity. Each is capable of accurate measurement under certain conditions and within specific limitations. The following sections describe the various instruments in more detail.

PSYCHROMETERS

A typical industrial psychrometer consists of a pair of matched electrical or mechanical temperature sensors, one of which is kept wet with a moistened wick. A blower aspirates the sensor, which lowers the temperature at the moistened temperature sensor. The lowest temperature depression occurs when the evaporation rate required to saturate the moist air adjacent to the wick is constant. This is a steady-state, open-loop, nonequilibrium process, which depends on the purity of the water, cleanliness of the wick, ventilation rate, radiation effects, size and accuracy of the temperature sensors, and transport properties of the gas.

ASHRAE *Standard* 41.6 recommends an airflow over both the wet and dry bulbs of 600 to 1000 fpm for transverse ventilation and 300 to 500 fpm for axial ventilation.

The **sling psychrometer** consists of two thermometers mounted side by side in a frame fitted with a handle for whirling the device through the air. The thermometers are spun until their readings become steady. In the **ventilated or aspirated psychrometer**, the thermometers remain stationary, and a small fan, blower, or syringe moves air across the thermometer bulbs. Various designs are used in the laboratory, and commercial models are available.

Other temperature sensors, such as thermocouples and thermistors, are also used and can be adapted for recording temperatures or

for use where a small instrument is required. Small-diameter wet-bulb sensors operate with low ventilation rates.

Charts and tables showing the relationship between the temperatures and humidity are available. Data are usually based on a barometric pressure equal to one standard atmosphere. To meet special needs, charts can be produced that apply to nonstandard pressure (e.g., the ASHRAE 7500 ft psychrometric chart). Alternatively, mathematical calculations can be made (Kusuda 1965). Uncertainties of 3 to 7% rh are typical for psychrometer-based derivation. The degree of uncertainty is a function of the accuracy of temperature measurements (wet- and dry-bulb), knowledge of the barometric pressure, and conformance to accepted operational procedures such as those outlined in ASHRAE *Standard* 41.6.

In air temperatures below 32°F, water on the wick may either freeze or supercool. Because the wet-bulb temperature is different for ice and water, the state must be known and the proper chart or table used. Some operators remove the wick from the wet bulb for freezing conditions and dip the bulb in water a few times; this allows water to freeze on the bulb between dips, forming a film of ice. Because the wet-bulb depression is slight at low temperatures, precise temperature readings are essential. A psychrometer can be used at high temperatures, but if the wet-bulb depression is large, the wick must remain wet and water supplied to the wick must be cooled so as not to influence the wet-bulb temperature by carrying sensible heat to it (Richardson 1965; Worrall 1965).

Greenspan and Wexler (1968) and Wentzel (1961) developed devices to measure adiabatic saturation temperature.

DEW-POINT HYGROMETERS

Condensation Dew-Point Hygrometers

The condensation (chilled-mirror) dew-point hygrometer is an accurate and reliable instrument with a wide humidity range. However, these features are gained at increased complexity and cost compared to the psychrometer. In the condensation hygrometer, a surface is cooled (thermoelectrically, mechanically, or chemically) until dew or frost begins to condense out. The condensate surface is maintained electronically in vapor-pressure equilibrium with the surrounding gas, while surface condensation is detected by optical, electrical, or nuclear techniques. The measured surface temperature is then the dew-point temperature.

The largest source of error stems from the difficulty in measuring condensate surface temperature accurately. Typical industrial versions of the instrument are accurate to $\pm 1.0^\circ\text{F}$ over wide temperature spans. With proper attention to the condensate surface temperature measuring system, errors can be reduced to about $\pm 0.4^\circ\text{F}$. Condensation hygrometers can be made surprisingly compact using solid-state optics and thermoelectric cooling.

Wide span and minimal errors are two of the main features of this instrument. A properly designed condensation hygrometer can measure dew points from 200°F down to frost points of -100°F . Typical condensation hygrometers can cool to 150°F below ambient temperature, establishing lower limits of the instrument to dew points corresponding to approximately 0.5% rh. Accuracies for measurements above -40°F can be $\pm 2^\circ\text{F}$ or better, deteriorating to $\pm 4^\circ\text{F}$ at lower temperatures.

The response time of a condensation dew-point hygrometer is usually specified in terms of its cooling/heating rate, typically 4°F/s for thermoelectric cooled mirrors. This makes it somewhat faster than a heated salt hygrometer. Perhaps the most significant feature of the condensation hygrometer is its fundamental measuring technique, which essentially renders the instrument self-calibrating. For calibration, it is necessary only to manually override the surface cooling control loop, causing the surface to heat, and confirm that the instrument recools to the same dew point when the loop is closed. Assuming that the surface temperature measuring system is correct, this is a reasonable check on the instrument's performance.

Although condensation hygrometers can become contaminated, they can easily be cleaned and returned to service with no impairment to performance.

Salt-Phase Heated Hygrometers

Another instrument in which the temperature varies with ambient dew-point temperature is variously designated as a self-heating salt-phase transition hygrometer or a heated electrical hygrometer. This device usually consists of a tubular substrate covered by glass fiber fabric, with a spiral bifilar winding for electrodes. The surface is covered with a salt solution, usually lithium chloride. The sensor is connected in series with a ballast and a 24 V (ac) supply. When the instrument is operating, electrical current flowing through the salt film heats the sensor. The salt's electrical resistance characteristics are such that a balance is reached with the salt at a critical moisture content corresponding to a saturated solution. The sensor temperature adjusts automatically so that the water vapor pressures of the salt film and ambient atmosphere are equal.

With lithium chloride, this sensor cannot be used to measure relative humidity below approximately 12% (the equilibrium relative humidity of this salt), and it has an upper dew-point limit of about 160°F. The regions of highest precision are between -10 and 93°F , and above 105°F dew point. Another problem is that the lithium chloride solution can be washed off when exposed to water. In addition, this type of sensor is subject to contamination problems, which limits its accuracy. Its response time is also very slow; it takes approximately 2 min for a 67% step change.

MECHANICAL HYGROMETERS

Many organic materials change in dimension with changes in humidity; this action is used in a number of simple and effective humidity indicators, recorders, and controllers (see Chapter 7). They are coupled to pneumatic leak ports, mechanical linkages, or electrical transduction elements to form hygrometers.

Commonly used organic materials are human hair, nylon, Dacron, animal membrane, animal horn, wood, and paper. Their inherent nonlinearity and hysteresis must be compensated for within the hygrometer. These devices are generally unreliable below 32°F. The response is generally inadequate for monitoring a changing process, and can be affected significantly by exposure to extremes of humidity. Mechanical hygrometers require initial calibration and frequent recalibration; however, they are useful because they can be arranged to read relative humidity directly, and they are simpler and less expensive than most other types.

ELECTRICAL IMPEDANCE AND CAPACITANCE HYGROMETERS

Many substances adsorb or lose moisture with changing relative humidity and exhibit corresponding changes in electrical impedance or capacitance.

Dunmore Hygrometers

This sensor consists of dual electrodes on a tubular or flat substrate; it is coated with a film containing salt, such as lithium chloride, in a binder to form an electrical connection between windings. The relation of sensor resistance to humidity is usually represented by graphs. Because the sensor is highly sensitive, the graphs are a series of curves, each for a given temperature, with intermediate values found by interpolation. Several resistance elements, called Dunmore elements, cover a standard range. Systematic calibration is essential because the resistance grid varies with time and contamination as well as with exposure to temperature and humidity extremes.

Polymer Film Electronic Hygrometers

These devices consist of a hygroscopic organic polymer deposited by means of thin or thick film processing technology on a water-permeable substrate. Both capacitance and impedance sensors are available. The impedance devices may be either ionic or electronic conduction types. These hygrometers typically have integrated circuits that provide temperature correction and signal conditioning. The primary advantages of this sensor technology are small size; low cost; fast response times (on the order of 1 to 120 s for 64% change in relative humidity); and good accuracy over the full range, including the low end, where most other devices are less accurate.

Ion Exchange Resin Electric Hygrometers

A conventional ion exchange resin consists of a polymer with a high relative molecular mass and polar groups of positive or negative charge in cross-link structure. Associated with these polar groups are ions of opposite charge that are held by electrostatic forces to the fixed polar groups. In the presence of water or water vapor, the electrostatically held ions become mobile; thus, when a voltage is impressed across the resin, the ions are capable of electrolytic conduction. The **Pope cell** is one example of an ion exchange element. It is a wide-range sensor, typically covering 15 to 95% rh; therefore, one sensor can be used where several Dunmore elements would be required. The Pope cell, however, has a nonlinear characteristic from approximately 1000 Ω at 100% rh to several megohms at 10% rh.

Impedance-Based Porous Ceramic Electronic Hygrometers

Using oxides' adsorption characteristics, humidity-sensitive ceramic oxide devices use either ionic or electronic measurement techniques to relate adsorbed water to relative humidity. Ionic conduction is produced by dissociation of water molecules, forming surface hydroxyls. The dissociation causes proton migration, so the device's impedance decreases with increasing water content. The ceramic oxide is sandwiched between porous metal electrodes that connect the device to an impedance-measuring circuit for linearizing and signal conditioning. These sensors have excellent sensitivity, are resistant to contamination and high temperature (up to 400°F), and may get fully wet without sensor degradation. These sensors are accurate to about $\pm 1.5\%$ rh ($\pm 1\%$ rh when temperature-compensated) and have a moderate cost.

Aluminum Oxide Capacitive Sensor

This sensor consists of an aluminum strip that is anodized by a process that forms a porous oxide layer. A very thin coating of cracked chromium or gold is then evaporated over this structure. The aluminum base and cracked chromium or gold layer form the two electrodes of what is essentially an aluminum oxide capacitor.

Water vapor is rapidly transported through the cracked chromium or gold layer and equilibrates on the walls of the oxide pores in a manner functionally related to the vapor pressure of water in the atmosphere surrounding the sensor. The number of water molecules adsorbed on the oxide structure determines the capacitance between the two electrodes.

ELECTROLYTIC HYGROMETERS

In electrolytic hygrometers, air is passed through a tube, where moisture is adsorbed by a highly effective desiccant (usually phosphorous pentoxide) and electrolyzed. The airflow is regulated to 0.0035 cfm at a standard temperature and pressure. As the incoming water vapor is absorbed by the desiccant and electrolyzed into hydrogen and oxygen, the current of electrolysis determines the mass of water vapor entering the sensor. The flow rate of the entering gas is controlled precisely to maintain a standard sample mass

flow rate into the sensor. The instrument is usually designed for use with moisture/air ratios in the range of less than 1 ppm to 1000 ppm, but can be used with higher humidities.

PIEZOELECTRIC SORPTION

This hygrometer compares the changes in frequency of two hygroscopically coated quartz crystal oscillators. As the crystal's mass changes because of absorption of water vapor, the frequency changes. The amount of water sorbed on the sensor is a function of relative humidity (i.e., partial pressure of water as well as ambient temperature).

A commercial version uses a hygroscopic polymer coating on the crystal. Humidity is measured by monitoring the change in the vibration frequency of the quartz crystal when the crystal is alternately exposed to wet and dry gas.

SPECTROSCOPIC (RADIATION ABSORPTION) HYGROMETERS

Radiation absorption devices operate on the principle that selective absorption of radiation is a function of frequency for different media. Water vapor absorbs **infrared** radiation at 2 to 3 μm wavelengths and **ultraviolet** radiation centered about the Lyman-alpha line at 0.122 μm . The amount of absorbed radiation is directly related to the absolute humidity or water vapor content in the gas mixture, according to Beer's law. The basic unit consists of an energy source and optical system for isolating wavelengths in the spectral region of interest, and a measurement system for determining the attenuation of radiant energy caused by water vapor in the optical path. Absorbed radiation is measured extremely quickly and independent of the degree of saturation of the gas mixture. Response times of 0.1 to 1 s for 90% change in moisture content are common. Spectroscopic hygrometers are primarily used where a noncontact application is required; this may include atmospheric studies, industrial drying ovens, and harsh environments. The primary disadvantages of this device are its high cost and relatively large size.

GRAVIMETRIC HYGROMETERS

Humidity levels can be measured by extracting and finding the mass of water vapor in a known quantity or atmosphere. For precise laboratory work, powerful desiccants, such as phosphorous pentoxide and magnesium perchlorate, are used for extraction; for other purposes, calcium chloride or silica gel is satisfactory.

When the highest level of accuracy is required, the gravimetric hygrometer, developed and maintained by NIST, is the ultimate in the measurement hierarchy. The gravimetric hygrometer gives the absolute water vapor content, where the mass of absorbed water and precise measurement of the gas volume associated with the water vapor determine the mixing ratio or absolute humidity of the sample. This system is the primary standard because the required measurements of mass, temperature, pressure, and volume can be made with extreme precision. However, its complexity and required attention to detail limit its usefulness.

CALIBRATION

For many hygrometers, the need for recalibration depends on the accuracy required, the sensor's stability, and the conditions to which the sensor is subjected. Many hygrometers should be calibrated regularly by exposure to an atmosphere maintained at a known humidity and temperature, or by comparison with a transfer standard hygrometer. Complete calibration usually requires observation of a series of temperatures and humidities. Methods for producing known humidities include saturated salt solutions (Greenspan 1977); sulfuric acid solutions; and mechanical systems, such as the divided flow, two-pressure (Amdur 1965); two-temperature (Till and Handegord 1960); and NIST two-pressure

humidity generator (Hasegawa 1976). All these systems rely on precise methods of temperature and pressure control in a controlled environment to produce a known humidity, usually with accuracies of 0.5 to 1.0%. The operating range for the precision generator is typically 5 to 95% rh.

PRESSURE MEASUREMENT

Pressure is the force exerted per unit area by a medium, generally a liquid or gas. Pressure so defined is sometimes called **absolute pressure**. Thermodynamic and material properties are expressed in terms of absolute pressures; thus, the properties of a refrigerant are given in terms of absolute pressures. **Vacuum** refers to pressures below atmospheric.

Differential pressure is the difference between two absolute pressures, or the difference between two relative pressures measured with respect to the same reference pressure. Often, it can be very small compared to either of the absolute pressures (these are often referred to as low-range, high-line differential pressures). A common example of differential pressure is the pressure drop, or difference between inlet and outlet pressures, across a filter or flow element.

Gage pressure is a special case of differential pressure where the reference pressure is atmospheric pressure. Many pressure gages, including most refrigeration test sets, are designed to make gage pressure measurements, and there are probably more gage pressure measurements made than any other. Gage pressure measurements are often used as surrogates for absolute pressures. However, because of variations in atmospheric pressure caused by elevation (e.g., atmospheric pressure in Denver, Colorado, is about 81% of sea-level pressure) and weather changes, using gage pressures to determine absolute pressures can significantly restrict the accuracy of the measured pressure, unless corrections are made for the local atmospheric pressure at the time of measurement.

Pressures can be further classified as static or dynamic. **Static pressures** have a small or undetectable change with time; **dynamic pressures** include a significant pulsed, oscillatory, or other time-dependent component. Static pressure measurements are the most common, but equipment such as blowers and compressors can generate significant oscillatory pressures at discrete frequencies. Flow in pipes and ducts can generate resonant pressure changes, as well as turbulent “noise” that can span a wide range of frequencies.

Units

A plethora of pressure units, many of them poorly defined, are in common use. The international (SI) unit is the newton per square metre, called the pascal (Pa). Although the bar and standard atmosphere are used, they should not be introduced where they are not used at present. Although not internationally recognized, the pound per square inch (psi) is widely used. Units based on the length of liquid columns, including inches of mercury (in. Hg), mm of mercury (mm Hg), and inches of water (in. of water) (often used for low-range differential pressure measurements) are also used, but are not as rigorously defined (and thus a potential source of error). In the case of pounds per square inch, the type of pressure measurement is often indicated by a modification of the unit (i.e., both psi and psia are used to indicate absolute pressure measurements, psid indicates a differential measurement, and psig indicates a gage measurement). No such standard convention exists for other units, and unless explicitly stated, reported values are assumed to be absolute pressures. Conversion factors for different pressure units can be found in Chapter 38.

The difference between the conversion factors for inches of mercury and inches of water at the different temperatures is indicative of the errors that can arise from uncertainties about the definitions of these units.

INSTRUMENTS

Broadly speaking, pressure instruments can be divided into three different categories: standards, mechanical gages, and electromechanical transducers. Standards instruments are used for the most accurate calibrations. The liquid-column manometer, which is the most common and potentially the most accurate standard, is used for a variety of applications, including field applications. Mechanical pressure gages are generally the least expensive and the most common. However, electromechanical transducers have become much less expensive and are easier to use, so they are being used more often.

Pressure Standards

Liquid-column manometers measure pressure by determining the vertical displacement of a liquid of known density in a known gravitational field. Typically, they are constructed as a U-tube of transparent material (glass or plastic). The pressure to be measured is applied to one side of the U-tube. If the other (reference) side is evacuated (zero pressure), the manometer measures absolute pressure; if the reference side is open to the atmosphere, it measures gage pressure; if the reference side is connected to some other pressure, the manometer measures the differential between the two pressures. Manometers filled with water and different oils are often used to measure low-range differential pressures. In some low-range instruments, one tube of the manometer is inclined to enhance readability. Mercury-filled manometers are used for higher-range differential and absolute pressure measurements. In the latter case, the reference side is evacuated, generally with a mechanical vacuum pump. Typical full-scale ranges for manometers vary from 0.10 in. of water to 3 atm.

For pressures above the range of manometers, standards are generally of the piston-gage, pressure-balance, or deadweight-tester type. These instruments apply pressure to the bottom of a vertical piston, which is surrounded by a close-fitting cylinder (typical clearances are millionths of an inch). The pressure generates a force approximately equal to the pressure times the area of the piston. This force is balanced by weights stacked on the top of the piston. If the mass of the weights, local acceleration of gravity, and area of the piston (or more properly, the “effective area” of the piston and cylinder assembly) are known, the applied pressure can be calculated. Piston gages usually generate gage pressures with respect to the atmospheric pressure above the piston. They can be used to measure absolute pressures either indirectly, by separately measuring the atmospheric pressure and adding it to the gage pressure determined by the piston gage, or directly, by surrounding the top of the piston and weights with an evacuated bell jar. Piston gage full-scale ranges vary from 5 to 200,000 psi.

At the other extreme, very low absolute pressures (below about 0.4 in. of water), a number of different types of standards are used. These tend to be specialized and expensive instruments found only in major standards laboratories. However, one low-pressure standard, the **McLeod gage**, has been used for field applications. Unfortunately, although its theory is simple and straightforward, it is difficult to use accurately, and major errors can occur when it is used to measure gases that condense or are adsorbed (e.g., water). In general, other gages should be used for most low-pressure or vacuum applications.

Mechanical Pressure Gages

Mechanical pressure gages couple a pressure sensor to a mechanical readout, typically a pointer and dial. The most common type uses a **Bourdon tube** sensor, which is essentially a coiled metal tube of circular or elliptical cross section. Increasing pressure applied to the inside of the tube causes it to uncoil. A mechanical linkage translates the motion of the end of the tube to the rotation of a pointer. In most cases, the Bourdon tube is surrounded

by atmospheric pressure, so that the gages measure gage pressure. A few instruments surround the Bourdon tube with a sealed enclosure that can be evacuated for absolute measurements or connected to another pressure for differential measurements. Available instruments vary widely in cost, size, pressure range, and accuracy. Full-scale ranges can vary from 5 to 100,000 psi. Accuracy of properly calibrated and used instruments can vary from 0.1 to 10% of full scale. Generally there is a strong correlation between size, accuracy, and price; larger instruments are more accurate and expensive.

For better sensitivity, some low-range mechanical gages (sometimes called **aneroid gages**) use corrugated diaphragms or capsules as sensors. The capsule is basically a short bellows sealed with end caps. These sensors are more compliant than a Bourdon tube, and a given applied pressure causes a larger deflection of the sensor. The inside of a capsule can be evacuated and sealed to measure absolute pressures or connected to an external fitting to allow differential pressures to be measured. Typically, these gages are used for low-range measurements of 1 atm or less. In better-quality instruments, accuracies can be 0.1% of reading or better.

Electromechanical Transducers

Mechanical pressure gages are generally limited by inelastic behavior of the sensing element, friction in the readout mechanism, and limited resolution of the pointer and dial. These effects can be eliminated or reduced by using electronic techniques to sense the distortion or stress of a mechanical sensing element and electronically convert that stress or distortion to a pressure reading. A wide variety of sensors is used, including Bourdon tubes, capsules, diaphragms, and different resonant structures whose vibration frequency varies with the applied pressure. Capacitive, inductive, and optical lever sensors are used to measure the sensor element's displacement. In some cases, feedback techniques may be used to constrain the sensor in a null position, minimizing distortion and hysteresis of the sensing element. Temperature control or compensation is often included. Readout may be in the form of a digital display, analog voltage or current, or a digital code. Size varies, but for transducers using a diaphragm fabricated as part of a silicon chip, the sensor and signal-conditioning electronics can be contained in a small transistor package, and the largest part of the device is the pressure fitting. The best of these instruments achieve long-term instabilities of 0.01% or less of full scale, and corresponding accuracies when properly calibrated. Performance of less-expensive instruments can be more on the order of several percent.

Although the dynamic response of most mechanical gages is limited by the sensor and readout, the response of some electromechanical transducers can be much faster, allowing measurements of dynamic pressures at frequencies up to 1 kHz and beyond in the case of transducers specifically designed for dynamic measurements. Manufacturers' literature should be consulted as a guide to the dynamic response of specific instruments.

As the measured pressure drops below about 1.5 psia, it becomes increasingly difficult to sense mechanically. A variety of gages have been developed that measure some other property of the gas that is related to the pressure. In particular, **thermal conductivity gages**, known as thermocouple, thermistor, Pirani, and convection gages, are used for pressures down to about 0.0004 in. of water. These gages have a sensor tube with a small heated element and a temperature sensor; the temperature of the heated element is determined by the thermal conductivity of the gas, and the output of the temperature sensor is displayed on an analog or digital electrical meter contained in an attached electronics unit. The accuracy of thermal conductivity gages is limited by their nonlinearity, dependence on gas species, and tendency to read high when contaminated. Oil contamination is a particular problem. However, these gages are small, reasonably rugged, and relatively inexpensive; in the hands of a

typical user, they give far more reliable results than a McLeod gage. They can be used to check the base pressure in a system that is being evacuated before being filled with refrigerant. They should be checked periodically for contamination by comparing the reading with that from a new, clean sensor tube.

General Considerations

Accurate values of atmospheric or barometric pressure are required for weather prediction and aircraft altimetry. In the United States, a network of calibrated instruments, generally accurate to within 0.1% of reading and located at airports, is maintained by the National Weather Service, the Federal Aviation Administration, and local airport operating authorities. These agencies are generally cooperative in providing current values of atmospheric pressure that can be used to check the calibration of absolute pressure gages or to correct gage pressure readings to absolute pressures. However, pressure readings generally reported for weather and altimetry purposes are not the true atmospheric pressure, but rather a value adjusted to an equivalent sea level pressure. Therefore, unless the location is near sea level, it is important to ask for the station or true atmospheric pressure rather than using the adjusted values broadcast by radio stations. Further, atmospheric pressure decreases with increasing elevation at a rate (near sea level) of about 0.001 in. Hg/ft, and corresponding corrections should be made to account for the difference in elevation between the instruments being compared.

Gage-pressure instruments are sometimes used to measure absolute pressures, but their accuracy can be compromised by uncertainties in atmospheric pressure. This error can be particularly serious when gage-pressure instruments are used to measure vacuum (negative gage pressures). For all but the most crude measurements, absolute-pressure gages should be used for vacuum measurements; for pressures below about 0.4 in. of water, a thermal conductivity gage should be used.

All pressure gages are susceptible to temperature errors. Several techniques are used to minimize these errors: sensor materials are generally chosen to minimize temperature effects, mechanical readouts can include temperature compensation elements, electromechanical transducers may include a temperature sensor and compensation circuit, and some transducers are operated at a controlled temperature. Clearly, temperature effects are of greater concern for field applications, and it is prudent to check the manufacturers' literature for the temperature range over which the specified accuracy can be maintained. Abrupt temperature changes can also cause large transient errors that may take some time to decay.

Readings of some electromechanical transducers with a resonant or vibrating sensor can depend on the gas species. Although some of these units can achieve calibrated accuracies of the order of 0.01% of reading, they are typically calibrated with dry air or nitrogen, and readings for other gases can be in error by several percent, possibly much more for refrigerants and other high-density gases. High-accuracy readings can be maintained by calibrating these devices with the gas to be measured. Manufacturers' literature should be consulted.

Measuring dynamic pressures is limited not just by the frequency response of the pressure gage, but also by the hydraulic or pneumatic time constant of the connection between the gage and the system to be monitored. Generally, the longer the connecting lines and the smaller their diameter, the lower the system's frequency response. Further, even if only the static component of the pressure is of interest, and a gage with a low-frequency response is used, a significant pulsating or oscillating pressure component can cause significant errors in pressure gage readings and, in some cases, can damage the gage, particularly one with a mechanical readout mechanism. In these cases, a filter or snubber should be used to reduce the higher-frequency components.

AIR VELOCITY MEASUREMENT

HVAC engineers measure the flow of air more often than any other gas, and usually at or near atmospheric pressure. Under this condition, air can be treated as an incompressible (i.e., constant-density) fluid, and simple formulas give sufficient precision to solve many problems. Instruments that measure fluid velocity and their application range and precision are listed in Table 4.

AIRBORNE TRACER TECHNIQUES

Tracer techniques are suitable for measuring velocity in an open space. Typical tracers include smoke, feathers, pieces of lint, and radioactive or nonradioactive gases. Measurements are made by timing the rate of movement of solid tracers or by monitoring the change in concentration level of gas tracers.

Smoke is a useful qualitative tool in studying air movements. Smoke can be obtained from titanium tetrachloride (irritating to nasal membranes) or by mixing potassium chlorate and powdered sugar (nonirritating) and firing the mixture with a match. The latter process produces considerable heat and should be confined to a pan away from flammable materials. Titanium tetrachloride smoke works well for spot tests, particularly for leakage through casings and ducts, because it can be handled easily in a small, pistol-like ejector. Another alternative is theatrical smoke, which is nontoxic, but requires proper illumination.

Fumes of ammonia water and sulfuric acid, if allowed to mix, form a white precipitate. Two bottles, one containing ammonia water and the other containing acid, are connected to a common nozzle by rubber tubing. A syringe forces air over the liquid surfaces in the bottles; the two streams mix at the nozzle and form a white cloud.

A satisfactory test smoke also can be made by bubbling an airstream through ammonium hydroxide and then hydrochloric acid (Nottage et al. 1952). Smoke tubes, smoke candles, and smoke bombs are available for studying airflow patterns.

ANEMOMETERS

Deflecting Vane Anemometers

The deflecting vane anemometer consists of a pivoted vane enclosed in a case. Air exerts pressure on the vane as it passes through the instrument from an upstream to a downstream opening. A hair spring and a damping magnet resist vane movement. The instrument gives instantaneous readings of directional velocities on an indicating scale. With fluctuating velocities, needle swings must be visually averaged. This instrument is useful for studying air motion in a room, locating objectionable drafts, measuring air velocities at supply and return diffusers and grilles, and measuring laboratory hood face velocities.

Propeller or Revolving (Rotating) Vane Anemometers

The propeller anemometer consists of a light, revolving, wind-driven wheel connected through a gear train to a set of recording dials that read linear feet of air passing in a measured length of time. It is made in various sizes, though 3, 4, and 6 in. are the most common. Each instrument requires individual calibration. At low velocities, the mechanism's friction drag is considerable, and is usually compensated for by a gear train that overspeeds. For this reason, the correction is often additive at the lower range and subtractive at the upper range, with the least correction in the middle range. The best instruments have starting speeds of 50 fpm or higher; therefore, they cannot be used below that air speed. Electronic revolving vane anemometers, with optical or magnetic pickups to sense the rotation of the vane, are available in vane sizes as small as 1/2 in. diameter.

Cup Anemometers

The cup anemometer is primarily used to measure outdoor, meteorological wind speeds. It consists of three or four hemispherical

cups mounted radially from a vertical shaft. Wind from any direction with a vector component in the plane of cup rotation causes the cups and shaft to rotate. Because it is primarily used to measure meteorological wind speeds, the instrument is usually constructed so that wind speeds can be recorded or indicated electrically at a remote point.

Thermal Anemometers

The thermal (or hot-wire, or hot-film) anemometer consists of a heated RTD, thermocouple junction, or thermistor sensor constructed at the end of a probe; it is designed to provide a direct, simple method of determining air velocity at a point in the flow field. The probe is placed into an airstream, and air movement past the electrically heated velocity sensor tends to cool the sensor in proportion to the speed of the airflow. The electronics and sensor are commonly combined into a portable, hand-held device that interprets the sensor signal and provides a direct reading of air velocity in either analog or digital display format. Often, the sensor probe also incorporates an ambient temperature-sensing RTD or thermistor, in which case the indicated air velocity is "temperature compensated" to "standard" air density conditions (typically 0.0748 lb/ft³).

Thermal anemometers have long been used in fluid flow research. Research anemometer sensors have been constructed using very fine wires in configurations that allow characterization of fluid flows in one, two, and three dimensions, with sensor/electronics response rates up to several hundred kilohertz. This technology has been incorporated into more ruggedized sensors suitable for measurements in the HVAC field, primarily for unidirectional airflow measurement. Omnidirectional sensing instruments suitable for thermal comfort studies are also available.

The principal advantages of thermal anemometers are their wide dynamic range and their ability to sense extremely low velocities. Commercially available portable instruments often have a typical accuracy (including repeatability) of 2 to 5% of reading over the entire velocity range. Accuracies of $\pm 2\%$ of reading or better are obtainable from microcontroller (microprocessor)-based thermistor and RTD sensor assemblies, some of which can be factory-calibrated to known reference standards (e.g., NIST air speed tunnels). An integrated microcontroller also allows an array of sensor assemblies to be combined in one duct or opening, providing independently derived velocity and temperature measurements at each point.

Limitations of thermistor-based velocity measuring devices depend on sensor configuration, specific thermistor type used, and the application. At low velocities, thermal anemometers can be significantly affected by their own thermal plumes (from self-heating). Products using this technology can be classified as hand-held instruments or permanently mounted probes and arrays, and as those with analog electronic transmitters and those that are microcontroller-based.

Limitations of hand-held and analog electronic thermal anemometers include the following: (1) the unidirectional sensor must be carefully aligned in the airstream (typically to within $\pm 20^\circ$ rotation) to achieve accurate results; (2) the velocity sensor must be kept clean because contaminant build-up can change the calibration (which may change accuracy performance); and (3) because of the inherent high speed of response of thermal anemometers, measurements in turbulent flows can yield fluctuating velocity measurements. Electronically controlled time-integrated functions are now available in many digital air velocity meters to help smooth these turbulent flow measurements.

Microcontroller-based thermal dispersion devices are typically configured as unidirectional instruments, but may have multiple velocity-sensing elements capable of detecting flow direction. These devices can be used to measure a "bleed" air velocity between two spaces or across a fixed orifice. With mathematical conversion, these measured velocities can closely approximate equivalents in

Table 4 Air Velocity Measurement

Measurement Means	Application	Range, fpm	Precision	Limitations
Smoke puff or airborne solid tracer	Low air velocities in rooms; highly directional	5 to 50	10 to 20%	Awkward to use but valuable in tracing air movement.
Deflecting vane anemometer	Air velocities in rooms, at outlets, etc.; directional	30 to 24,000	5%	Requires periodic calibration check.
Revolving (rotating) vane anemometer	Moderate air velocities in ducts and rooms; somewhat directional	100 to 3000	2 to 5%	Subject to significant errors when variations in velocities with space or time are present. Easily damaged. Affected by turbulence intensity. Requires periodic calibration.
Thermal (hot-wire or hot-film) anemometer	a. Low air velocities; directional and omnidirectional available b. Transient velocity and turbulence	50 to 10,000	2 to 10%	Requires accurate calibration at frequent intervals. Some are relatively costly. Affected by thermal plume because of self-heating.
Pitot-static tube	Standard (typically hand-held) instrument for measuring single-point duct velocities	180 to 10,000 with micromanometer; 600 to 10,000 with draft gages; 10,000 up with manometer	2 to 5%	Accuracy falls off at low end of range because of square-root relationship between velocity and dynamic pressure. Also affected by alignment with flow direction.
Impact tube and sidewall or other static tap	High velocities, small tubes, and where air direction may be variable	120 to 10,000 with micromanometer; 600 to 10,000 with draft gages; 10,000 up with manometer	2 to 5%	Accuracy depends on constancy of static pressure across stream section.
Cup anemometer	Meteorological	Up to 12,000	2 to 5%	Poor accuracy at low air velocity (<500 fpm).
Ultrasonic	Large instruments: meteorological Small instruments: in-duct and room air velocities	1 to 6000	1 to 2%	High cost.
Laser Doppler velocimeter (LDV)	Calibration of air velocity instruments	1 to 6000	1 to 3%	High cost and complexity limit LDVs to laboratory applications. Requires seeding of flow with particles, and transparent optical access (window).
Particle image velocimetry (PIV)	Full-field (2D, 3D) velocity measurements in rooms, outlets	0.02 to 100	10%	High cost and complexity limits measurements to laboratory applications. Requires seeding of flow with particles, and transparent optical access (window).
Pitot array, self-averaging differential pressure, typically using equalizing manifolds	In duct assemblies, ducted or fan inlet probes	600 to 10,000	±2 to >40% of reading	Performance depends heavily on quality and range of associated differential pressure transmitter. Very susceptible to measurement errors caused by duct placement and temperature changes. Nonlinear output (square-root function). Mathematical averaging errors likely because of sampling method. Must be kept clean to function properly. Must be set up and field-calibrated to hand-held reference, or calibrated against nozzle standard.
Piezometer and piezoring variations, self-averaging differential pressure using equalizing manifolds	Centrifugal fan inlet cone	600 to 10,000	±5 to >40% of reading	Performance depends heavily on quality and range of required differential pressure transmitter. Very susceptible to measurement errors caused by inlet cone placement, inlet obstructions, and temperature changes. Nonlinear output (square-root function). Must be kept clean. Must be field-calibrated to hand-held reference.
Vortex shedding	In-duct assemblies, ducted or fan inlet probes	450 to 6000	±2.5 to 10% of reading	Highest cost per sensing point. Largest physical size. Low-temperature accuracy questionable. Must be set up and field-calibrated to hand-held reference.
Thermal (analog electronic) using thermistors	In-duct assemblies or ducted probes	50 to 5000	±2 to 40% of reading	Mathematical averaging errors may be caused by analog electronic circuitry when averaging nonlinear signals. Sensing points may not be independent. May not be able to compensate for temperatures beyond a narrow range. Must be set up and field-calibrated to hand-held reference. Must be recalibrated regularly to counteract drift.
Thermal dispersion (microcontroller-based) using thermistors to independently determine temperatures and velocities	Ducted or fan inlet probes, bleed velocity sensors	20 to 10,000	±2 to 10% of reading	Cost increases with number of sensor assemblies in array. Not available with flanged frame. Honeycomb air straighteners not recommended by manufacturer. Accuracy verified only to -20°F. Not suitable for abrasive or high-temperature environments.
Thermal (analog electronic) using RTDs	In-duct assemblies or ducted probes; stainless steel and platinum RTDs have industrial environment capabilities	100 to 18,000	±1 to 20% of reading	Requires long duct/pipe runs. Sensitive to placement conditions. Mathematical averaging errors may be caused by analog electronic circuitry when averaging nonlinear signals. Must be recalibrated regularly to counteract drift. Fairly expensive.

differential pressure down to five decimal places (in. of water). They can be used for space pressure control, to identify minute changes in flow direction, or for estimating volumetric flow rates across a fixed orifice by equating to velocity pressure.

In the HVAC field, thermal anemometers are suitable for a variety of applications. They are particularly well-suited to the low velocities associated with outside air intake measurement and control, return or relief fan tracking for pressurization in variable-air-volume (VAV) systems, VAV terminal box measurement, unit ventilator and packaged equipment intake measurement, space pressurization for medical isolation, and laboratory fume hood face velocity measurements (typically in the 50 to 200 fpm range). Thermal anemometers can also take multipoint traverse measurements in ventilation ductwork.

Laser Doppler Velocimeters (or Anemometers)

The laser Doppler velocimeter (LDV) or laser Doppler anemometer (LDA) is an extremely complex system that collects scattered light produced by particles (i.e., seed) passing through the intersection volume of two intersecting laser beams of the same light frequency, which produces a regularly spaced fringe pattern (Mease et al. 1992). The scattered light consists of bursts containing regularly spaced oscillations whose frequency is linearly proportional to the speed of the particle. Because of their cost and complexity, they are usually not suitable for in situ field measurements. Rather, the primary HVAC application of LDV systems is calibrating systems used to calibrate other air velocity instruments.

The greatest advantage of an LDV is its performance at low air speeds: as low as 15 fpm with uncertainty levels of 1% or less (Mease et al. 1992). In addition, it is nonintrusive in the flow; only optical access is required. It can be used to measure fluctuating components as well as mean speeds and is available in one-, two-, and even three-dimensional configurations. Its biggest disadvantages are its high cost and extreme technological complexity, which requires highly skilled operators. Modern fiber-optic systems require less-skilled operators but at a considerable increase in cost.

Particle Image Velocimetry (PIV)

Particle image velocimetry (PIV) is an optical method that measures fluid velocity by determining the displacement of approximately neutrally buoyant seed particles introduced in the flow. Particle displacements are determined from images of particle positions at two instants of time. Usually, statistical (correlation) methods are used to identify the displacement field.

The greatest advantage of PIV is its ability to examine two- and three-dimensional velocity fields over a region of flow. The method usually requires laser light (sheet) illumination, and is typically limited to a field area of less than 10 ft². Accuracy is usually limited to about ±10% by the resolution of particle displacements, which must be small enough to remain in the field of view during the selected displacement time interval. For more comprehensive information on PIV, including estimates of uncertainty, see Raffel et al. (1998).

PITOT-STATIC TUBES

The pitot-static tube, in conjunction with a suitable manometer or differential pressure transducer, provides a simple method of determining air velocity at a point in a flow field. Figure 6 shows the construction of a standard pitot tube (ASHRAE Standard 51) and the method of connecting it with inclined manometers to display both static pressure and velocity pressure. The equation for determining air velocity from measured velocity pressure is

$$V = C \sqrt{\frac{2p_w g_c}{\rho}} \tag{5}$$

Fig. 6 Standard Pitot Tube

where

- V = velocity, fpm
- p_w = velocity pressure (pitot-tube manometer reading), in. of water
- ρ = density of air, lb_m/ft³
- g_c = gravitational constant = 32.174 lb_m·ft/lb_f·s²
- C = unit conversion factor = 136.8

The type of manometer or differential pressure transducer used with a pitot-static tube depends on the magnitude of velocity pressure being measured and on the desired accuracy. Over 1500 fpm, a draft gage of appropriate range is usually satisfactory. If the pitot-static tube is used to measure air velocities lower than 1500 fpm, a precision manometer or comparable pressure differential transducer is essential.

Example Calculation

Step 1. Numerical evaluation. Let $p_w = 0.3740 \pm 0.005$ in. of water and $\rho = 0.0740 \pm 0.0010$ lb_m/ft³. Then,

$$V = C \sqrt{\frac{2p_w g_c}{\rho}} = (136.8) \sqrt{\frac{2(0.3740)(32.174)}{(0.0740)}} = 2467 \text{ fpm}$$

Step 2. Uncertainty estimate. Let the typical bias (i.e., calibration) uncertainty of the pitot tube be $u_{V,bias} = \pm 1\%$ of reading. The uncertainty in the velocity measurement is thus estimated to be

$$\begin{aligned} u_V &= \sqrt{(u_{V,bias})^2 + (u_{V,prec})^2} \\ &= \sqrt{(u_{V,bias})^2 + \left[\frac{1}{2}(u_{p_w})\right]^2 + \left[\frac{1}{2}(u_{\rho})\right]^2} \\ &= \sqrt{(0.01)^2 + \left[\frac{1}{2}\left(\frac{0.005}{0.3740}\right)\right]^2 + \left[\frac{1}{2}\left(\frac{0.0010}{0.0740}\right)\right]^2} \\ &= \pm 0.014 = \pm 1.4\% \end{aligned}$$

Therefore,

$$U_V = \pm u_V V = \pm (0.014)(2467 \text{ fpm}) = \pm 34 \text{ fpm}$$

In summary,

$$V = 2467 \pm 34 \text{ fpm}$$

Other pitot-static tubes have been used and calibrated. To meet special conditions, various sizes of pitot-static tubes geometrically

Duct Dimensions	No. of Points for Traverse Lines	Position Relative to Inner Wall

Log-Linear Rule for Circular Ducts

Fig. 7 Measuring Points for Rectangular and Round Duct Traverse

similar to the standard tube can be used. For relatively high velocities in ducts of small cross-sectional area, total pressure readings can be obtained with an impact (pitot) tube. Where static pressure across the stream is relatively constant, as in turbulent flow in a straight duct, a sidewall tap to obtain static pressure can be used with the impact tube to obtain the velocity pressure head. One form of impact tube is a small streamlined tube with a fine hole in its upstream end and its axis parallel to the stream.

If the Mach number of the flow is greater than about 0.3, the effects of compressibility should be included in the computation of the air speed from pitot-static and impact (stagnation or pitot) tube measurements (Mease et al. 1992).

MEASURING FLOW IN DUCTS

Because velocity in a duct is seldom uniform across any section, and a pitot tube reading or thermal anemometer indicates velocity at only one location, a traverse is usually made to determine average velocity. Generally, velocity is lowest near the edges or corners and greatest at or near the center.

To determine velocity in a traverse plane, a straight average of individual point velocities gives satisfactory results when point velocities are determined by the **log-Tchebycheff (log-T) rule** or, if care is taken, by the **equal-area method**. Figure 7 shows suggested sensor locations for traversing round and rectangular ducts. The log-Tchebycheff rule provides the greatest accuracy because its

location of traverse points accounts for the effect of wall friction and the fall-off of velocity near wall ducts. The log-T method is now recommended for rectangular ducts with H and W > 18 in. For circular ducts, the log-T and log-linear methods are similar. Log-T minimizes the positive error (measured greater than actual) caused by the failure to account for losses at the duct wall. This error can occur when using the older method of equal subareas to traverse rectangular ducts.

When using the log-T method for a rectangular duct traverse, measure a minimum of 25 points. For a circular duct traverse, the log-linear rule and three symmetrically disposed diameters may be used (Figure 7). Points on two perpendicular diameters may be used where access is limited.

If possible, measuring points should be located at least 7.5 hydraulic diameters downstream and 3 hydraulic diameters upstream from a disturbance (e.g., caused by a turn). Compromised traverses as close as 2 hydraulic diameters downstream and 1 hydraulic diameter upstream can be performed with an increase in measurement error. Because field-measured airflows are rarely steady and uniform, particularly near disturbances, accuracy can be improved by increasing the number of measuring points. Straightening vanes (ASHRAE Standard 51) located 1.5 duct diameters ahead of the traverse plane improve measurement precision.

When velocities at a traverse plane fluctuate, the readings should be averaged on a time-weighted basis. Two traverse readings in short succession also help to average out velocity variations that

occur with time. If negative velocity pressure readings are encountered, they are considered a measurement value of zero and calculated in the average velocity pressure. ASHRAE *Standard* 111 has further information on measuring flow in ducts.

AIRFLOW-MEASURING HOODS

Flow-measuring hoods are portable instruments designed to measure supply or exhaust airflow through diffusers and grilles in HVAC systems. The assembly typically consists of a fabric hood section, a plastic or metal base, an airflow-measuring manifold, a meter, and handles for carrying and holding the hood in place.

For volumetric airflow measurements, the flow-measuring hood is placed over a diffuser or grille. The fabric hood captures and directs airflow from the outlet or inlet across the flow-sensing manifold in the base of the instrument. The manifold consists of a number of tubes containing upstream and downstream holes in a grid, designed to simultaneously sense and average multiple velocity points across the base of the hood. Air from the upstream holes flows through the tubes past a sensor and then exits through the downstream holes. Sensors used by different manufacturers include swinging vane anemometers, electronic micromanometers, and thermal anemometers. In electronic micromanometers, air does not actually flow through the manifold, but the airtight sensor senses the pressure differential from the upstream to downstream series of holes. The meter on the base of the hood interprets the signal from the sensor and provides a direct reading of volumetric flow in either an analog or digital display format.

As a performance check in the field, the indicated flow of a measuring hood can be compared to a duct traverse flow measurement (using a pitot-tube or thermal anemometer). All flow-measuring hoods induce some back pressure on the air-handling system because the hood restricts flow out of the diffuser. This added resistance alters the true amount of air coming out of the diffuser. In most cases, this error is negligible and is less than the accuracy of the instrument. For proportional balancing, this error need not be taken into account because all similar diffusers have about the same amount of back pressure. To determine whether back pressure is significant, a velocity traverse can be made in the duct ahead of the diffuser with and without the hood in place. The difference in average velocity of the traverse indicates the degree of back-pressure compensation required on similar diffusers in the system. For example, if the average velocity is 800 fpm with the hood in place and 820 fpm without the hood, the indicated flow reading can be multiplied by 1.025 on similar diffusers in the system ($820/800 = 1.025$). As an alternative, the designer of the air-handling system can predict the head-induced airflow reduction by using a curve supplied by the hood manufacturer. This curve indicates the pressure drop through the hood for different flow rates.

FLOW RATE MEASUREMENT

Various means of measuring fluid flow rate are listed in Table 5. Values for volumetric or mass flow rate measurement (ASME *Standard* PTC 19.5; Benedict 1984) are often determined by measuring pressure difference across an orifice, nozzle, or venturi tube. The various meters have different advantages and disadvantages. For example, the orifice plate is more easily changed than the complete nozzle or venturi tube assembly. However, the nozzle is often preferred to the orifice because its discharge coefficient is more precise. The venturi tube is a nozzle followed by an expanding recovery section to reduce net pressure loss. Differential pressure flow measurement has benefited through workshops addressing fundamental issues, textbooks, research, and improved standards (ASME *Standards* B40.100, MFC-1M, MFC-9M, MFC-10M; DeCarlo 1984; Mattingly 1984; Miller 1983).

Fluid meters use a wide variety of physical techniques to measure flow (ASME *Standard* PTC 19.5; DeCarlo 1984; Miller 1983);

more common ones are described in this section. To validate accuracy of flow rate measurement instruments, calibration procedures should include documentation of traceability to the calibration facility. The calibration facility should, in turn, provide documentation of traceability to national standards.

Flow Measurement Methods

Direct. Both gas and liquid flow can be measured accurately by timing a collected amount of fluid that is measured gravimetrically or volumetrically. This method is common for calibrating other metering devices, but it is particularly useful where flow rate is low or intermittent and where a high degree of accuracy is required. These systems are generally large and slow, but in their simplicity, they can be considered primary devices.

The **variable-area meter** or **rotameter** is a convenient direct-reading flowmeter for liquids and gases. This is a vertical, tapered tube in which the flow rate is indicated by the position of a float suspended in the upward flow. The float's position is determined by its buoyancy and the upward fluid drag.

Displacement meters measure total liquid or gas flow over time. The two major types of displacement meters used for gases are the conventional gas meter, which uses a set of bellows, and the wet test meter, which uses a water displacement principle.

Indirect. The **Thomas meter** is used in laboratories to measure high gas flow rates with low pressure losses. Gas is heated by electric heaters, and the temperature rise is measured by two resistance thermometer grids. When heat input and temperature rise are known, the mass flow of gas is calculated as the quantity of gas that removes the equivalent heat at the same temperature rise.

A velocity traverse (made using a pitot tube or other velocity-measuring instrument) measures airflow rates in the field or calibrates large nozzles. This method can be imprecise at low velocities and impracticable where many test runs are in progress.

Another field-estimating method measures pressure drop across elements with known pressure drop characteristics, such as heating and cooling coils or fans. If the pressure drop/flow rate relationship has been calibrated against a known reference (typically, at least four points in the operating range), the results can be precise. If the method depends on rating data, it should be used for check purposes only.

VENTURI, NOZZLE, AND ORIFICE FLOWMETERS

Flow in a pipeline can be measured by a venturi meter (Figure 8), flow nozzle (Figure 9), or orifice plate (Figure 10). American Society of Mechanical Engineers (ASME) *Standard* MFC-3M describes

Fig. 8 Typical Herschel-Type Venturi Meter

Fig. 9 Dimensions of ASME Long-Radius Flow Nozzles

Fig. 10 Sharp-Edge Orifice with Pressure Tap Locations
From ASME PTC 19.5. Reprinted with permission of ASME.

measurement of fluid flow in pipes using the orifice, nozzle, and venturi; ASME Standard PTC 19.5 specifies their construction.

Assuming an incompressible fluid (liquid or slow-moving gas), uniform velocity profile, frictionless flow, and no gravitational effects, the principle of conservation of mass and energy can be applied to the venturi and nozzle geometries to give

$$w = \rho V_1 A_1 = \rho V_2 A_2 = A_2 \sqrt{\frac{2g_c \rho (p_1 - p_2)}{1 - \beta^4}} \quad (6)$$

where

w = mass flow rate, lb_m/s

- V = velocity of stream, fps
- A = flow area, ft^2
- g_c = gravitational constant = $32.174 \text{ lb}_m \cdot \text{ft}/\text{lb}_f \cdot \text{s}^2$
- ρ = density of fluid, lb_m/ft^3
- p = absolute pressure, lb_f/ft^2
- β = ratio of diameters D_2/D_1 for venturi and sharp-edge orifice and d/D for flow nozzle, where D = pipe diameter and d = throat diameter

Note: Subscript 1 refers to entering conditions; subscript 2 refers to throat conditions.

Because flow through the meter is not frictionless, a correction factor C is defined to account for friction losses. If the fluid is at a high temperature, an additional correction factor F_a should be included to account for thermal expansion of the primary element. Because this amounts to less than 1% at 500°F, it can usually be omitted. Equation (6) then becomes

$$w = CA_2 \sqrt{\frac{2g_c \rho (p_1 - p_2)}{1 - \beta^4}} \quad (7)$$

where C is the friction loss correction factor.

The factor C is a function of geometry and Reynolds number. Values of C are given in ASME Standard PTC 19.5. The jet passing through an orifice plate contracts to a minimum area at the vena contracta located a short distance downstream from the orifice plate. The contraction coefficient, friction loss coefficient C , and approach factor $1/(1 - \beta^4)^{0.5}$ can be combined into a single constant K , which is a function of geometry and Reynolds number. The orifice flow rate equations then become

$$Q = KA_2 \sqrt{\frac{2g_c (p_1 - p_2)}{\rho}} \quad (8)$$

where

- Q = discharge flow rate, cfs
- A_2 = orifice area, ft^2
- $p_1 - p_2$ = pressure drop as obtained by pressure taps, lb_f/ft^2

Values of K are shown in ASME Standard PTC 19.5.

Valves, bends, and fittings upstream from the flowmeter can cause errors. Long, straight pipes should be installed upstream and downstream from flow devices to ensure fully developed flow for proper measurement. ASHRAE *Standard* 41.8 specifies upstream and downstream pipe lengths for measuring flow of liquids with an orifice plate. ASME *Standard* PTC 19.5 gives piping requirements between various fittings and valves and the venturi, nozzle, and orifice. If these conditions cannot be met, flow conditioners or straightening vanes can be used (ASME *Standards* PTC 19.5, MFC-10M; Mattingly 1984; Miller 1983).

Compressibility effects must be considered for gas flow if pressure drop across the measuring device is more than a few percent of the initial pressure.

Nozzles are sometimes arranged in parallel pipes from a common manifold; thus, the capacity of the testing equipment can be changed by shutting off the flow through one or more nozzles. An apparatus designed for testing airflow and capacity of air-conditioning equipment is described by Wile (1947), who also presents pertinent information on nozzle discharge coefficients, Reynolds numbers, and resistance of perforated plates. Some laboratories refer to this apparatus as a code tester.

VARIABLE-AREA FLOWMETERS (ROTAMETERS)

In permanent installations where high precision, ruggedness, and operational ease are important, the variable-area flowmeter is satisfactory. It is frequently used to measure liquids or gases in small-diameter pipes. For ducts or pipes over 6 in. in diameter, the expense of this meter may not be warranted. In larger systems, however, the meter can be placed in a bypass line and used with an orifice.

The variable-area meter (Figure 11) commonly consists of a float that is free to move vertically in a transparent tapered tube. The fluid to be metered enters at the narrow bottom end of the tube and moves upward, passing at some point through the annulus formed between the float and the inside wall of the tube. At any particular flow rate, the float assumes a definite position in the tube; a calibrated scale on the tube shows the float's location and the fluid flow rate.

The float's position is established by a balance between the fluid pressure forces across the annulus and gravity on the float. The buoyant force $V_f(\rho_f - \rho)g/g_c$ supporting the float is balanced by the pressure difference acting on the cross-sectional area of the float $A_f \Delta p$, where ρ_f , A_f , and V_f are, respectively, the float density, float cross-sectional area, and float volume. The pressure difference across the annulus is

$$\Delta p = \frac{V_f(\rho_f - \rho)g}{A_f g_c} \tag{9}$$

The mass flow follows from Equation (8) as

$$w = KA_2 \sqrt{\frac{2V_f(\rho_f - \rho)g\rho}{A_f}} \tag{10}$$

Flow for any fluid is nearly proportional to the area, so that calibration of the tube is convenient. To use the meter for different fluids, the flow coefficient variation for any float must be known. Float design can reduce variation of the flow coefficient with Reynolds number; float materials can reduce the dependence of mass flow calibration on fluid density.

POSITIVE-DISPLACEMENT METERS

Many positive-displacement meters are available for measuring total liquid or gas volumetric flow rates. The measured fluid flows progressively into compartments of definite size. As the compartments fill, they rotate so that the fluid discharges from the meter.

Fig. 11 Variable-Area Flowmeter

The flow rate through the meter equals the product of the compartment volume, number of compartments, and rotation rate of the rotor. Most of these meters have a mechanical register calibrated to show total flow.

TURBINE FLOWMETERS

Turbine flowmeters are volumetric flow-rate-sensing meters with a magnetic stainless steel turbine rotor suspended in the flow stream of a nonmagnetic meter body. The fluid stream exerts a force on the blades of the turbine rotor, setting it in motion and converting the fluid's linear velocity to an angular velocity. Design motivation for turbine meters is to have the rotational speed of the turbine proportional to the average fluid velocity and thus to the volume rate of fluid flow (DeCarlo 1984; Mattingly 1992; Miller 1983).

The rotor's rotational speed is monitored by an externally mounted pickoff assembly. The **magnetic pickoff** contains a permanent magnet and coil. As the turbine rotor blades pass through the field produced by the permanent magnet, a shunting action induces ac voltage in the winding of the coil wrapped around the magnet. A sine wave with a frequency proportional to the flow rate develops. With the **radio frequency pickoff**, an oscillator applies a high-frequency carrier signal to a coil in the pickoff assembly. The rotor blades pass through the field generated by the coil and modulate the carrier signal by shunting action on the field shape. The carrier signal is modulated at a rate corresponding to the rotor speed, which is proportional to the flow rate. With both pickoffs, pulse frequency is a measure of flow rate, and the total number of pulses measures total volume (Mattingly 1992; Shafer 1961; Woodring 1969).

Because output frequency of the turbine flowmeter is proportional to flow rate, every pulse from the turbine meter is equivalent to a known volume of fluid that has passed through the meter; the sum of these pulses yields total volumetric flow. Summation is done by electronic counters designed for use with turbine flowmeters; they combine a mechanical or electronic register with the basic electronic counter.

Turbine flowmeters should be installed with straight lengths of pipe upstream and downstream from the meter. The length of the

Table 5 Volumetric or Mass Flow Rate Measurement

Measurement Means	Application	Range	Precision	Limitations
Orifice and differential pressure measurement system	Flow through pipes, ducts, and plenums for all fluids	Above Reynolds number of 5000	1 to 5%	Discharge coefficient and accuracy influenced by installation conditions.
Nozzle and differential pressure measurement system	Flow through pipes, ducts, and plenums for all fluids	Above Reynolds number of 5000	0.5 to 2.0%	Discharge coefficient and accuracy influenced by installation conditions.
Venturi tube and differential pressure measurement system	Flow through pipes, ducts, and plenums for all fluids	Above Reynolds number of 5000	0.5 to 2.0%	Discharge coefficient and accuracy influenced by installation conditions.
Timing given mass or volumetric flow	Liquids or gases; used to calibrate other flowmeters	Any	0.1 to 0.5%	System is bulky and slow.
Rotameters	Liquids or gases	Any	0.5 to 5.0%	Should be calibrated for fluid being metered.
Displacement meter	Relatively small volumetric flow with high pressure loss	As high as 1000 cfm, depending on type	0.1 to 2.0% depending on type	Most types require calibration with fluid being metered.
Gasometer or volume displacement	Short-duration tests; used to calibrate other flowmeters	Total flow limited by available volume of containers	0.5 to 1.0%	—
Thomas meter (temperature rise of stream caused by electrical heating)	Elaborate setup justified by need for good accuracy	Any	1%	Uniform velocity; usually used with gases.
Element of resistance to flow and differential pressure measurement system	Used for check where system has calibrated resistance element	Lower limit set by readable pressure drop	1 to 5%	Secondary reading depends on accuracy of calibration.
Turbine flowmeters	Liquids or gases	Any	0.25 to 2.0%	Uses electronic readout.
Single- or multipoint instrument for measuring velocity at specific point in flow	Primarily for installed air-handling systems with no special provision for flow measurement	Lower limit set by accuracy of velocity measurement instrumentation	2 to 10%	Accuracy depends on uniformity of flow and completeness of traverse. May be affected by disturbances near point of measurement.
Heat input and temperature changes with steam and water coil	Check value in heater or cooler tests	Any	1 to 3%	—
Laminar flow element and differential pressure measurement system	Measure liquid or gas volumetric flow rate; nearly linear relationship with pressure drop; simple and easy to use	0.0001 to 2000 cfm	1%	Fluid must be free of dirt, oil, and other impurities that could plug meter or affect its calibration.
Magneto hydrodynamic flowmeter (electromagnetic)	Measures electrically conductive fluids, slurries; meter does not obstruct flow; no moving parts	0.1 to 10,000 gpm	1%	At present state of the art, conductivity of fluid must be greater than 5 $\mu\text{mho/cm}$.
Swirl flowmeter and vortex shedding meter	Measure liquid or gas flow in pipe; no moving parts	Above Reynolds number of 10^4	1%	—

inlet and outlet pipes should be according to manufacturers' recommendations or pertinent standards. Where recommendations of standards cannot be accommodated, the meter installation should be calibrated. Some turbine flowmeters can be used in bidirectional flow applications. A fluid strainer, used with liquids of poor or marginal lubricity, minimizes bearing wear.

The lubricity of the process fluid and the type and quality of rotor bearings determine whether the meter is satisfactory for the particular application. When choosing turbine flowmeters for use with fluorocarbon refrigerants, attention must be paid to the type of bearings used in the meter and to the oil content of the refrigerant. For these applications, sleeve-type rather than standard ball bearings are recommended. The amount of oil in the refrigerant can severely affect calibration and bearing life.

In metering liquid fluorocarbon refrigerants, the liquid must not flash to a vapor (cavitate), which tremendously increases flow volume. Flashing results in erroneous measurements and rotor speeds that can damage bearings or cause a failure. Flashing can be avoided by maintaining adequate back pressure on the downstream side of the meter (Liptak 1972).

AIR INFILTRATION, AIRTIGHTNESS, AND OUTDOOR AIR VENTILATION RATE MEASUREMENT

Air infiltration is the flow of outdoor air into a building through unintentional openings. **Airtightness** refers to the building envelope's ability to withstand flow when subjected to a pressure differential. The **outdoor air ventilation rate** is the rate of outdoor airflow intentionally introduced to the building for dilution of occupant- and building-generated contaminants. Measurement approaches to determine these factors are described briefly here, and in greater detail in Chapter 16.

Air infiltration depends on the building envelope's airtightness and the pressure differentials across the envelope. These differentials are induced by wind, stack effect, and operation of building mechanical equipment. For meaningful results, the air infiltration rate should be measured under typical conditions.

Airtightness of a residential building's envelope can be measured relatively quickly using building pressurization tests. In this technique, a large fan or blower mounted in a door or window induces a

large and roughly uniform pressure difference across the building shell. The airflow required to maintain this pressure difference is then measured. The more leakage in the building, the more airflow is required to induce a specific indoor/outdoor pressure difference. Building airtightness is characterized by the airflow rate at a reference pressure, normalized by the building volume or surface area. Under proper test conditions, results of a pressurization test are independent of weather conditions. Instrumentation requirements for pressurization testing include air-moving equipment, a device to measure airflow, and a differential pressure gage.

Commercial building envelope leakage can also be measured using building pressurization tests. Bahnfleth et al. (1999) describe a protocol for testing envelope leakage of tall buildings using the building's air-handling equipment.

Outdoor airflow can be measured directly using the flow rate measurement techniques described in this chapter. Take care in selecting the instrument most suitable for the operating conditions, range of airflows, and temperatures expected. The outdoor airflow rate is normally measured during testing and balancing, during commissioning, or for continuous ventilation flow rate control using permanently mounted flow sensors.

An additional factor that may be of interest is the building's air exchange rate, which compares airflow into the building with the building's volume. Typically, this includes both mechanical ventilation and infiltration. Building air exchange rates can be measured by injecting a tracer gas (ideally, a chemically stable, nontoxic gas not normally present in buildings) into a building and monitoring and analyzing the tracer gas concentration response. Equipment required for tracer testing includes (1) a means of injecting the tracer gas and (2) a tracer gas monitor. Various tracer gas techniques are used, distinguished by their injection strategy and analysis approach. These techniques include constant concentration (equilibrium tracer), decay or growth (ASTM *Standard* E741), and constant injection. Decay is the simplest of these techniques, but the other methods may be satisfactory if care is taken. A common problem in tracer gas testing is poor mixing of the tracer gas with the airstreams being measured.

Carbon Dioxide

Carbon dioxide is often used as a tracer gas because CO₂ gas monitors are relatively inexpensive and easy to use, and occupant-generated CO₂ can be used for most tracer gas techniques. Bottled CO₂ or CO₂ fire extinguishers are also readily available for tracer gas injection. Carbon dioxide may be used as a tracer gas to measure ventilation rates under the conditions and methods described in ASTM *Standard* D6245-98, for diagnostic purposes and point-in-time snapshots of the system's ventilation capabilities. CO₂ sensors are also used in building controls strategies to optimize ventilation by approximating the level of occupancy in a space; this is one method of demand-controlled ventilation. The concentration output may be used in a mathematical formula that allows the system to modulate ventilation rates when spaces with high density have highly variable or intermittent occupancy (e.g., churches, theaters, gymnasiums). This method of control is less effective in lower-density occupancies and spaces with more stable populations (Persily and Emmerich 2001). Carbon dioxide may also be used together with outdoor air intake rate data to estimate the current population of a space.

Because the steady-state concentration balance formula in Appendix C of ANSI/ASHRAE *Standard* 62.1-2007 depends totally on the validity of the assumed variables in the formula, CO₂ sensing for direct ventilation control should be used with caution, and possibly supplemented with other control measurements to establish the base and maximum design ventilation boundaries not to be exceeded. Also, ensure that intake air rates never fall below those required for building pressurization, which could affect energy use, comfort, health, and indoor air quality.

CO₂ input for ventilation control does not address contaminants generated by the building itself, and therefore cannot be used without providing a base level of ventilation for non-occupant-generated contaminants that have been shown to total a significant fraction if not a majority of those found in the space.

CARBON DIOXIDE MEASUREMENT

Carbon dioxide has become an important measurement parameter for HVAC&R engineers, particularly in indoor air quality (IAQ) applications. Although CO₂ is generally not of concern as a specific toxin in indoor air, it is used as a surrogate indicator of odor related to human occupancy. ANSI/ASHRAE *Standard* 62.1 recommends specific minimum outdoor air ventilation rates to ensure adequate indoor air quality.

NONDISPERSIVE INFRARED CO₂ DETECTORS

The most widespread technology for IAQ applications is the nondispersive infrared (NDIR) sensor (Figure 12). This device makes use of the strong absorption band that CO₂ produces at 4.2 μm when excited by an infrared light source. IAQ-specific NDIR instruments, calibrated between 0 and 5000 ppm, are typically accurate within 150 ppm, but the accuracy of some sensors can be improved to within 50 ppm if the instrument is calibrated for a narrower range. Portable NDIR meters are available with direct-reading digital displays; however, response time varies significantly among different instruments. Most NDIR cell designs facilitate very rapid CO₂ sample diffusion, although some instruments now in widespread use respond more slowly, resulting in stabilization times greater than 5 min (up to 15 min), which may complicate walk-through inspections.

Calibration

In a clean, stable environment, NDIR sensors can hold calibration for months, but condensation, dust, dirt, and mechanical shock may offset calibration. As with all other CO₂ sensor technologies, NDIR sensor readings are proportional to pressure, because the density of gas molecules changes when the sample pressure changes. This leads to errors in CO₂ readings when the barometric pressure changes from the calibration pressure. Weather-induced errors will be small, but all CO₂ instruments should be recalibrated if used at an altitude that is significantly different from the calibration altitude. Some NDIR sensors are sensitive to cooling effects when placed in an airstream. This is an important consideration when locating a fixed sensor or when using a portable system to evaluate air-handling system performance, because airflow in supply and return ducts may significantly shift readings.

Fig. 12 Nondispersive Infrared Carbon Dioxide Sensor

Applications

Nondispersive infrared sensors are well suited for equilibrium tracer and tracer decay ventilation studies, and faster-response models are ideal for a quick, basic evaluation of human-generated pollution and ventilation adequacy. When properly located, these sensors are also appropriate for continuous monitoring and for control strategies using equilibrium tracer and air fraction tracer calculations.

AMPEROMETRIC ELECTROCHEMICAL CO₂ DETECTORS

Amperometric electrochemical CO₂ sensors (Figure 13) use a measured current driven between two electrodes by the reduction of CO₂ that diffuses across a porous membrane. Unlike NDIR sensors, which normally last the lifetime of the instrument, electrochemical CO₂ sensors may change in electrolyte chemistry over time (typically 12 to 18 months) and should be replaced periodically. These sensors typically hold their calibration for several weeks, but they may drift more if exposed to low humidity; this drift makes them less suitable for continuous monitoring applications. At low humidity (below 30% rh), the sensors must be kept moist to maintain specified accuracy.

Amperometric electrochemical sensors require less power than NDIR sensors, usually operating continuously for weeks where NDIR instruments typically operate for 6 h (older models) to 150 h (newer models). The longer battery life can be advantageous for spot checks and walk-throughs, and for measuring CO₂ distribution throughout a building and within a zone. Unlike most NDIR sensors, amperometric electrochemical sensors are not affected by high humidity, although readings may be affected if condensate is allowed to form on the sensor.

PHOTOACOUSTIC CO₂ DETECTORS

Open-Cell Sensors

Open-cell photoacoustic CO₂ sensors (Figure 14) operate as air diffuses through a permeable membrane into a chamber that is

Fig. 13 Amperometric Carbon Dioxide Sensor

Fig. 14 Open-Cell Photoacoustic Carbon Dioxide Sensor

pulsed with filtered light at the characteristic CO₂ absorption frequency of 4.2 μm. The light energy absorbed by the CO₂ heats the sample chamber, causing a pressure pulse, which is sensed by a piezoresistor. Open-cell photoacoustic CO₂ sensors are presently unavailable in portable instruments, in part because any vibration during transportation would affect calibration and might affect the signal obtained for a given concentration of CO₂. Ambient acoustical noise may also influence readings. For continuous monitoring, vibration is a concern, as are temperature and airflow cooling effects. However, if a sensor is located properly and the optical filter is kept relatively clean, photoacoustic CO₂ sensors may be very stable. Commercially available open-cell photoacoustic transmitters do not allow recalibration to adjust for pressure differences, so an offset should be incorporated in any control system using these sensors at an altitude or duct pressure other than calibration conditions.

Closed-Cell Sensors

Closed-cell photoacoustic sensors (Figure 15) operate under the same principle as the open-cell version, except that samples are pumped into a sample chamber that is sealed and environmentally stabilized. Two acoustic sensors are sometimes used in the chamber to minimize vibration effects. Closed-cell units, available as portable or fixed monitors, come with particle filters that are easily replaced (typically at 3- to 6-month intervals) if dirt or dust accumulates on them. Closed-cell photoacoustic monitors allow recalibration to correct for drift, pressure effects, or other environmental factors that might influence accuracy.

POTENTIOMETRIC ELECTROCHEMICAL CO₂ DETECTORS

Potentiometric electrochemical CO₂ sensors use a porous fluorocarbon membrane that is permeable to CO₂, which diffuses into a carbonic acid electrolyte, changing the electrolyte's pH. This change is monitored by a pH electrode inside the cell. The pH electrode isopotential drift prohibits long-term monitoring to the accuracy and resolution required for continuous measurement or control or for detailed IAQ evaluations, although accuracy within 100 ppm, achievable short-term over the 2000 ppm range, may be adequate for basic ventilation and odor evaluations. In addition, this type of sensor has a slow response, which increases the operator time necessary for field applications or for performing a walk-through of a building.

COLORIMETRIC DETECTOR TUBES

Colorimetric detector tubes contain a chemical compound that discolors in the presence of CO₂ gas, with the amount of discoloration related to the CO₂ concentration. These detector tubes are often used to spot-check CO₂ levels; when used properly, they are

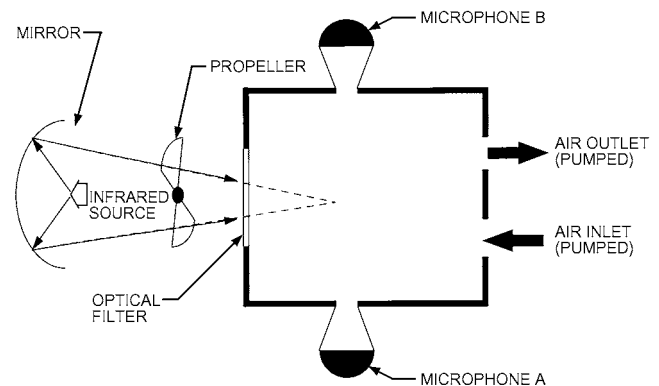

Fig. 15 Closed-Cell Photoacoustic Carbon Dioxide Sensor

accurate to within 25%. If numerous samples are taken (i.e., six or more), uncertainty may be reduced. However, CO₂ detector tubes are generally not appropriate for specific ventilation assessment because of their inaccuracy and inability to record concentration changes over time.

LABORATORY MEASUREMENTS

Laboratory techniques for measuring CO₂ concentration include mass spectroscopy, thermal conductivity, infrared spectroscopy, and gas chromatography. These techniques typically require taking on-site **grab samples** for laboratory analysis. Capital costs for each piece of equipment are high, and significant training is required. A considerable drawback to grab sampling is that CO₂ levels change significantly during the day and over the course of a week, making it sensible to place sensors on site with an instrument capable of recording or data logging measurements continuously over the course of a workweek. An automated grab sampling system capturing many samples of data would be quite cumbersome and expensive if designed to provide CO₂ trend information over time. However, an advantage to laboratory techniques is that they can be highly accurate. A mass spectrometer, for example, can measure CO₂ concentration to within 5 ppm from 0 to 2000 ppm. All laboratory measurement techniques are subject to errors resulting from interfering agents. A gas chromatograph is typically used in conjunction with the mass spectrometer to eliminate interference from nitrous oxide (N₂O), which has an equivalent mass, if samples are collected in a hospital or in another location where N₂O might be present.

ELECTRIC MEASUREMENT

Ammeters

Ammeters are low-resistance instruments for measuring current. They should be connected in series with the circuit being measured (Figure 16). Ideally, they have the appearance of a short circuit, but in practice, all ammeters have a nonzero input impedance that influences the measurement to some extent.

Ammeters often have several ranges, and it is good practice when measuring unknown currents to start with the highest range and then reduce the range to the appropriate value to obtain the most sensitive reading. Ammeters with range switches maintain circuit continuity during switching. On some older instruments, it may be necessary to short-circuit the ammeter terminals when changing the range.

Current transformers are often used to increase the operating range of ammeters. They may also provide isolation/protection from a high-voltage line. Current transformers have at least two separate windings on a magnetic core (Figure 17). The primary winding is connected in series with the circuit in which the current is measured. In a clamp-on probe, the transformer core is actually opened and then connected around a single conductor carrying the current to be measured. That conductor serves as the primary winding. The secondary winding carries a scaled-down version of the primary current, which is connected to an ammeter. Depending on instrument type, the ammeter reading may need to be multiplied by the ratio of the transformer.

When using an auxiliary current transformer, the secondary circuit must not be open when current is flowing in the primary winding; dangerously high voltage may exist across the secondary terminals. A short-circuiting blade between the secondary terminals should be closed before the secondary circuit is opened at any point.

Transformer accuracy can be impaired by residual magnetism in the core when the primary circuit is opened at an instant when flux is large. The transformer core may be left magnetized, resulting in ratio and phase angle errors. The primary and secondary windings should be short-circuited before making changes.

Voltmeters

Voltmeters are high-resistance instruments that should be connected across the load (in parallel), as shown in Figure 18. Ideally, they have the appearance of an open circuit, but in practice, all voltmeters have some finite impedance that influences measurement to some extent.

Voltage transformers are often used to increase the operating range of a voltmeter (Figure 19). They also provide isolation from high voltages and prevent operator injury. Like current transformers, voltage transformers consist of two or more windings on a magnetic core. The primary winding is generally connected across the high voltage to be measured, and the secondary winding is connected to the voltmeter. It is important not to short-circuit the secondary winding of a voltage transformer.

Wattmeters

Wattmeters measure the active power of an ac circuit, which equals the voltage multiplied by that part of the current in phase with the voltage. There are generally two sets of terminals: one to connect the load voltage and the other to connect in series with the load current. Current and voltage transformers can be used to extend the range of a wattmeter or to isolate it from high voltage. Figures 20 and 21 show connections for single-phase wattmeters, and Figure 22 shows use of current and voltage transformers with a single-phase wattmeter.

Wattmeters with multiple current and voltage elements are available to measure polyphase power. Polyphase wattmeter connections are shown in Figures 23 and 24.

Power-Factor Meters

Power-factor meters measure the ratio of active to apparent power (product of voltage and current). Connections for power-factor meters and wattmeters are similar, and current and voltage transformers can be used to extend their range. Connections for single-phase and polyphase power-factor meters are shown in Figures 25 and 26, respectively.

ROTATIVE SPEED MEASUREMENT

Tachometers

Tachometers, or direct-measuring rpm counters, vary from hand-held mechanical or electric meters to shaft-driven and electronic pulse counters. They are used in general laboratory and shop work to check rotative speeds of motors, engines, and turbines.

Stroboscopes

Optical rpm counters produce a controlled high-speed electronic flashing light, which the operator directs on a rotating member, increasing the rate of flashes until reaching synchronism (the optical effect that rotation has stopped). At this point, the rpm measured is equal to the flashes per minute emitted by the strobe unit. Care must be taken to start at the bottom of the instrument scale and work up because multiples of the rpm produce almost the same optical effect as true synchronism. Multiples can be indicated by positioning suitable marks on the shaft, such as a bar on one side and a circle on the opposite side. If, for example, the two are seen superimposed, then the strobe light is flashing at an even multiple of the true rpm.

AC Tachometer-Generators

A tachometer-generator consists of a rotor and a stator. The rotor is a permanent magnet driven by the equipment. The stator is a winding with a hole through the center for the rotor. Concentricity is not critical; bearings are not required between rotor and stator. The output can be a single-cycle-per-revolution signal whose voltage is a linear function of rotor speed. The polypole configuration that generates 10 cycles per revolution allows measurement of

speeds as low as 20 rpm without causing the indicating needle to flutter. The output of the ac tachometer-generator is rectified and connected to a dc voltmeter.

SOUND AND VIBRATION MEASUREMENT

Measurement systems for determining sound pressure level, intensity level, and mechanical vibration generally use transducers to convert mechanical signals into electrical signals, which are then processed electronically or digitally to characterize the measured mechanical signals. These measurement systems contain one or more of the following elements, which may or may not be contained in a single instrument:

- A transducer, or an assembly of transducers, to convert sound pressure or mechanical vibration (time-varying strain, displacement, velocity, acceleration, or force) into an electrical signal that is quantitatively related to the mechanical quantity being measured
- Amplifiers and networks to provide functions such as electrical impedance matching, signal conditioning, integration, differentiation, frequency weighting, and gain
- Signal-processing equipment to quantify those aspects of the signal that are being measured (peak value, rms value, time-weighted average level, power spectral density, or magnitude or phase of a complex linear spectrum or transfer function)
- A device such as a meter, oscilloscope, digital display, or level recorder to display the signal or the aspects of it that are being quantified
- An interface that allows cable, wireless, or memory card output

The relevant range of sound and vibration signals can vary over more than 12 orders of magnitude in amplitude and more than 8 orders of magnitude in frequency, depending on the application. References on instrumentation, measurement procedures, and signal analysis are given in the Bibliography. Product and application notes, technical reviews, and books published by instrumentation manufacturers are an excellent source of additional reference material. See Chapter 47 of the 2007 *ASHRAE Handbook—HVAC Applications* and Chapter 8 of this volume for further information on sound and vibration.

SOUND MEASUREMENT

Microphones

A microphone is a transducer that transforms an acoustical signal into an electrical signal. The two predominant transduction principles used in sound measurement (as opposed to broadcasting or recording) are the electrostatic and the piezoelectric. **Electrostatic (capacitor) microphones** are available either as electret microphones, which do not require an external polarizing voltage, or as condenser microphones, which do require an external polarizing voltage, typically in the range of 28 to 200 V (dc). **Piezoelectric microphones** may be manufactured using either natural piezoelectric crystals or poled ferroelectric crystals. The types of response characteristics of measuring microphones are pressure, free field, and random incidence (diffuse field).

The sensitivity and the frequency range over which the microphone has uniform sensitivity (flat frequency response) vary with sensing element diameter (surface area) and microphone type. Other critical factors that may affect microphone/preamplifier performance or response are atmospheric pressure, temperature, relative humidity, external magnetic and electrostatic fields, mechanical vibration, and radiation. Microphone selection is based on long- and short-term stability; the match between performance characteristics (e.g., sensitivity, frequency response, amplitude linearity, self-noise) and the expected amplitude of sound pressure,

frequency, range of analysis, and expected environmental conditions of measurement; and any other pertinent considerations, such as size and directional characteristics.

Sound Measurement Systems

Microphone preamplifiers, amplifiers, weighting networks, filters, analyzers, and displays are available either separately or integrated into a measuring instrument such as a sound level meter, personal noise exposure meter, measuring amplifier, or real-time fractional octave or Fourier [e.g., fast Fourier transform (FFT)] signal analyzer. Instruments included in a sound measurement system depend on the purpose of the measurement and the frequency range and resolution of signal analysis. For community and industrial noise measurements for regulatory purposes, the instrument, signal processing, and quantity to be measured are usually dictated by the pertinent regulation. The optimal instrument set generally varies for measurement of different characteristics such as sound power in HVAC ducts, sound power emitted by machinery, noise criteria (NC) numbers, sound absorption coefficients, sound transmission loss of building partitions, and reverberation times (T_{60}).

Frequency Analysis

Measurement criteria often dictate using filters to analyze the signal, to indicate the spectrum of the sound being measured. Filters of different bandwidths for different purposes include fractional octave band (one, one-third, one-twelfth, etc.), constant-percentage bandwidth, and constant (typically narrow) bandwidth. The filters may be analog or digital and, if digital, may or may not be capable of real-time data acquisition during measurement, depending on the bandwidth of frequency analysis. FFT signal analyzers are generally used in situations that require very narrow-resolution signal analysis when the amplitudes of the sound spectra vary significantly with respect to frequency. This may occur in regions of resonance or when it is necessary to identify narrow-band or discrete sine-wave signal components of a spectrum in the presence of other such components or of broadband noise. However, when the frequency varies (e.g., because of nonconstant rpm of a motor), results from FFT analyzers can be difficult to interpret because the change in rpm provides what looks like a broadband signal.

Sound Chambers

Special rooms and procedures are required to characterize and calibrate sound sources and receivers. The rooms are generally classified into three types: anechoic, hemianechoic, and reverberant. The ideal **anechoic** room has all boundary surfaces that completely absorb sound energy at all frequencies. The ideal **hemianechoic** room would be identical to the ideal anechoic room, except that one surface would totally reflect sound energy at all frequencies. The ideal **reverberant** room would have boundary surfaces that totally reflect sound energy at all frequencies.

Anechoic chambers are used to perform measurements under conditions approximating those of a free sound field. They can be used in calibrating and characterizing individual microphones, microphone arrays, acoustic intensity probes, reference sound power sources, loudspeakers, sirens, and other individual or complex sources of sound.

Hemianechoic chambers have a hard reflecting floor to accommodate heavy machinery or to simulate large factory floor or outdoor conditions. They can be used in calibrating and characterizing reference sound power sources, obtaining sound power levels of noise sources, and characterizing sound output of emergency vehicle sirens when mounted on an emergency motor vehicle.

Reverberation chambers are used to perform measurements under conditions approximating those of a diffuse sound field. They can be used in calibrating and characterizing random-incidence microphones and reference sound power sources, obtaining sound

power ratings of equipment and sound power levels of noise sources, measuring sound absorption coefficients of building materials and panels, and measuring transmission loss through building partitions and components such as doors and windows.

The choice of which room type to use often depends on the test method required for the subject units, testing costs, or room availability.

Calibration

A measurement system should be calibrated as a system from microphone or probe to indicating device before it is used to perform absolute measurements of sound. Acoustic calibrators and pistonphones of fixed or variable frequency and amplitude are available for this purpose. These calibrators should be used at a frequency low enough that the pressure, free-field, and random-incidence response characteristics of the measuring microphone(s) are, for practical purposes, equivalent, or at least related in a known quantitative manner for that specific measurement system. In general, the sound pressure produced by these calibrators may vary, depending on microphone type, whether the microphone has a protective grid, atmospheric pressure, temperature, and relative humidity. Correction factors and coefficients are required when conditions of use differ from those existing during the calibration of the acoustic calibrator or pistonphone. For demanding applications, precision sound sources and measuring microphones should periodically be sent to the manufacturer, a private testing laboratory, or a national standards laboratory for calibration.

VIBRATION MEASUREMENT

Except for seismic instruments that record or indicate vibration directly with a mechanical or optomechanical device connected to the test surface, vibration measurements use an electromechanical or interferometric vibration transducer. Here, the term *vibration transducer* refers to a generic electromechanical vibration transducer. Electromechanical and interferometric vibration transducers belong to a large and varied group of transducers that detect mechanical motion and furnish an electrical signal that is quantitatively related to a particular physical characteristic of the motion. Depending on design, the electrical signal may be related to mechanical strain, displacement, velocity, acceleration, or force. The operating principles of vibration transducers may involve optical interference; electrodynamic coupling; piezoelectric (including poled ferroelectric) or piezoresistive crystals; or variable capacitance, inductance, reluctance, or resistance. A considerable variety of vibration transducers with a wide range of sensitivities and bandwidths is commercially available. Vibration transducers may be contacting (e.g., seismic transducers) or noncontacting (e.g., interferometric, optical, or capacitive).

Transducers

Seismic transducers use a spring-mass resonator within the transducer. At frequencies much greater than the fundamental natural frequency of the mechanical resonator, the relative displacement between the base and the seismic mass of the transducer is nearly proportional to the displacement of the transducer base. At frequencies much lower than the fundamental resonant frequency, the relative displacement between the base and the seismic mass of the transducer is nearly proportional to the acceleration of the transducer base. Therefore, seismic displacement transducers and seismic electrodynamic velocity transducers tend to have a relatively compliant suspension with a low resonant frequency; piezoelectric accelerometers and force transducers have a relatively stiff suspension with a high resonant frequency.

Strain transducers include the metallic resistance gage and piezoresistive strain gage. For dynamic strain measurements, these are usually bonded directly to the test surface. The accuracy with which a bonded strain gage replicates strain occurring in the test structure

is largely a function of how well the strain gage was oriented and bonded to the test surface.

Displacement transducers include the capacitance gage, fringe-counting interferometer, seismic displacement transducer, optical approaches, and the linear variable differential transformer (LVDT). Velocity transducers include the reluctance (magnetic) gage, laser Doppler interferometer, and seismic electrodynamic velocity transducer. Accelerometers and force transducers include the piezoelectric, piezoresistive, and force-balance servo.

Vibration Measurement Systems

Sensitivity, frequency limitations, bandwidth, and amplitude linearity of vibration transducers vary greatly with the transduction mechanism and the manner in which the transducer is applied in a given measurement apparatus. Contacting transducers' performance can be significantly affected by the mechanical mounting methods and points of attachment of the transducer and connecting cable and by the mechanical impedance of the structure loading the transducer. Amplitude linearity varies significantly over the operating range of the transducer, with some transducer types or configurations being inherently more linear than others. Other factors that may critically affect performance or response are temperature; relative humidity; external acoustic, magnetic, and electrostatic fields; transverse vibration; base strain; chemicals; and radiation. A vibration transducer should be selected based on its long- and short-term stability; the match between its performance characteristics (e.g., sensitivity, frequency response, amplitude linearity, self-noise) and the expected amplitude of vibration, frequency range of analysis, and expected environmental conditions of measurement; and any other pertinent considerations (e.g., size, mass, and resonant frequency).

Vibration exciters, or **shakers**, are used in structural analysis, vibration analysis of machinery, fatigue testing, mechanical impedance measurements, and vibration calibration systems. Vibration exciters have a table or moving element with a drive mechanism that may be mechanical, electrodynamic, piezoelectric, or hydraulic. They range from relatively small, low-power units for calibrating transducers (e.g., accelerometers) to relatively large, high-power units for structural and fatigue testing.

Conditioning amplifiers, power supplies, preamplifiers, charge amplifiers, voltage amplifiers, power amplifiers, filters, controllers, and displays are available either separately or integrated into a measuring instrument or system, such as a structural analysis system, vibration analyzer, vibration monitoring system, vibration meter, measuring amplifier, multichannel data-acquisition and modal analysis system, or real-time fractional-octave or FFT signal analyzer. The choice of instruments to include in a vibration measurement system depends on the mechanical quantity to be determined, purpose of the measurement, and frequency range and resolution of signal analysis. For vibration measurements, the signal analysis is relatively narrow in bandwidth and may be relatively low in frequency, to accurately characterize structural resonances. Accelerometers with internal integrated circuitry are available to provide impedance matching or servo control for measuring very-low-frequency acceleration (servo accelerometers). Analog integration and differentiation of vibration signals is available through integrating and differentiating networks and amplifiers, and digital is available through FFT analyzers. Vibration measurements made for different purposes (e.g., machinery diagnostics and health monitoring, balancing rotating machinery, analysis of torsional vibration, analysis of machine-tool vibration, modal analysis, analysis of vibration isolation, stress monitoring, industrial control) generally have different mechanical measurement requirements and a different optimal set of instrumentation.

Calibration

Because of their inherent long- and short-term stability, amplitude linearity, wide bandwidth, wide dynamic range, low noise, and

wide range of sensitivities, seismic accelerometers have traditionally been used as a reference standard for dynamic mechanical measurements. A measurement system should be calibrated as a system from transducer to indicating device before it is used to perform absolute dynamic measurements of mechanical quantities. Calibrated reference vibration exciters, standard reference accelerometers, precision conditioning amplifiers, and precision calibration exciters are available for this purpose. These exciters and standard reference accelerometers can be used to transfer a calibration to another transducer. For demanding applications, a calibrated exciter or standard reference accelerometer with connecting cable and conditioning amplifier should periodically be sent to the manufacturer, a private testing laboratory, or a national standards laboratory for calibration.

LIGHTING MEASUREMENT

Light level, or **illuminance**, is usually measured with a photocell made from a semiconductor such as silicon or selenium. Photocells produce an output current proportional to incident luminous flux when linked with a microammeter, color- and cosine-corrected filters, and multirange switches; they are used in inexpensive handheld light meters and more precise instruments. Different cell heads allow multirange use in precision meters.

Cadmium sulfide photocells, in which resistance varies with illumination, are also used in light meters. Both gas-filled and vacuum photoelectric cells are in use.

Small survey-type meters are not as accurate as laboratory meters; their readings should be considered approximate, although consistent, for a given condition. Their range is usually from 5 to 5000 footcandles. Precision low-level meters have cell heads with ranges down to 0 to 2 footcandles.

A photometer installed in a revolving head is called a **goniophotometer** and is used to measure the distribution of light sources or luminaires. To measure total luminous flux, the luminaire is placed in the center of a sphere painted inside with a high-reflectance white with a near-perfect diffusing matte surface. Total light output is measured through a small baffled window in the sphere wall.

To measure irradiation from germicidal lamps, a filter of fused quartz with fluorescent phosphor is placed over the light meter cell.

If meters are used to measure the number of lumens per unit area diffusely leaving a surface, luminance (cd/in^2) instead of illumination (footcandles) is read. Light meters can be used to measure luminance, or electronic lux meters containing a phototube, an amplifier, and a microammeter can read luminance directly. For a perfectly diffuse reflecting surface, which has a constant luminance regardless of viewing angle, the unit of footlamberts in lumens/ ft^2 is sometimes applied.

Chapter 2 of the IESNA (2000) *Lighting Handbook* gives detailed information on measurement of light.

THERMAL COMFORT MEASUREMENT

Thermal comfort depends on the combined influence of clothing, activity, air temperature, air velocity, mean radiant temperature, and air humidity. Thermal comfort is influenced by heating or cooling of particular body parts through radiant temperature asymmetry (plane radiant temperature), draft (air temperature, air velocity, turbulence), vertical air temperature differences, and floor temperature (surface temperature).

A general description of thermal comfort is given in Chapter 9, and guidelines for an acceptable thermal environment are given in ASHRAE *Standard 55* and ISO *Standard 7730*. ASHRAE *Standard 55* also includes required measuring accuracy. In addition to specified accuracy, ISO *Standard 7726* includes recommended measuring locations and a detailed description of instruments and methods.

Clothing and Activity Level

These values are estimated from tables (Chapter 9; ISO *Standards* 8996, 9920). Thermal insulation of clothing (clo-value) can be measured on a thermal mannequin (McCullough et al. 1985; Olesen 1985). Activity (met-value) can be estimated from measuring CO_2 and O_2 in a person's expired air.

Air Temperature

Various types of thermometers may be used to measure air temperature. Placed in a room, the sensor registers a temperature between air temperature and mean radiant temperature. One way of reducing the radiant error is to make the sensor as small as possible, because the convective heat transfer coefficient increases as size decreases, whereas the radiant heat transfer coefficient is constant. A smaller sensor also provides a favorably low time constant. Radiant error can also be reduced by using a shield (an open, polished aluminum cylinder) around the sensor, using a sensor with a low-emittance surface, or artificially increasing air velocity around the sensor (aspirating air through a tube in which the sensor is placed).

Air Velocity

In occupied zones, air velocities are usually small (0 to 100 fpm), but do affect thermal sensation. Because velocity fluctuates, the mean value should be measured over a suitable period, typically 3 min. Velocity fluctuations with frequencies up to 1 Hz significantly increase human discomfort caused by draft, which is a function of air temperature, mean air velocity, and turbulence (see Chapter 9). Fluctuations can be given as the standard deviation of air velocity over the measuring period (3 min) or as the turbulence intensity (standard deviation divided by mean air velocity). Velocity direction may change and is difficult to identify at low air velocities. An omnidirectional sensor with a short response time should be used. A thermal anemometer is suitable. If a hot-wire anemometer is used, the direction of measured flow must be perpendicular to the hot wire. Smoke puffs can be used to identify the direction.

Plane Radiant Temperature

This refers to the uniform temperature of an enclosure in which the radiant flux on one side of a small plane element is the same as in the actual nonuniform environment. It describes the radiation in one direction. Plane radiant temperature can be calculated from surface temperatures of the environment (half-room) and angle factors between the surfaces and a plane element (ASHRAE *Standard 55*). It may also be measured by a net-radiometer or a radiometer with a sensor consisting of a reflective disk (polished) and an absorbent disk (painted black) (Olesen et al. 1989).

Mean Radiant Temperature

This is the uniform temperature of an imaginary black enclosure in which an occupant would exchange the same amount of radiant heat as in the actual nonuniform enclosure. Mean radiant temperature can be calculated from measured surface temperatures and the corresponding angle factors between the person and surfaces. It can also be determined from the plane radiant temperature in six opposite directions, weighted according to the projected area factors for a person. For more information, see Chapter 9.

Because of its simplicity, the instrument most commonly used to determine the mean radiant temperature is a **black globe thermometer** (Bedford and Warmer 1935; Vernon 1932). This thermometer consists of a hollow sphere usually 6 in. in diameter, coated in flat black paint with a thermocouple or thermometer bulb at its center. The temperature assumed by the globe at equilibrium results from a balance between heat gained and lost by radiation and convection.

Mean radiant temperatures are calculated from

$$\bar{t}_r = \left[(t_g + 459.67)^4 + \frac{4.74 \times 10^7 V_a^{0.6}}{\varepsilon D^{0.4}} (t_g - t_a) \right]^{1/4} - 459.67 \quad (11)$$

where

$$\begin{aligned} \bar{t}_r &= \text{mean radiant temperature, } ^\circ\text{F} \\ t_g &= \text{globe temperature, } ^\circ\text{F} \\ V_a &= \text{air velocity, fpm} \\ t_a &= \text{air temperature, } ^\circ\text{F} \\ D &= \text{globe diameter, ft} \\ \epsilon &= \text{emissivity (0.95 for black globe)} \end{aligned}$$

According to Equation (11), air temperature and velocity around the globe must also be determined. The globe thermometer is spherical, but mean radiant temperature is defined in relation to the human body. For sedentary people, the globe represents a good approximation. For people who are standing, the globe, in a radiant nonuniform environment, overestimates the radiation from floor or ceiling; an ellipsoidal sensor gives a closer approximation. A black globe also overestimates the influence of short-wave radiation (e.g., sunshine). A flat gray color better represents the radiant characteristic of normal clothing (Olesen et al. 1989). The hollow sphere is usually made of copper, which results in an undesirably high time constant. This can be overcome by using lighter materials (e.g., a thin plastic bubble).

Air Humidity

The water vapor pressure (absolute humidity) is usually uniform in the occupied zone of a space; therefore, it is sufficient to measure absolute humidity at one location. Many of the instruments listed in Table 3 are applicable. At ambient temperatures that provide comfort or slight discomfort, the thermal effect of humidity is only moderate, and highly accurate humidity measurements are unnecessary.

CALCULATING THERMAL COMFORT

When the thermal parameters have been measured, their combined effect can be calculated by the thermal indices in Chapter 9. For example, the effective temperature (Gagge et al. 1971) can be determined from air temperature and humidity. Based on the four environmental parameters and an estimation of clothing and activity, the **predicted mean vote** (PMV) can be determined with the aid of tables (Chapter 9; Fanger 1982; ISO *Standard* 7730). The PMV is an index predicting the average thermal sensation that a group of occupants may experience in a given space.

For certain types of normal activity and clothing, measured environmental parameters can be compared directly with those in ASHRAE *Standard* 55 or ISO *Standard* 7730.

INTEGRATING INSTRUMENTS

Several instruments have been developed to evaluate the combined effect of two or more thermal parameters on human comfort. Madsen (1976) developed an instrument that gives information on the occupants' expected thermal sensation by directly measuring the PMV value. The comfort meter has a heated elliptical sensor that simulates the body (Figure 27). The estimated clothing (insulation

Fig. 27 Madsen's Comfort Meter
(Madsen 1976)

value), activity in the actual space, and humidity are set on the instrument. The sensor then integrates the thermal effect of air temperature, mean radiant temperature, and air velocity in approximately the same way the body does. The electronic instrument gives the measured operative and equivalent temperature, calculated PMV, and predicted percentage of dissatisfied (PPD).

MOISTURE CONTENT AND TRANSFER MEASUREMENT

Little off-the-shelf instrumentation exists to measure the moisture content of porous materials or moisture transfer through those materials. However, many measurements can be set up with a small investment of time and money. Three moisture properties are most commonly sought: (1) the sorption isotherm, the amount of water vapor a hygroscopic material adsorbs from humid air; (2) vapor permeability, the rate at which water vapor passes through a given material; and (3) liquid diffusivity, the rate at which liquid water passes through a porous material.

Sorption Isotherm

A sorption isotherm relates the **equilibrium moisture content** (EMC) of a hygroscopic material to the ambient relative humidity under constant temperature. Moisture content is the ratio of a sample's total mass of water to dry mass. Determining a sorption isotherm involves exposing a sample of material to a known relative humidity at a known temperature and then measuring the sample's moisture content after sufficient time has elapsed for the sample to reach equilibrium with its surroundings. Hysteresis in the sorption behavior of most hygroscopic materials requires that measurements be made for both increasing (adsorption isotherm) and decreasing relative humidity (desorption isotherm).

Ambient relative humidity can be controlled using saturated salt solutions or mechanical refrigeration equipment (Carotenuto et al. 1991; Cunningham and Spratt 1984; Tveit 1966). Precise measurements of the relative humidity produced by various salt solutions were reported by Greenspan (1977). ASTM *Standard* E104 describes the use of saturated salt solutions. A sample's EMC is usually determined gravimetrically using a precision balance. The sample's dry mass, necessary to calculate moisture content, can be found by oven drying or desiccant drying. Oven dry mass may be lower than desiccant dry mass because of the loss of volatiles other than water in the oven (Richards et al. 1992).

A major difficulty in measuring sorption isotherms of engineering materials is the long time required for many materials to reach equilibrium (often as long as weeks or months). The rate-limiting mechanism for these measurements is usually the slow process of vapor diffusion into the pores of the material. Using smaller samples can reduce diffusion time. Note that, although EMC isotherms are traditionally plotted as a function of relative humidity, the actual transport to or from materials is determined by vapor pressure differences. Thus, significant moisture content changes can occur because of changes in either the material vapor pressure or the surrounding air long before equilibrium is reached.

Vapor Permeability

Diffusive transfer of water vapor through porous materials is often described by a modified form of Fick's law:

$$w_v'' = -\mu \frac{dp}{dx} \quad (12)$$

where

$$\begin{aligned} w_v'' &= \text{mass of vapor diffusing through unit area per unit time, gr/h} \cdot \text{ft}^2 \\ dp/dx &= \text{vapor pressure gradient, in. Hg/in.} \\ \mu &= \text{vapor permeability, gr} \cdot \text{in/h} \cdot \text{ft}^2 \cdot \text{in. Hg} \end{aligned}$$

In engineering practice, permeance may be used instead of permeability. **Permeance** is simply permeability divided by the material

thickness in the direction of vapor flow; thus, permeability is a material property, whereas permeance depends on thickness.

Permeability is measured with wet-cup, dry-cup, or modified cup tests. Specific test methods for measuring water vapor permeability are given in *ASTM Standard E96*.

For many engineering materials, vapor permeability is a strong function of mean relative humidity. Wet and dry cups cannot adequately characterize this dependence on relative humidity. Instead, a modified cup method can be used, in which pure water or desiccant in a cup is replaced with a saturated salt solution (Burch et al. 1992; McLean et al. 1990). A second saturated salt solution is used to condition the environment outside the cup. Relative humidities on both sides of the sample material can be varied from 0 to 100%. Several cups with a range of mean relative humidities are used to map out the dependence of vapor permeability on relative humidity.

In measuring materials of high permeability, the finite rate of vapor diffusion through air in the cup may become a factor. Air-film resistance could then be a significant fraction of the sample's resistance to vapor flow. Accurate measurement of high-permeability materials may require an accounting of diffusive rates across all air gaps (Fanney et al. 1991).

Liquid Diffusivity

Transfer of liquid water through porous materials may be characterized as a diffusion-like process:

$$w_l'' = -\rho D_l \frac{d\gamma}{dx} \quad (13)$$

where

w_l' = mass of liquid transferred through unit area per unit time, lb/h · ft²

ρ = liquid density, lb/ft³

D_l = liquid diffusivity, ft²/h

$d\gamma/dx$ = moisture content gradient, ft⁻¹

D_l typically depends strongly on moisture content.

Transient measurement methods deduce the functional form of $D_l\gamma$ by observing the evolution of a one-dimensional moisture content profile over time. An initially dry specimen is brought into contact with liquid water. Free water migrates into the specimen, drawn in by surface tension. The resulting moisture content profile, which changes with time, must be differentiated to find the material's liquid diffusivity (Bruce and Klute 1956).

Determining the transient moisture content profile typically involves a noninvasive and nondestructive method of measuring local moisture content. Methods include gamma ray absorption (Freitas et al. 1991; Kumaran and Bomberg 1985; Quenard and Sallee 1989), x-ray radiography (Ambrose et al. 1990), neutron radiography (Prazak et al. 1990), and nuclear magnetic resonance (NMR) (Gummerson et al. 1979).

Uncertainty in liquid diffusivity measurement is often large because of the need to differentiate noisy experimental data.

HEAT TRANSFER THROUGH BUILDING MATERIALS

Thermal Conductivity

The thermal conductivity of a heat insulator, as defined in Chapter 25, is a unit heat transfer factor. Two methods of determining the thermal conductivity of flat insulation are the **guarded hot plate** and the **heat flow meter apparatus**, according to *ASTM Standards C177* and *C518*, respectively. Both methods use parallel isothermal plates to induce a steady temperature gradient across the thickness of the specimen(s). The guarded hot plate is considered an absolute method for determining thermal conductivity. The heat flow meter apparatus requires calibration with a specimen of known thermal

conductivity, usually determined in the guarded hot plate. The heat flow meter apparatus is calibrated by determining the voltage output of its heat flux transducer(s) as a function of the heat flux through the transducer(s).

Basic guarded hot plate design consists of an electrically heated plate and two liquid-cooled plates. Two similar specimens of a material are required for a test; one is mounted on each side of the hot plate. A cold plate is then pressed against the outside of each specimen by a clamp screw. The heated plate consists of two sections separated by a small gap. During tests, the central (metering) and outer (guard) sections are maintained at the same temperature to minimize errors caused by edge effects. The electric energy required to heat the metering section is measured carefully and converted to heat flow. Thermal conductivity of the material can be calculated under steady-state conditions using this heat flow quantity, area of the metering section, temperature gradient, and specimen thickness. Thermal conductivity of cylindrical or pipe insulation (Chapter 25) is determined similarly, but an equivalent thickness must be calculated to account for the cylindrical shape (*ASTM Standard C335*). Transient methods have been developed by D'Eustachio and Schreiner (1952), Hooper and Chang (1953), and Hooper and Lepper (1950) using a line heat source within a slender probe. These instruments are available commercially and have the advantages of rapidity and a small test specimen requirement. The probe is a useful research and development tool, but it has not been as accepted as the guarded hot plate, heat flow meter apparatus, or pipe insulation apparatus.

Thermal Conductance and Resistance

Thermal conductances (C-factors) and resistances (R-values) of many building assemblies can be calculated from the conductivities and dimensions of their components, as described in Chapter 27. Test values can also be determined experimentally by testing large, representative specimens in the hot box apparatus described in *ASTM Standards C976* and *C1363*. This laboratory apparatus measures heat transfer through a specimen under controlled air temperature, air velocity, and radiation conditions. It is especially suited for large, nonhomogeneous specimens.

For in situ measurements, heat flux and temperature transducers are useful in measuring the dynamic or steady-state behavior of opaque building components (*ASTM Standard C1046*). A heat flux transducer is simply a differential thermopile within a core or substrate material. Two types of construction are used: (1) multiple thermocouple junctions wrapped around a core material, or (2) printed circuits with a uniform array of thermocouple junctions. The transducer is calibrated by determining its voltage output as a function of the heat flux through the transducer. For in situ measurements, the transducer is installed in either the wall or roof, or mounted on an exterior surface with tape or adhesive. Data obtained can be used to compute the thermal conductance or resistance of the building component (*ASTM Standard C1155*).

AIR CONTAMINANT MEASUREMENT

Three measures of particulate air contamination include the number, projected area, and mass of particles per unit volume of air (*ASTM 2004*). Each requires an appropriate sampling technique.

Particles are counted by capturing them in impingers, impactors, membrane filters, or thermal or electrostatic precipitators. Counting may be done by microscope, using stage counts if the sample covers a broad range of sizes (Nagda and Rector 2001).

Electronic particle counters can give rapid data on particle size distribution and concentration. **Inertial particle counters** use acceleration to separate sampled particles into different sizes. Real-time **aerodynamic particle sizers (APS)** use inertial effects to separate particles by size, but instead of capturing the particles, they are sized optically (Cox and Miro 1997), and can provide continuous

sampling; however, they tend to be very expensive. Other, less costly types of **optical particle counters (OPCs)** are also available, but they typically require careful calibration using the type of particle that is being measured for accurate results (Baron and Willeke 2001). Their accuracy also depends heavily on appropriate maintenance and proper application. Correction for particle losses (dropout in the sampling lines) during sampling can be particularly important for accurate concentration measurements. Concentration uncertainty (random measurement uncertainty) also depends on the number of particles sampled in a given sampling interval.

Particle counters have been used in indoor office environments as well as in cleanrooms, and in aircraft cabin air quality testing (Cox and Miro 1997).

Projected area determinations are usually made by sampling onto a filter paper and comparing the light transmitted or scattered by this filter to a standard filter. The staining ability of dusts depends on the projected area and refractive index per unit volume. For sampling, filters must collect the minimum-sized particle of interest, so membrane or glass fiber filters are recommended.

To determine particle mass, a measured quantity of air is drawn through filters, preferably of membrane or glass fiber, and the filter mass is compared to the mass before sampling. Electrostatic or thermal precipitators and various impactors have also been used. For further information, see ACGIH (1983), Lodge (1989), and Lundgren et al. (1979).

Chapter 45 of the 2007 *ASHRAE Handbook—HVAC Applications* presents information on measuring and monitoring gaseous contaminants. Relatively costly analytical equipment, which must be calibrated and operated carefully by experienced personnel, is needed. Numerous methods of sampling the contaminants, as well as the laboratory analysis techniques used after sampling, are specified. Some of the analytical methods are specific to a single pollutant; others can present a concentration spectrum for many compounds simultaneously.

COMBUSTION ANALYSIS

Two approaches are used to measure the thermal output or capacity of a boiler, furnace, or other fuel-burning device. The direct or **calorimetric test** measures change in enthalpy or heat content of the fluid, air, or water heated by the device, and multiplies this by the flow rate to arrive at the unit's capacity. The indirect test or **flue gas analysis** method determines heat losses in flue gases and the jacket and deducts them from the heat content (higher heating value) of measured fuel input to the appliance. A **heat balance** simultaneously applies both tests to the same device. The indirect test usually indicates the greater capacity, and the difference is credited to radiation from the casing or jacket and unaccounted-for losses.

With small equipment, the expense of the direct test is usually not justified, and the indirect test is used with an arbitrary radiation and unaccounted-for loss factor.

FLUE GAS ANALYSIS

Flue gases from burning fossil fuels generally contain carbon dioxide (CO_2) and water, with some small amounts of hydrogen (H_2), carbon monoxide (CO), nitrogen oxides (NO_x), sulfur oxides (SO_x), and unburned hydrocarbons. However, generally only concentrations of CO_2 (or O_2) and CO are measured to determine completeness of combustion and efficiency.

Nondispersive infrared (NDIR) analyzers are the most common laboratory instruments for measuring CO and CO_2 . Their advantages include the following: (1) they are not very sensitive to flow rate, (2) no wet chemicals are required, (3) they have a relatively fast response, (4) measurements can be made over a wide range of concentrations, and (5) they are not sensitive to the presence of contaminants in ambient air.

In the laboratory, oxygen is generally measured with an instrument that uses O_2 's paramagnetic properties. Paramagnetic instruments are generally used because of their excellent accuracy and because they can be made specific to the measurement of oxygen.

For field testing and burner adjustment, portable combustion testing equipment is available. These instruments generally measure O_2 and CO with electrochemical cells. The CO_2 is then calculated by an on-board microprocessor and, together with temperature, is used to calculate thermal efficiency. A less expensive approach is to measure CO_2 , O_2 , and CO with a portable Orsat apparatus.

DATA ACQUISITION AND RECORDING

Almost every type of transducer and sensor is available with the necessary interface system to make it computer-compatible. The transducer itself begins to lose its identity when integrated into a system with features such as linearization, offset correction, self-calibration, and so forth. This has eliminated concern about the details of signal conditioning and amplification of basic transducer outputs, although engineering judgment is still required to review all data for validity, accuracy, and acceptability before making decisions based on the results. The personal computer is integrated into every aspect of data recording, including sophisticated graphics, acquisition and control, and analysis. Internet or intranet connections allow easy access to remote personal-computer-based data-recording systems from virtually any locale.

Direct output devices can be either multipurpose or specifically designed for a given sensor. Traditional chart recorders still provide a visual indication and a hard copy record of the data, but their output is now rarely used to process data. These older mechanical stylus-type devices use ink, hot wire, pressure, or electrically sensitive paper to provide a continuous trace. They are useful up to a few hundred hertz. Thermal and ink recorders are confined to chart speeds of a few inches per second for recording relatively slow processes. Simple indicators and readouts are used mostly to monitor the output of a sensor visually, and have now usually been replaced by modern digital indicators. Industrial environments commonly use signal transmitters for control or computer data-handling systems to convert the signal output of the primary sensor into a compatible common signal span (e.g., the standard 4-20 mA current loop). All signal conditioning (ranging, zero suppression, reference-justification compensation) is provided at the transmitter. Thus, all recorders and controllers in the system can have an identical electrical span, with variations only in charts and scales offering the advantages of interchangeability and economy in equipment cost. Long signal transmission lines can be used, and receiving devices can be added to the loop without degrading performance. Newer instruments may be digitally bus-based, which removes the degradation that may occur with analog signals. These digital instruments are usually immune to noise, based on the communications scheme that is used. They also may allow for self-configuration of the sensor in the field to the final data acquisition device.

The vast selection of available hardware, often confusing terminology, and the challenge of optimizing the performance/cost ratio for a specific application make configuring a data acquisition system difficult. A system specifically configured to meet a particular measurement need can quickly become obsolete if it has inadequate flexibility. Memory size, recording speed, and signal processing capability are major considerations in determining the correct recording system. Thermal, mechanical, electromagnetic interference, portability, and meteorological factors also influence the selection.

Digital Recording

A digital data acquisition system must contain an interface, which is a system involving one or several analog-to-digital converters, and,

in the case of multichannel inputs, circuitry for multiplexing. The interface may also provide excitation for transducers, calibration, and conversion of units. The digital data are arranged into one or several standard digital bus formats. Many data acquisition systems are designed to acquire data rapidly and store large records of data for later recording and analysis. Once the input signals have been digitized, the digital data are essentially immune to noise and can be transmitted over great distances.

Information is transferred to a computer/recorder from the interface as a pulse train, which can be transmitted as 4-, 8-, 12-, 16-, or 32-bit words. An 8-bit word is a byte; many communications methods are rated according to their bytes per second transfer rate. Digital data are transferred in either serial or parallel mode. Serial transmission means that the data are sent as a series of pulses, one bit at a time. Although slower than parallel systems, serial interfaces require only two wires, which lowers their cabling cost. The speed of serial transmissions is rated according to the symbols per second rate, or baud rate. In parallel transmission, the entire data word is transmitted at one time. To do this, each bit of a data word has to have its own transmission line; other lines are needed for clocking and control. Parallel mode is used for short distances or when high data transmission rates are required. Serial mode must be used for long-distance communications where wiring costs are prohibitive.

The two most popular interface bus standards currently used for data transmission are the IEEE 488, or general-purpose interface bus (GPIB), and the RS232 serial interface. The **IEEE 488 bus** system feeds data down eight parallel wires, one data byte at a time. This parallel operation allows it to transfer data rapidly at up to 1 million characters per second. However, the IEEE 488 bus is limited to a cable length of 65 ft and requires an interface connection on every meter for proper termination. The **RS232** system feeds data serially down two wires, one bit at a time. An RS232 line may be over 1000 ft long. For longer distances, it may feed a modem to send data over standard telephone lines. Newer digital bus protocols are now available to digitally transmit data using proprietary or standardized methods and TCP/IP or USB connections between the data acquisition unit and a personal computer. These newer buses can provide faster throughput than the older IEEE 488 and RS232 methods, have no length constraints, and may also be available with wireless connections. A local area network (LAN) may be available in a facility for transmitting information. With appropriate interfacing, transducer data are available to any computer connected to the network.

Bus measurements can greatly simplify three basic applications: data gathering, automated limit testing, and computer-controlled processes. Data gathering collects readings over time. The most common applications include aging tests in quality control, temperature tests in quality assurance, and testing for intermittents in service. A controller can monitor any output indefinitely and then display the data directly on screen or record it on magnetic tape or disks for future use.

In automated limit testing, the computer compares each measurement with programmed limits. The controller converts readings to a good/bad readout. Automatic limit testing is highly cost-effective when working with large number of parameters of a particular unit under test.

In computer-controlled processes, the IEEE 488 bus system becomes a permanent part of a larger, completely automated system. For example, a large industrial process may require many electrical sensors that feed a central computer controlling many parts of the manufacturing process. An IEEE 488 bus controller collects readings from several sensors and saves the data until asked to dump an entire batch of readings to a larger central computer at one time. Used in this manner, the IEEE 488 bus controller serves as a slave of the central computer.

Dynamic range and accuracy must be considered in a digital recording system. **Dynamic range** refers to the ratio of the maximum input signal for which the system is useful to the noise floor of

the system. The **accuracy** figure for a system is affected by the signal noise level, nonlinearity, temperature, time, crosstalk, and so forth. In selecting an 8-, 12-, or 16-bit analog-to-digital converter, the designer cannot assume that system accuracy is necessarily determined by the resolution of the encoders (i.e., 0.4%, 0.025%, and 0.0016%, respectively). If the sensor preceding the converter is limited to 1% full-scale accuracy, for example, no significant benefits are gained by using a 12-bit system over an 8-bit system and suppressing the least significant bit. However, a greater number of bits may be required to cover a larger dynamic range.

Data-Logging Devices

Data loggers digitally store electrical signals (analog or digital) to an internal memory storage component. The signal from connected sensors is typically stored to memory at timed intervals ranging from MHz to hourly sampling. Some data loggers store data based on an event (e.g., button push, contact closure). Many data loggers can perform linearization, scaling, or other signal conditioning and allow logged readings to be either instantaneous or averaged values. Most data loggers have built-in clocks that record the time and date together with transducer signal information. Data loggers range from single-channel input to 256 or more channels. Some are general-purpose devices that accept a multitude of analog and/or digital inputs, whereas others are more specialized to a specific measurement (e.g., a portable anemometer with built-in data-logging capability) or application (e.g., a temperature, relative humidity, CO₂, and CO monitor with data logging for IAQ applications). Stored data are generally downloaded using a serial interface with a temporary direct connection to a personal computer. Remote data loggers may also download by modem through land-based or wireless telephone lines. Some data loggers are designed to allow downloading directly to a printer, or to an external hard drive or tape drive that can later be connected to a PC.

With the reduction in size of personal computers (laptops, notebooks, hand-held PCs, and palmtops), the computer itself is now being used as the data logger. These mobile computers may be left in the field, storing measurements from sensors directly interfaced into the computer. Depending on the particular application and number of sensors to be read, a computer card mounted directly into the PC may eliminate the external data acquisition device completely.

SYMBOLS

- A = flow area, ft²
 a = thermocouple constant
 C = correction factor
 c_p = specific heat at constant pressure, Btu/lb_m·°F
 D = distance; diameter
 d = throat diameter
 D_l = liquid diffusivity, ft²/h
 dy/dx = moisture content gradient, ft⁻¹
 dp/dx = vapor pressure gradient, in. Hg/in.
 E = voltage
 F_a = thermal expansion correction factor
 g_c = gravitational constant = 32.174 lb_m/ft·lb_f·s²
 H = height
 J = mechanical equivalent of heat = 778.3 ft·lb_f/Btu
 K = sensitivity (Figure 1); differential expansion coefficient for liquid in glass; constant (function of geometry and Reynolds number)
 n = number of degrees that liquid column emerged from bath
 p = absolute pressure, lb_f/ft²
 p_w = velocity pressure (pitot-tube manometer reading), in. of water
 P_{wet} = wetted perimeter
 Q = discharge flow rate, cfs
 R = resistance, Ω
 r = (see Figure 9)
 S = spot size
 t = temperature, °F; wall thickness
 \bar{t}_r = mean radiant temperature, °F
 V = velocity, fpm; volume
 W = width
 w = mass flow rate, lb_m/s
 w''_l = mass of liquid transferred through unit area per unit time, lb/h·ft²
 w''_v = mass of vapor diffusing through unit area per unit time, gr/h·ft²

X = variable; velocity of stream, fps

Greek

β = systematic (bias) error; ratio of diameters D_2/D_1 for venturi and sharp-edge orifice and d/D for flow nozzle

δ = deviation

ε = random error; emissivity (0.95 for black globe)

μ = mean; vapor permeability, gr·in/h·ft²·in. Hg

ρ = density, lb_m/ft³

Subscripts

1 = entering conditions; state 1

2 = throat conditions; state 2

a = air

b = bath

c = cross-sectional

e = equivalent of stream velocity

eff = effective

g = globe

h = hydraulic

i = pertaining to variable X

k = reading number

s = average of emergent liquid column of n degrees

$true$ = true

CHAPTER 37

ABBREVIATIONS AND SYMBOLS

<i>Abbreviations for Text, Drawings, and Computer Programs</i>	37.1
<i>Letter Symbols</i>	37.1
<i>Dimensionless Numbers</i>	37.4
<i>Mathematical Symbols</i>	37.4
<i>Subscripts</i>	37.5
<i>Graphical Symbols for Drawings</i>	37.5
<i>Piping System Identification</i>	37.10

THIS chapter contains information about abbreviations and symbols for heating, ventilating, air-conditioning, and refrigerating (HVAC&R) engineers.

Abbreviations are shortened forms of names and expressions used in text, drawings, and computer programs. This chapter discusses conventional English-language abbreviations that may be different in other languages. A **letter symbol** represents a quantity or a unit, not its name, and is independent of language. Because of this, use of a letter symbol is preferred over abbreviations for unit or quantity terms. Letter symbols necessary for individual chapters are defined in the chapters where they occur.

Abbreviations are never used for mathematical signs, such as the equality sign (=) or division sign (/), except in computer programming, where the abbreviation functions as a letter symbol. Mathematical operations are performed only with symbols. Abbreviations should be used only where necessary to save time and space; avoid their usage in documents circulated in foreign countries.

Graphical symbols in this chapter of piping, ductwork, fittings, and in-line accessories can be used on scale drawings and diagrams.

Identifying piping by legend and color promotes greater safety and lessens the chance of error in emergencies. Piping identification is now required throughout the United States by the Occupational Safety and Health Administration (OSHA) for some industries and by many federal, state, and local codes.

ABBREVIATIONS FOR TEXT, DRAWINGS, AND COMPUTER PROGRAMS

Table 1 gives some abbreviations, as well as others commonly found on mechanical drawings and abbreviations (symbols) used in computer programming. Abbreviations specific to a single subject are defined in the chapters in which they appear. Additional abbreviations used on drawings can be found in the section on Graphical Symbols for Drawings.

Computer Programs

The abbreviations (symbols) used for computer programming for the HVAC&R industries have been developed by ASHRAE Technical Committee 1.5, Computer Applications. These symbols identify computer variables, subprograms, subroutines, and functions commonly applied in the industry. Using these symbols enhances comprehension of the program listings and provides a clearly defined nomenclature in applicable computer programs.

Certain programming languages differentiate between real numbers (numbers with decimals) and integers (numbers without decimals) by reserving certain initial letters of a variable for integer numbers. Many of the symbols listed in this chapter begin with these letters and, in order to make them real numbers, must be prefixed with a noninteger letter.

Some symbols have two or more options listed. The longest abbreviation is preferred and should be used if possible. However, it is sometimes necessary to shorten the symbol to further identify the variable. For instance, the area of a wall cannot be defined as WALLAREA because some computer languages restrict the number of letters in a variable name. Therefore, a shorter variable symbol is applied, and WALLAREA becomes WALLA or WAREA.

Many advanced computer programming languages such as Basic, C, and C++ do not have the limitations of older computer language compilers. It is good programming practice to include the complete name of each variable and to define any abbreviations in the comments section at the beginning of each module of code. Abbreviations should be used to help clarify the variables in an equation and not to obscure the readability of the code.

In Table 1, the same symbol is sometimes used for different terms. This liberty is taken because it is unlikely that the two terms would be used in the same program. If such were the case, one of the terms would require a suffix or prefix to differentiate it from the other.

LETTER SYMBOLS

Letter symbols include symbols for physical quantities (quantity symbols) and symbols for the units in which these quantities are measured (unit symbols). **Quantity symbols**, such as *I* for electric current, are listed in this chapter and are printed in italic type. A **unit symbol** is a letter or group of letters such as ft for foot or a special sign such as ° for degrees and is printed in Roman type. Subscripts and superscripts are governed by the same principles. Letter symbols are restricted mainly to the English and Greek alphabets.

Quantity symbols may be used in mathematical expressions in any way consistent with good mathematical usage. The product of two quantities, *a* and *b*, is indicated by *ab*. The quotient is *a/b*, or *ab⁻¹*. To avoid misinterpretation, parentheses must be used if more than one slash (/) is used in an algebraic term; for example, (*a/b*)/*c* or *a/(b/c)* is correct, but not *a/b/c*.

Subscripts and superscripts, or several of them separated by commas, may be attached to a single basic letter (kernel), but not to other subscripts or superscripts. A symbol that has been modified by a superscript should be enclosed in parentheses before an exponent is added (*X_a*)³. Symbols can also have alphanumeric marks such as ' (prime), + (plus), and * (asterisk).

More detailed information on the general principles of letter symbol standardization are in standards listed at the end of this chapter. The letter symbols, in general, follow these standards, which are out of print:

Y10.3M	Letter Symbols for Mechanics and Time-Related Phenomena
Y10.4-82	Letter Symbols for Heat and Thermodynamics

Other symbols chosen by an author for a physical magnitude not appearing in any standard list should be ones that do not already have different meanings in the field of the text.

The preparation of this chapter is assigned to TC 1.6, Terminology.

Table 1 Abbreviations for Text, Drawings, and Computer Programs

Term	Text	Drawings	Program
above finished floor	—	AFF	—
absolute	abs	ABS	ABS
accumulat(e, -or)	acc	ACCUM	ACCUM
air condition(-ing, -ed)	—	AIR COND	—
air-conditioning unit(s)	—	ACU	ACU
air-handling unit	—	AHU	AHU
air horsepower	ahp	AHP	AHP
alteration	altrn	ALTRN	—
alternating current	ac	AC	AC
altitude	alt	ALT	ALT
ambient	amb	AMB	AMB
American National Standards Institute ¹	ANSI	ANSI	—
American wire gage	AWG	AWG	—
ampere (amp, amps)	amp	AMP	AMP, AMPS
angle	—	—	ANG
angle of incidence	—	—	ANGI
apparatus dew point	adp	ADP	ADP
approximate	approx.	APPROX	—
area	—	—	A
atmosphere	atm	ATM	—
average	avg	AVG	AVG
azimuth	az	AZ	AZ
azimuth, solar	—	—	SAZ
azimuth, wall	—	—	WAZ
barometer(-tric)	baro	BARO	—
bill of material	b/m	BOM	—
boiling point	bp	BP	BP
brake horsepower	bhp	BHP	BHP
Brown & Sharpe wire gage	B&S	B&S	—
British thermal unit	Btu	BTU	BTU
Celsius	°C	°C	°C
center to center	c to c	C TO C	—
circuit	ckt	CKT	CKT
clockwise	cw	CW	—
coefficient	coeff.	COEF	COEF
coefficient, valve flow	C _v	C _v	CV
coil	—	—	COIL
compressor	cprsr	CMPR	CMPR
condens(-er, -ing, -ation)	cond	COND	COND
conductance	—	—	C
conductivity	endct	CNDCT	K
conductors, number of (3)	3/c	3/c	—
contact factor	—	—	CF
cooling load	clg load	CLG LOAD	CLOAD
counterclockwise	ccw	CCW	—
cubic feet	ft ³	CU FT	CUFT, CFT
cubic inch	in ³	CU IN	CUIN, CIN
cubic feet per minute	cfm	CFM	CFM
cfm, standard conditions	scfm	SCFM	SCFM
cubic ft per sec, standard	scfs	SCFS	SCFS
decibel	dB	DB	DB
degree	deg. or °	DEG or °	DEG
density	dens	DENS	RHO
depth or deep	dp	DP	DPTH
dew-point temperature	dpt	DPT	DPT
diameter	dia.	DIA	DIA
diameter, inside	ID	ID	ID
diameter, outside	OD	OD	OD
difference or delta	diff., Δ	DIFF	D, DELTA
diffuse radiation	—	—	DFRAD
direct current	dc	DC	DC
direct radiation	dir radn	DIR RADN	DIRAD
dry	—	—	DRY
dry-bulb temperature	dbt	DBT	DB, DBT
effectiveness	—	—	EFT
effective temperature ²	ET*	ET*	ET
efficiency	eff	EFF	EFF
efficiency, fin	—	—	FEFF
efficiency, surface	—	—	SEFF

Term	Text	Drawings	Program
electromotive force	emf	EMF	—
elevation	elev.	EL	ELEV
entering	entr	ENT	ENT
entering water temperature	EWT	EWT	EWT
entering air temperature	EAT	EAT	EAT
enthalpy	—	—	H
entropy	—	—	S
equivalent direct radiation	edr	EDR	—
equivalent feet	equiv ft	EQIV FT	EQFT
equivalent inches	equiv in	EQIV IN	EQIN

¹Abbreviations of most proper names use capital letters in both text and drawings.
²The asterisk (*) is used with ET*, effective temperature, as in Chapter 9 of this volume.
³These are surface heat transfer coefficients.
⁴Letter L also used for *Logarithm* of these temperature differences in computer programming.

LETTER SYMBOLS

Symbol	Description of Item	Typical Units
<i>a</i>	acoustic velocity	fps or fpm
<i>A</i>	area	ft ²
<i>b</i>	breadth or width	ft
<i>B</i>	barometric pressure	psia or in. Hg
<i>c</i>	concentration	lb/ft ³ , mol/ft ³
<i>c</i>	specific heat	Btu/lb·°F
<i>c_p</i>	specific heat at constant pressure	Btu/lb·°F
<i>c_v</i>	specific heat at constant volume	Btu/lb·°F
<i>C</i>	coefficient	—
<i>C</i>	fluid capacity rate	Btu/h·°F
<i>C</i>	thermal conductance	Btu/h·ft ² ·°F
<i>C_L</i>	loss coefficient	—
<i>C_P</i>	coefficient of performance	—
<i>d</i>	prefix meaning differential	—
<i>d</i> or <i>D</i>	diameter	ft
<i>D_e</i> or <i>D_h</i>	equivalent or hydraulic diameter	ft
<i>D_v</i>	mass diffusivity	ft ² /s
<i>e</i>	base of natural logarithms	—
<i>E</i>	energy	Btu
<i>E</i>	electrical potential	V
<i>f</i>	film conductance (alternate for <i>h</i>)	Btu/h·ft ² ·°F
<i>f</i>	frequency	Hz
<i>f_D</i>	friction factor, Darcy-Weisbach formulation	—
<i>f_F</i>	friction factor, Fanning formulation	—
<i>F</i>	force	lb _f
<i>F_{ij}</i>	angle factor (radiation)	—
<i>g</i>	gravitational acceleration	ft/s ²
<i>G</i>	mass velocity	lb/h·ft ²
<i>h</i>	heat transfer coefficient	Btu/h·ft ² ·°F
<i>h</i>	hydraulic head	ft
<i>h</i>	specific enthalpy	Btu/lb
<i>h_a</i>	enthalpy of dry air	Btu/lb
<i>h_D</i>	mass transfer coefficient	lb/h·ft ² ·lb per ft ³
<i>h_s</i>	enthalpy of moist air at saturation	Btu/lb
<i>H</i>	total enthalpy	Btu
<i>I</i>	electric current	A
<i>J</i>	mechanical equivalent of heat	ft·lb _f /Btu
<i>k</i>	thermal conductivity	Btu/h·ft·°F
<i>k</i> (or <i>γ</i>)	ratio of specific heats, <i>c_p/c_v</i>	—
<i>K</i>	proportionality constant	—
<i>K_D</i>	mass transfer coefficient	lb/h·ft ²
<i>l</i> or <i>L</i>	length	ft
<i>L_p</i>	sound pressure	dB
<i>L_w</i>	sound power	dB
<i>m</i> or <i>M</i>	mass	lb
<i>M</i>	molecular weight	lb/lb mol
<i>n</i> or <i>N</i>	number in general	—
<i>N</i>	rate of rotation	rpm
<i>p</i> or <i>P</i>	pressure	psi
<i>p_a</i>	partial pressure of dry air	psi
<i>p_s</i>	partial pressure of water vapor in moist air	psi
<i>p_w</i>	vapor pressure of water in saturated moist air	psi
<i>P</i>	power	hp, watts
<i>q</i>	time rate of heat transfer	Btu/h
<i>Q</i>	total heat transfer	Btu
<i>Q</i>	volumetric flow rate	cfm

natural log	ln
logarithm to base 10	log

SUBSCRIPTS

These are to be affixed to the appropriate symbols. Several subscripts may be used together to denote combinations of various states, points, or paths. Often the subscript indicates that a particular property is to be kept constant in a process.

a, b, \dots	referring to different phases, states or physical conditions of a substance, or to different substances
a	air
a	ambient
b	barometric (pressure)
c	referring to critical state or critical value
c	convection
db	dry bulb
dp	dew point
e	base of natural logarithms
f	referring to saturated liquid
f	film
fg	referring to evaporation or condensation
F	friction
g	referring to saturated vapor
h	referring to change of phase in evaporation
H	water vapor
i	referring to saturated solid
i	internal
if	referring to change of phase in melting
ig	referring to change of phase in sublimation
k	kinetic
L	latent
m	mean value
M	molar basis
p	referring to constant pressure conditions or processes
p	potential
r	refrigerant
r	radiant or radiation
s	referring to moist air at saturation
s	sensible
s	referring to isentropic conditions or processes
s	static (pressure)
s	surface
t	total (pressure)
T	referring to isothermal conditions or processes
v	referring to constant volume conditions or processes
v	vapor
v	velocity (pressure)
w	wall
w	water
wb	wet bulb
0	referring to initial or standard states or conditions
$1, 2, \dots$	different points in a process, or different instants of time

GRAPHICAL SYMBOLS FOR DRAWINGS

Graphical symbols have been extracted from ANSI/ASHRAE Standard 134-2005. Additional symbols are from current practice and extracted from ASME Standards Y32.2.3 and Y32.2.4.

Valves, Special Duty

- Check, swing gate
- Check, spring
- Control, electric-pneumatic
- Control, pneumatic-electric
- Hose end drain
- Lock shield
- Needle
- Pressure-reducing regulator
- Quick-opening
- Quick-closing
- Safety or relief
- Solenoid
- Square-head cock
- Unclassified (number and specify)

Fittings

The following fittings are shown without connection notations. This reflects current practice. The symbol for the body of a fitting is the same for all types of connections, unless otherwise specified. The types of connections are often specified for a range of pipe sizes, but are shown with the fitting symbol where required. For example, an elbow would be:

Fitting	Symbol
Bushing	
Cap	
Cross	
Elbow, 90°	
Elbow, 45°	
Elbow, facing toward viewer	

^a Includes fusion; specify type.

Elbow, facing away from viewer
 Elbow, base-supported
 Lateral
 Reducer, concentric
 Reducer, eccentric, flat on bottom
 Reducer, eccentric, flat on top
 Tee
 Tee, facing toward viewer
 Tee, facing away from viewer

Receiver, low-pressure

Intercooler

Intercooler/desuperheater

Energy Recovery Equipment

Condenser, double bundle

Air to Air Energy Recovery

Rotary heat wheel

Coil loop

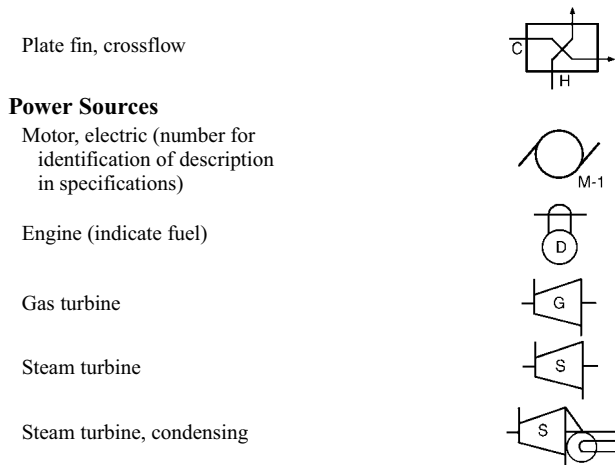

Heat pipe

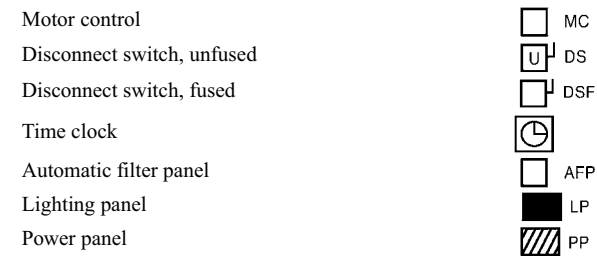

Fixed plate

Electrical Equipment^a

Symbols for electrical equipment shown on mechanical drawings are usually geometric figures with an appropriate name or abbreviation, with details described in the specifications. The following are some common examples.^b

^a See ARI Standard 130 for preferred symbols of common electrical parts.
^b Number each symbol if more than one; see ASME Standard Y32.4.

PIPING SYSTEM IDENTIFICATION

The material in piping systems is identified to promote greater safety and lessen the chances of error, confusion, or inaction in times of emergency. Primary identification should be by means of a lettered legend naming the material conveyed by the piping. In addition to, but not instead of lettered identification, color can be used to identify the hazards or use of the material.

The data in this section have been extracted from ASME Standard A13.1.

Definitions

Piping Systems. Piping systems include pipes of any kind, fittings, valves, and pipe coverings. Supports, brackets, and other accessories are not included. Pipes are defined as conduits for the transport of gases, liquids, semiliquids, or fine particulate dust.

Materials Inherently Hazardous to Life and Property. There are four categories of hazardous materials:

- Flammable or explosive materials that are easily ignited, including materials known as fire producers or explosives
- Chemically active or toxic materials that are corrosive or are in themselves toxic or productive of poisonous gases
- Materials at extreme temperatures or pressures that, when released from the piping, cause a sudden outburst with the potential for inflicting injury or property damage by burns, impingement, or flashing to vapor state
- Radioactive materials that emit ionizing radiation

Materials of Inherently Low Hazard. All materials that are not hazardous by nature, and are near enough to ambient pressure and temperature that people working on systems carrying these materials run little risk through their release.

Table 2 Examples of Legends

HOT WATER
AIR 100 PSIG
H.P. RETURN
STEAM 100 PSIG

Table 3 Classification of Hazardous Materials and Designation of Colors^a

Classification	Color Field	Colors of Letters for Legend
Materials Inherently Hazardous		
Flammable or explosive	Yellow	Black
Chemically active or toxic	Yellow	Black
Extreme temperatures or pressures	Yellow	Black
Radioactive ^b	Purple	Yellow
Materials of Inherently Low Hazard		
Liquid or liquid admixture ^c	Green	Black
Gas or gaseous admixture	Blue	White
Fire Quenching Materials		
Water, foam, CO ₂ , Halon, etc.	Red	White

^a When preceding color scheme is used, colors should be as recommended in latest revision of NEMA Standard Z535.1.
^b Previously specified radioactive markers using yellow or purple are acceptable if already installed and/or until existing supplies are depleted, subject to applicable federal regulations.
^c Markers with black letters on green field are acceptable if already installed and/or until existing supplies are depleted.

Fig. 1 Visibility of Pipe Markings

Fire Quenching Materials. This classification includes sprinkler systems and other piped fire fighting or fire protection equipment. This includes water (for fire fighting), chemical foam, CO₂, Halon, and so forth.

Method of Identification

Legend. The legend is the primary and explicit identification of content. Positive identification of the content of the piping system is by lettered legend giving the name of the contents, in full or abbreviated form, as shown in Table 2. Arrows should be used to indicate the direction of flow. Use the legend to identify contents exactly and to provide temperature, pressure, and other details necessary to identify the hazard.

The legend shall be brief, informative, pointed, and simple. Legends should be applied close to valves and adjacent to changes in direction, branches, and where pipes pass through walls or floors, and as frequently as needed along straight runs to provide clear and positive identification. Identification may be applied by stenciling, tape, or markers (see Figure 1). The number and location of identification markers on a particular piping system is based on judgment.

Color. Colors listed in Table 3 are used to identify the characteristic properties of the contents. Color can be shown on or contiguous to the piping by any physical means, but it should be used

Table 4 Size of Legend Letters

Outside Diameter of Pipe or Covering, in.	Length of Color Field A, in.	Size of Letters B, in.
3/4 to 1 1/4	8	1/2
1 1/2 to 2	8	3/4
2 1/2 to 6	12	1-1/4
8 to 10	24	2-1/2
over 10	32	3-1/2

in combination with a legend. Color can be used in continuous total length coverage or in intermittent displays.

Visibility. Pipe markings should be highly visible. If pipe lines are above the normal line of vision, the lettering is placed below the horizontal centerline of the pipe (Figure 1).

Type and Size of Letters. Provide the maximum contrast between color field and legend (Table 3). Table 4 shows the size of letters recommended. Use of standard size letters of 1/2 in. or larger is recommended. For identifying materials in pipes of less than 3/4 in. in diameter and for valve and fitting identification, use a permanently legible tag.

Unusual or Extreme Situations. When the piping layout occurs in or creates an area of limited accessibility or is extremely complex, other identification techniques may be required. While a certain amount of imagination may be needed, the designer should always clearly identify the hazard and use the recommended color and legend guidelines.

CODES AND STANDARDS

ARI. 1988. Graphic electrical/electronic symbols for air-conditioning and refrigeration equipment. *Standard* 130-88.

*Conversion factor is exact.

Notes: 1. Units are U.S. values unless noted otherwise.

2. Litre is a special name for the cubic decimetre. 1 L = 1 dm³ and 1 mL = 1 cm³.

The preparation of this chapter is assigned to TC 1.6, Terminology.

Table 2 Conversion Factors

Notes: Conversions with * are exact.
The Btu and calorie are based on the International Table.

All temperature conversions and factors are exact.
The term centigrade is obsolete and should not be used.

When making conversions, remember that a converted value is no more precise than the original value. For many applications, rounding off the converted value to the same number of significant

figures as those in the original value provides sufficient accuracy.
See ANSI *Standard* SI-10-1997 (available from ASTM or IEEE) for additional conversions.

CHAPTER 39

CODES AND STANDARDS

THE Codes and Standards listed here represent practices, methods, or standards published by the organizations indicated. They are useful guides for the practicing engineer in determining test methods, ratings, performance requirements, and limits of HVAC&R equipment. Copies of the standards can be obtained from most of the organizations listed in the Publisher column, from Global Engineering Documents at global.ihs.com, or from CSSINFO at cssinfo.com. Addresses of the organizations are given at the end of the chapter. A comprehensive database with over 250,000 industry, government, and international standards is at www.nssn.org.

COMPOSITE INDEX

ASHRAE HANDBOOK SERIES

This index covers the current Handbook series published by ASHRAE. The four volumes in the series are identified as follows:

- R = 2006 Refrigeration
- A = 2007 HVAC Applications
- S = 2008 HVAC Systems and Equipment
- F = 2009 Fundamentals

Alphabetization of the index is letter by letter; for example, **Heat-ers** precedes **Heat exchangers**, and **Floors** precedes **Floor slabs**.

The page reference for an index entry includes the book letter and the chapter number, which may be followed by a decimal point and the beginning page in the chapter. For example, the page number S31.4 means the information may be found in the 2008 HVAC Systems and Equipment volume, Chapter 31, beginning on page 4.

Each Handbook volume is revised and updated on a four-year cycle. Because technology and the interests of ASHRAE members change, some topics are not included in the current Handbook series but may be found in the earlier Handbook editions cited in the index.

- Abbreviations**, F37
- Absorbents**
 - liquid, F2.14; F32.3
 - refrigerant pairs, F2.15
- Absorption**
 - ammonia/water, F30.1, 69
 - hydrogen cycle, R41.8
 - technology, R41.7
 - chillers, S3.4
 - turbines in, S17.4
 - coefficient of performance (COP), F2.13
 - concepts
 - coupling, F2.16
 - double-effect
 - calculations, F2.18
 - cascaded, F2.16
 - cycle characteristics, F2.14
 - dehumidification, S23.10
 - equipment, R41.1
 - evolving technologies, R41.10
 - ideal thermal, F2.13
 - industrial exhaust gas cleaning, S29.17
 - refrigeration cycles, F2.13
 - ammonia/water, F30.1, 69
 - lithium bromide/water, F30.1, 69
 - types, F2.16
 - modeling analysis and performance simulation, F2.16
 - phase constraints, F2.13
 - representations, F2.15
 - solar cooling, A33.18, 26; S36.3, 9
 - water/lithium bromide technology
 - components, R41.1
 - control, R41.6
 - double-effect chillers, R41.3
 - maintenance, R41.7
 - operation, R41.6
 - single-effect chillers, R41.2
 - single-effect heat transformers, R41.3
 - terminology, R41.1
 - working fluids, F2.14
- Acoustics**. *See* **Sound**
