UNDERGRADUATE TOP **in COMPUTER SCIENCE**

Introduction to Operating System Design and Implementation The OSP 2 Approach

Undergraduate Topics in Computer Science (UTiCS) delivers high-quality instructional content for undergraduates studying in all areas of computing and information science. From core foundational and theoretical material to final-year topics and applications, UTiCS books take a fresh, concise, and modern approach and are ideal for self-study or for a one- or two-semester course. The texts are all authored by established experts in their fields, reviewed by an international advisory board, and contain numerous examples and problems. Many include fully worked solutions.

Preface

 $\mathcal{O}S\mathcal{P}$ *2* is both an implementation of a modern operating system, and a flexible environment for generating implementation projects appropriate for an introductory course in operating system design. It is intended to complement the use of an introductory textbook on operating systems and contains enough projects for up to three semesters. These projects expose students to many essential features of operating systems, while at the same time isolating them from low-level machine-dependent concerns. Thus, even in one semester, students can learn about page replacement strategies in virtual memory management, cpu scheduling strategies, disk seek time optimization, and other issues in operating system design.

OSP ² is written in the Java programming language and students program their *OSP ²* projects in Java as well. Therefore as prerequisites for using *OSP ²* , students are expected to have solid Java programming skills; be well-versed in object-oriented programming concepts such as classes, objects, methods, and inheritance; to have taken an undergraduate Computer Science course in data structures; and to have working knowledge of a Java programming environment, i.e., javac, java, text editing, etc. *OSP ²* is the successor to the original OSP software, which was released in 1990 and programmed in C.

OSP ² consists of a number of modules, each of which performs a basic operating systems service, such as device scheduling, cpu scheduling, interrupt handling, file management, memory management, process management, resource management, and interprocess communication. Projects can be organized in any desired order so as to progress in a manner consistent with the lecture material. The $\mathcal{OSP}2$ distribution comes with a reference Java implementation of each module, which is provided to the course instructor.

Each *OSP* 2 project has a well-defined API (application programming interface), that the student must implement in order to successfully complete the project. Thus, among other things, *OSP ²* teaches students to work with "open" environments where programming must be conducted to satisfy concrete sets of project requirements and where APIs must be used to interface to other subsystems.

Each *OSP* 2 project consists of a "partial load module" of standard *OSP* 2 modules to which the students link their implementation of the assigned modules. The result is a new and complete operating system, partially implemented by the student. Additionally, each project includes one or more "*.java" files, which contain class and method headings for each of the assigned modules. These files serve as *templates* in which the student is to fill in the code for the required methods. This ensures a consistent interface to *OSP ²* and eliminates much of the routine typing, both by the instructor and by the student.

The heart of $\mathcal{OSP2}$ is a simulator that gives the illusion of a computer system with a dynamically evolving collection of user processes to be multiprogrammed. All the other modules of *OSP ²* are built to respond appropriately to the simulator-generated events that drive the operating system. The simulator "understands" its interaction with the other modules in that it can often detect an erroneous response by a module to a simulated event. In such cases, the simulator will gracefully terminate execution of the program by delivering a meaningful error message to the user, indicating where the error might be found. This facility serves both as a debugging tool for the student and as teaching tool for the instructor, as it ensures that student programs acceptable to the simulator are virtually bug-free. (Verification by the simulator does not, of course, replace the need to examine student programs to ensure that they are properly designed and acceptable from a software engineering point of view.)

The difficulty of the job streams generated by the simulator can be dynamically adjusted by manipulating the *simulation parameters*. This yields a simple and effective way of testing the quality of student programs. There are also facilities that allow students to debug their programs, including a detailed system log of events and various hooks into the system that allow studentprovided methods to be called when an *OSP ²* warning or error is detected. Also, a graphical user interface (GUI) is available that provides a convenient way for students and instructors to enter simulation parameters and to view various statistics concerning the execution of *OSP ²* .

The underlying model in *OSP ²* is not a clone of any specific operating system. Rather it is an abstraction of the common features of several systems (although a bias towards Unix and the Mach operating systems can be seen, at times). Moreover, the *OSP ²* modules were designed to hide a number of low-level concerns, yet still encompass the most salient aspects of their real-life counterparts in modern systems. Their implementation is well-suited as the project component of an introductory course in operating systems.

How to Use this Book

This book is primarily a manual for students on how to program the *OSP ²* projects. Chapter \Box describes the overall organization of \mathcal{OSP} [2](#page-49-0). Chapter \Box takes the student through an example session with *OSP ²*. Each subsequent chapter constitutes a detailed description of one of the *OSP ²* projects, beginning with a statement of the goals of the project, followed by a short introduction to the basic OS concepts relevant to that chapter's subject matter. The latter is intended to help bridge the gap between the *OSP ²* manual and the course textbook. Before even the first assignment is handed out, students should read this Preface and Chapters \Box and \Box When a specific project is assigned (e.g. the thread-management project, project Threads) the appropriate chapter (Chapter \mathcal{I} in the case of THREADS) should be read carefully. Each project chapter provides a complete description of the API for the *OSP ²* module the students have been asked to implement, including a clear account of the functionality of each method in the project. Also provided is a list of methods from other project modules that may be needed to implement the project assignment. The student should refer to the relevant chapters for a more detailed account of these methods.

Goals of this Book

Besides serving as the student project manual for *OSP ²* , the goals of this book, and more broadly the *OSP ²* environment, are the following:

- To teach students fundamental operating system concepts in the following areas:
	- **–** process and thread management
	- **–** memory management
	- **–** file systems
	- **–** interprocess communication
	- **–** I/O device management
	- **–** resource management
- To give students the opportunity to practice these skills in a realistic operating systems programming environment.
- To provide students with challenging individual and group programming assignments which promote "active learning" to reinforce and amplify the

lecture material.

- To provide programming assignments that involve significant modifications to an actual, working operating system, thereby familiarizing students with the internals of OS implementation.
- To provide instructors with a flexible OS programming project that can easily accommodate their lecture schedule.

Acknowledgments

We would like to gratefully acknowledge the past members of the *OSP ²* development team, including Sanford Barr, who produced the original design and implementation of the event engine; William Ries, Adam Sah and Tomek Retelewski, who, along with Sanford, designed and implemented an earlier version of $\mathcal{OSP2}$ that was written in C++; Fang Yang, who was responsible for porting the event engine and several other modules from the C++ version to Java; Kevin McDonnell and Peter Litskevitch, for designing, implementing and documenting most of the modules in the current version; Jingjing Wei, for implementing the latest configurable version of the GUI; Eric Nuzzi, who devised a systematic testing protocol for the *OSP ²* code; Martin Bruggink, for implementing the PORTS module; Xiaohua Wu, for implementing the RESOURCES module; and David McManamon, for implementing the software that allows students to submit their solutions to *OSP ²* assignments electronically.

Some parts of *OSP ²* rely on third-party software. In particular, we thank Retrologic for developing their excellent Java obfuscator and releasing it under the Lesser Gnu Public License (LGPL).

Finally, we would like to thank Wayne Wheeler and Catherine Brett of Springer London Ltd for bringing their editorial expertise to bear on this project.

1 Organization of OSP *2*

1.1 Chapter Objective

The objective of this chapter is to provide the essential general information about \mathcal{OSP} *2*, which is necessary in order to begin working with the system. This includes a description of the organization (breakdown into modules), instructions on how to compile, run and submit *OSP ²* projects, and general guidelines about programming *OSP ²* . Because of its introductory nature, this chapter should be read/reviewed before taking on any of the *OSP ²* projects your instructor may assign to you.

1.2 Operating System Basics

As explained in the Preface to this book, *OSP ²* is organized as a collection of modules, each corresponding to a class of resource that *OSP ²* is intended to manage. For your *OSP ²* programming assignments, your instructor will assign you one or more of these modules to implement, plug back into the rest of the system, and run via a simulation to ensure that your code is working correctly and efficiently. This chapter describes in some detail this division of *OSP ²* into modules and also provides you with other helpful information you will need to carry out your assignments. First, though, we shall step back and ask ourselves the questions: What is an operating system, and what kind of operating system

is *OSP ²*?

What is an Operating System? In order to understand exactly what *OSP ²* is and how it is organized, it is useful to first consider the basic question: What is an operating system? Two generally held views are that an OS is an *extended machine*, and an OS is a *resource manager*. According to the first view, the function of an operating system is to present the user with the equivalent of an "extended machine" or "virtual machine" that is easier to program than the underlying hardware. This is accomplished through the operating system's *system call interface*: the collection of system calls that application programs may invoke to obtain one kind of service or another. For example, there are system calls to read and write files and to set the value of timers. Moreover, it is much easier to invoke these system calls to obtain system service as opposed to mucking around with hardware-specific instructions and machine registers, which one would be forced to do if there was no OS present.

Two well-known examples of system-call interfaces are the Win32 API (application programming interface) for various flavors of Microsoft Windows (Windows 2000/XP/Vista), and POSIX for the Unix flavor of operating systems, such as System V, BSD, and Linux. *OSP ²* has its own system call interface, and you will be introduced to the system calls (Java methods) that constitute this interface in the subsequent chapters of this book.

According to the second view, an operating system is responsible for efficiently and fairly managing the resources of a computer system. These include processors (CPUs); memory (physical and virtual); devices such as disks; files and directories; and network connections (ports). By efficient, we mean that the OS should aim to maximize resource utilization whenever possible. By fair, we mean that users programs should be granted equitable allocation of resources during their execution. Note that most of the example resources we have listed are physical ones. One exception is files and directories. The part of the OS responsible for these "logical resources" is often called the file system.

As we will make clear later in this chapter, the view of an operating system as a resource manager is well suited to *OSP ²* , as *OSP ²*'s system call interface is organized in terms of the various resources *OSP ²* is intended to manage. More specifically, *OSP ²* is organized into a number of modules—Java packages to be precise—and there is one such module for each type of resource *OSP ²* is asked to manage. For example, there is an *OSP ²* module for each of memory, devices, ports, etc., and each module exports (defines) a number of Java methods relevant to that module. Collectively, these methods make up *OSP ²* 's system call interface.

Different Flavors of Operating Systems. To better understand *OSP ²* , it is also useful to realize that there are different flavors of operating systems available for the choosing. Some of those that immediately come to mind, and which you have probably heard of, are Unix, Linux, Windows, and MacOS. These systems differ mainly in the way they are structured and, of course, in their system call interfaces. Systems like Windows XP/Vista, Solaris (a version of Unix from SUN Microsystems), and Mach (an OS developed at Carnegie Mellon University in the 1980s and which later influenced a number of commercial operating systems, e.g., MacOS X) can be viewed as object-oriented in the following sense: basic system resources are represented as objects and there exist well-defined message-passing interfaces between objects.

Although *OSP ²* is not modeled after any particular OS, a bias towards Unix and Mach can be seen in some parts of its architecture. The Unix bias is most evident in the FileSys package, where i-nodes are used to represent files stored on disk and directories map file names to i-numbers (inode indices). The Mach influence can be detected in the Ports package where Mach-like ports are used for interprocess communication. Mach also uses ports for exception handling (each process has an exception port), a topic not treated by *OSP ²*.

OSP ² is an object-oriented operating system in the truest sense of the term. It is written in the object-oriented programming language Java. System resources and data structures are represented by classes, thereby providing welldefined method-call interfaces between objects à la Windows XP/Vista. And subclassing is used to specialize objects; for example, the I/O Request Block (IORB) is a subclass of Event so that threads can wait on it and be notified of its occurrence.

Another way in which operating systems differ, and which in some sense distinguishes older operating systems from newer ones, is whether or not they support *threads*. In older systems like Unix, executing programs are organized as processes: the OS is responsible for scheduling processes on the CPU and switching the CPU from one process to another for the purposes of *multiprogramming*. Multiprogramming is a technique aimed at increasing resource utilization. The basic idea is to have more than one process memory-resident at a time, and to switch the CPU from a process that has become blocked waiting for some event, say, the completion of an I/O operation, to a process that is ready to execute. In this way, the CPU is kept busy doing useful work most of the time, just the kind of thing a resource manager should strive for.

To conclude our brief look at multiprogramming, we should consider a little more carefully what it means to switch the CPU from one process to another, an operation commonly referred to as a *context switch*. Several steps are involved. First, the currently executing process must be removed from the CPU and placed on a queue associated with the event on which it is waiting. Then the process the OS has decided to schedule next for execution must be *dispatched* on to the CPU. This involves resetting a number of machine registers (such as the program counter, general-purpose registers, memory-management registers, etc.) to values associated with the newly dispatched process when it was last running. The execution of this process can now resume. This is an admittedly simplified view of what's behind a context switch; the subject is treated more thoroughly in Chapter $\mathbf{\mathcal{L}}$

In newer systems like Mac, Solaris, and Windows 2000/XP/Vista, the schedulable and dispatchable units of execution are no longer processes but rather threads; a process simply serves as a container for one or more threads. Processes of this kind are usually referred to as *tasks*, and that shall be the convention adopted in this book. So what does it mean for a task to be a "container" for threads? It means that the constituent threads of a task share the resources allocated to the task, including memory, files, and communication ports. As a result, switching the CPU from one thread to another is a lot simpler than switching the CPU from one process to another process as required in an OS that does not support threads. As we shall see, *OSP ²* supports tasks and threads.

Operating Systems are Event-Driven. Operating systems are a perfect example of so-called *event-driven* systems. As the name applies, an event-driven system goes into action in response to the occurrence of some event that it is familiar with. For example, a GUI (graphical user interface) program is an event-driven system that responds to clicks of the mouse made by the user; the precise piece of code that gets executed depends on what widget (tool-bar item, button, radio dial, etc.) gets clicked. In the case of operating systems, the events that an OS responds to include system calls made by user (or even system) programs, hardware interrupts, and machine errors. Event-driven systems are typically structured as one large case-statement contained in a while-loop that "catches" the various events the system is intended to respond to. When an event is caught, the case in the case-statement corresponding to that event is executed.

This kind of event-loop structure is indeed present in operating systems. Consider, for example, how a system call gets executed in a typical OS.The calling program first pushes the parameters of the system call on the system stack. The system call number is placed in a register and a trap instruction is executed to switch from user mode to kernel mode. The kernel examines the system call number and branches to the correct system call handler, usually via a table of pointers to system call handlers indexed on the system call number. At that point, the system call handler runs and, when finished, control may be returned to the calling procedure at the instruction following the trap instruction.

Hardware interrupts are handled in a similar event-driven way by an OS. In this case, a portion of system memory is set aside for the *interrupt vector*. Using the device number of the device that caused the interrupt, the interrupt vector may be indexed into to find the address of the interrupt handler for this device.

OSP ² is also event-driven, not surprising given that, after all, it is an operating system. However, *OSP ²* responds to *simulated* events. That is, at the core of $\mathcal{OSP2}$ is a simulator called the *event engine* (see Figure [1.1\)](#page-19-0) that semi-randomly generates events of the kinds discussed above (system calls, hardware interrupts, etc.). In response to such an event, the appropriate Java method is called. For example, suppose the event engine generates an event corresponding to an instance of the system call for opening a file. Then the method open() in class FileSys will be called. Moreover, if your instructor has assigned module FILESYS to you as a project, then it is the code that you wrote for method open() that will be executed in response to the event. This is actually a somewhat simplified view of how things work in \mathcal{OSP} 2. Section [1.9](#page-35-0) explains *OSP ²* event handling in greater detail.

What this all means is that in $\mathcal{OSP2}$, there are no user programs per se that are being executed; all such programs are simulated by the event engine in the form of a stream of events that *OSP ²* responds to. There are several advantages to this simulation-based approach. First, events are passed through a so-called *interface layer* (IFL) of *OSP ²* that sits between the event engine and the various *OSP ²* modules in which the code for the system calls resides (see, again, Figure $\boxed{1.1}$). The IFL therefore has the opportunity to monitor the execution of system call methods, making sure that the actions taken by these methods are semantically correct. Should an error be detected in a student implementation of a system call method, the IFL can return a meaningful error message to the student. These messages can be a great help to you in debugging your code.

The IFL performs another useful role as far as students (and instructors!) are concerned: it gathers statistics about the system's performance as the event stream is processed. Example statistics collected by the IFL include cpu utilization, number of page faults, and disk-arm movement measured in number of tracks. These statistics are very helpful in gauging the performance of your cpu scheduling algorithm, page replacement scheme, disk scheduling algorithm, etc.

Another advantage of the simulation-based approach is that to debug the OS modules that the student writes there is no need to write and run user-level test programs (as would be the case if you were working with a real OS): the simulator provides the event stream for testing. Moreover, the make-up and intensity of this event stream generated by the event engine can be adjusted dynamically by manipulating the *simulation parameters*. For example, if the instructor has assigned module FileSys as a project, he can set the simulation parameters so that the event stream will contain a high percentage of file-system related events. This yields a simple and effective way of testing the quality of student programs.

User programs are not the only thing simulated in *OSP ²*. The underlying hardware is simulated as well and includes a CPU, disk, system clock, hardware timer, and interrupt vector. The simulated hardware of *OSP ²* is described fully in Section $\overline{1.4}$.

OSP ² **'s Microkernel Architecture.** An interesting topic in operatingsystem design is the *monolithic kernel* versus *microkernel* architecture distinction. Here the term "kernel" is used to refer to that portion of the operating system that runs in *kernel mode*: the more privileged mode of execution, as compared to *user mode*, where executing code has access to system data structures and services. Getting back to the monolithic-versus-microkernel distinction, a monolithic kernel groups together all operating-system functionality into a single process while a microkernel assigns only a few essential functions to the kernel, including address spaces, interprocess communication, and basic scheduling. The microkernel approach is also typified by well-encapsulated module boundaries for basic services with well-defined interfaces.

As depicted in Figure [1.1](#page-19-0) and described above, \mathcal{OSP} 2 is hierarchically structured, consisting of three main layers: the event engine, the IFL, and the student modules. Once control enters a student module, the system can be considered to be in kernel mode. Since there are no actual user programs in *OSP ²*, replaced instead by a stochastic simulation of user threads in the form of an event stream, there is no user mode in *OSP ²* to speak of. Therefore, the file system, task-management subsystem, virtual memory-management subsystem, etc. run in kernel mode.

Because of *OSP ²*'s pure object-oriented design, all OS subsystems, including the primitive ones dealing with activities such as thread scheduling and interprocess communication, are encapsulated in modules (classes) with welldefined method interfaces. The kind of architecture adopted by *OSP ²* is sometimes referred to as modified microkernel architecture.

1.3 *OSP 2* **Organization**

OSP ² comprises a number of projects that may be assigned to students as

programming assignments. Each project involves the implementation of a separate Java package consisting of one or more Java classes and their associated methods. Because of their role as potential programming assignments, we shall often refer to these packages as **student packages** or **student projects**. It should be understood, however, that reference implementations of these packages are part of the standard *OSP ²* distribution and must be in place for the system to function normally (unless the reference implementation of a package has been replaced by a student implementation). Each student package is responsible for managing its own class of system resources, as described in the following:

- Devices: Handles I/O requests for secondary storage devices such as disk drives.
- FileSys: Implements the file system including basic file operations and directory structures.
- Memory: Manages physical and virtual memory using techniques such as paging and segmentation.
- Resources: Manages abstract resources of the system using deadlock detection and deadlock avoidance algorithms.
- Tasks: Controls the creation and deletion of tasks, each of which is a container for a set of threads and their associated resources.
- Threads: Responsible for creating, killing, dispatching, suspending, and resuming threads, the fundamental units of execution in *OSP ²*.
- Ports: Implements an interprocess communication facility that allows threads to send messages to each other.

To illustrate how student projects are organized, consider the Memory module of $\mathcal{OSP}2$. This module corresponds to the Java package **osp.** Memory and contains the classes PageFaultHandler, PageTableEntry, and Frame-TableEntry, among others. Each of these classes is kept in its own .java file: PageFaultHandler.java, PageTableEntry.java, FrameTableEntry.java, etc. For the Memory project, students are expected to implement the various classes associated with these files.

At the heart of *OSP ²* is the **Event Engine**, the event-based simulator that drives the execution of the student packages. The events generated by the event engine are calls to methods in student packages, representing system calls (e.g. create a task, write a file) or hardware interrupts (e.g. disk interrupt, page fault). Collectively, they simulate the behavior of a stream of executing programs in a multiprogramming operating-system environment.

There is also a layer that sits between the event engine and the student layer, the so-called **Interface Layer** or *IFL*. The IFL monitors the execution of the student packages for the purpose of catching semantic errors in student code (and subsequently producing intelligible error or warning messages), and for gathering performance statistics. Thus, the IFL can be viewed as a protective "wrapper" around the student packages. The logical structure of *OSP ²* is depicted in Figure $\boxed{1.1}$

Figure 1.1 The logical structure of *OSP ²* .

1.4 Simulated Hardware in *OSP 2*

The Hardware and the Interrupts packages of *OSP ²* model the hardwareoriented aspects of the simulated multiprogramming operating system. Hardware consists of four Java classes, which we now describe. $\frac{1}{2}$ $\frac{1}{2}$ $\frac{1}{2}$

CPU: This class models the CPU of the simulated machine. It defines one method, interrupt(), which is used to generate an interrupt with the given type (e.g. disk interrupt, page fault). The interrupt vector supported by the Interrupts package is described later in this section.

Note that all the methods of the Hardware and Interrupts packages are declared as final, meaning that they cannot be subclassed. This is done for object-oriented design reasons: you should think of these classes as "perfect" or that, conceptually, they should have no subclasses. Many of the methods contained in other *OSP ²* packages are also declared to be final for the same reason.

Disk: This class represents a hard disk attached to the system and is declared as follows:

public class Disk extends Device;

It implements methods that provide access to the physical characteristics of the disk and its current state of operation. The methods in this class are:

- \diamond final public int getPlatters() Returns the number of platters.
- \diamond final public int getTracksPerPlatter() Returns the number of tracks per platter.
- final public int getSectorsPerTrack() Returns the number of sectors per track.
- \diamond final public int getBytesPerSector() Returns the number of bytes per sector.
- \diamond final public int getRevsPerTick() Returns the number of revolutions per tick.
- final public int getSeekTimePerTrack() Returns the average time it takes to move the head to the adjacent track.
- \diamond final public int getHeadPosition(int track) Returns the position of the disk head, i.e., the cylinder where the head is parked.

These methods might be used for implementing I/O schedulers; see Schedul-ing of Disk Requests, Chapter [6,](#page-110-0) for more information about *OSP* 2 devices.

- HClock: This class represents the hardware clock. It can be used to access the current simulation time using the following method:
	- \diamond public final static long get() Returns current simulation time.
- HTimer: This class represents the hardware timer. If set to a positive integer, a timer interrupt will occur after that many (simulated) clock ticks. This class provides the following methods:
	- \diamond public final static void set(int time) Sets timer. Time is relative to the current time. If time is zero or negative, timer interrupts are disabled.

 \diamond public final static long get()

Returns time left until the timer interrupt. Returns a negative number if timer interrupts are disabled.

The Interrupts package of *OSP ²* consists of one Java class, which is important for several student projects.

- InterruptVector: This class represents the hardware register called the **interrupt vector**. It contains information about the interrupt that just occurred. Interrupt handlers check the interrupt vector for the information about the interrupt so that they can properly handle the interrupt. Not all parts of the interrupt vector are relevant to every kind of interrupt. For instance, for timer interrupts, only the type of the interrupt (i.e., that it came from the timer device) is important. On the other hand, for a disk interrupt, the relevant information also includes the IORB (I/O Request Block; see Section \Box 6) that caused the interrupt. For a page fault, the relevant information includes the thread and the page that caused the interrupt, etc. The student is supposed to set and query the appropriate parameters of the interrupt vector depending on the type of interrupt. The methods provided by this class are:
	- \diamond final static public void setInterruptType(int newInterruptType) Sets the type of the interrupt: PageFault, DiskInterrupt, or Timer-Interrupt; see GlobalVariables for more details.
	- final static public int getInterruptType() Returns the type of the interrupt.
	- \diamond final static public ThreadCB getThread() Returns the thread that caused the interrupt.
	- \diamond final static public void setThread(ThreadCB thread) Sets the thread that is about to cause the interrupt. In this way, other modules can query the interrupt vector to find out which thread caused the interrupt.
	- \diamond final static public PageTableEntry getPage() Returns the page that caused the interrupt (pagefault).
	- \diamond final static public void setPage(PageTableEntry newPage) Sets the page that caused the interrupt. In this way, other modules can query the interrupt vector to find out which page has cause the page fault.
	- \diamond final static public void setReferenceType(int referenceType) Sets the reference type of a memory interrupt, i.e., MemoryRead, MemoryWrite, or MemoryLock; see GlobalVariables.
- \diamond final static public int getReferenceType() Returns the type of memory reference that caused the interrupt.
- \diamond final static public Event getEvent() Returns the event that caused the interrupt.
- \diamond final static public void setEvent(Event newEvent) Sets the event that is about to cause the interrupt.

The hardware components listed above are *provided* by the *OSP ²* system and are not to be implemented by the student. In contrast, *OSP ²* also has hardware, notably the **memory management unit** (or **MMU**), that is part of a student package, module Memory. *OSP ²* memory management is discussed in Chapter [5.](#page-83-0)

1.5 Utilities

The utilities package contains a number of classes that are needed purely for simulation support. It also provides a class, GlobalVariables, that is required by the student packages, and several other "utility" classes that assist students in implementing their projects.

The class GlobalVariables comprises a number of variables that define the nature of a memory reference (e.g. MemoryWrite), interrupt types (e.g. TimerInterrupt), and method return status (e.g. SUCCESS and FAILURE). It also defines constants such as NONE and SwapDeviceID. The former represents a common return value used for integer objects (e.g. the value returned when a free frame is not found) and the latter is the device number of the swap device.

All of these constants are integers and *must* be referred to using their symbolic names. For debugging, however, it is often useful to know what the corresponding numeric values are. This is accomplished with the help of the following methods:

- final static public String printableStatus(int status) Returns the printable representation of the following constants:
	- **–** ThreadReady status of a ready-to-run thread.
	- **–** ThreadRunning status of a running thread.
	- **–** ThreadWaiting status of a waiting thread. (There are multiple levels of waiting, so this status is printed as ThreadWaitingX, where X is the waiting level. See Chapter $\mathbf{\mathcal{D}}$ for details.)
- **–** ThreadKill status of a killed thread.
- **–** TaskLive status of a live task.
- **–** TaskTerm status of a killed task.
- **–** PortLive status of a live communication port.
- **–** PortDestroyed status of a destroyed communication port.

This method is useful for debugging. For instance, if you need to find out the status of a thread, you might want to display that status on the screen. But status is an integer, which does not hold much information for a human reader. The method printableStatus()will convert such an integer into, say, ThreadReady (a string).

- final static public String printableRequest(int request) Returns human-readable representations of request constants, which are:
	- **–** MemoryRead Memory read request (in refer()).
	- **–** MemoryWrite Memory write request (in refer()).
	- **–** MemoryLock Memory lock request (in lock()).
	- **–** FileRead File read request (in read()).
	- **–** FileWrite File write request (in write()).
- final static public String printableDevice(int device) Returns human-readable representations for devices, which are:
	- **–** SwapDeviceID the number of the swap device.
	- **–** Disk1, Disk2, Disk3, Disk4 the disk devices.
- final static public String printableInterrupt(int interrupt) Returns human-readable representations for interrupts, which are:
	- **–** PageFault Pagefault interrupt.
	- **–** DiskInterrupt Disk interrupt.
	- **–** TimerInterrupt Timer interrupt.
- \diamond final static public String printableRetCode(int retcode) Returns human-readable representations of method return-codes. The supported return-codes are:
	- **–** SUCCESS successful completion.
	- **–** FAILURE unsuccessful completion.

– NotEnoughMemory – returned by the page-fault handler when it cannot find a frame to satisfy a page fault.

\diamond static public String userOption

This variable is set using the command line option -userOption. It can be used to pass a parameter to the student program when *OSP ²* is invoked from command line. This variable is not used internally by the simulator and its use is solely up to the student's discretion.

Other useful classes in the Utilities package include:

- MyOut: The methods in this class can be used to insert messages into the *OSP ²* **system log** for debugging purposes. The system log tracks system events as they occur and messages inserted into the log by students are inserted in chronological order with other system events. The following methods are provided:
	- \diamond final public synchronized static void print (Object where, String msg)

Prints a message to the system log. The argument where must be an object from which the package and the class from where print is called can be derived. If print() is called from a non-static method, then the where argument should be *this* (the Java keyword that denotes the context object); otherwise, if print() is invoked from within a static method, then the where argument should be a string-object of the form "osp.packageName.className". For instance,

MyOut.print("osp.Tasks.TaskCB", "Hello World!");

 \diamond final public synchronized static void error(Object where, String msg)

Prints an error message to the system log and terminates *OSP ²* . The format of the where argument is the same as before. This method can be used to halt execution of *OSP ²* when a bug is discovered; further execution of *OSP ²* under these circumstance is probably not useful under the circumstances. The error() method also causes a stack trace and the current *OSP ²* snapshot to be included in the log for debugging purposes.

- \diamond final public synchronized static void checkCondition(boolean condition, Object where, String msg) Similar to error() except that the error message is printed and \mathcal{OSP} *2* is terminated only if the boolean condition is false.
- \diamond final public synchronized static void warning (Object where, String msg)

Similar to print() except that a *warning* message is printed to the log. Unlike error() and checkCondition() (but like print()), the execution of *OSP ²* can proceed after this method is called. Like method error(), a snapshot and a stack trace are included in the system log. This method can be used by the student to check conditions that are not necessarily fatal to the execution, but are still undesirable and must be fixed.

- \diamond final public synchronized static void snapshot() Although error(), warning(), and checkCondition() can be used to obtain the current *OSP ²* snapshot, the snapshot() method can be used to insert a snapshot into the system log at any time, not necessarily when a warning or an error condition is detected.
- GenericList: This class provides the following methods for maintaining doubly linked lists of objects:
	- \diamond public GenericList() implements GenericQueueInterface A constructor that creates an empty list.
	- \diamond public GenericList(Object obj) A constructor that creates a list and initializes it with a given object.
	- \diamond public final int length() Returns the length of the list.
	- \diamond public final boolean is Empty() Returns true if the list is empty, false otherwise.
	- \diamond public final synchronized void insert (Object obj) Inserts an object at the beginning of the list.
	- \diamond public final synchronized void append(Object obj) Appends an object to the end of the list.
	- \diamond public final synchronized Object remove(Object obj) Removes the specified object from the list and returns the object. Null, if the object is not found.
	- \diamond public final synchronized Object appendToCurrent(Object obj) Inserts the object obj into the list after the current item in the list. The current item is set by the enumerators (see below) as they traverse the list (after each call to nextElement()).
	- \diamond public final synchronized Object prependAtCurrent(Object obj) Inserts the object obj into the list before the current item in the list. The current item is set by the enumerators (see below) as they traverse the list (after each call to nextElement()).
- \diamond public final synchronized boolean contains(Object obj) Returns true if the specified object is in the list, false otherwise.
- \diamond public final synchronized <code>Object</code> removeHead() Removes the object at the head of the list and returns the object. Null, if the list is empty.

```
\diamond public final synchronized Object removeTail()
  Removes the object at the tail of the list and returns the object. Null,
  if the list is empty.
```
- \diamond public final synchronized <code>Object</code> getHead() Returns the object at the head of the list without removing the object.
- \diamond public final synchronized Object getTail() Returns the object at the tail of the list without removing the object.
- \diamond public final synchronized Enumeration forwardIterator()

An iterator is a general Java mechanism for dealing with collections such as sets and lists. A forward iterator returns an object of class Enumeration (a standard Java class), which can then be used to conveniently traverse the list. For instance,

```
GenericList list;
.....
Enumeration enum = list.forwardIterator();
while(enum.hasMoreElements()) {
   Object obj = enum.nextElement();
}
```
Each call to nextElement() advances the current pointer in the list. The current pointer is the point of insertion for the previously described methods appendToCurrent() and prependAtCurrent().

 \diamond public final synchronized Enumeration forwardIterator(Object first)

Works like forwardIterator() but starts the iteration from the first occurrence of the specified object in the list.

- \diamond public final synchronized Enumeration backwardIterator() Similar to forwardIterator() but traverses the list backwards.
- \diamond public final synchronized Enumeration backwardIterator(Object first) Like forwardIterator(Object first) but traverses the list backwards.
- GenericQueueInterface: The GenericQueueInterface that GenericList implements contains the following methods:
	- public int length(); Returns the number of elements in the queue.
	- \diamond public boolean is $Empty()$; Returns true if the queue is empty, false otherwise.
	- \diamond public boolean contains(Object obj); Returns true if the queue contains object obj, false otherwise.

This interface mandates only the methods that *OSP ²* itself uses internally. For classes that use this interface you might need to define additional methods, such as insertion into the queue and deletion of queue members.

1.6 *OSP 2* **Events**

Like any other operating system, $\mathcal{OSP2}$ is *event-driven*. When a thread executes an I/O operation, it blocks until the I/O completes. When one threads needs to communicate with another, it sends a message and might decide to block itself until a response arrives. When a thread blocks, we say that it is waiting for an **event** to occur (like the completion of an I/O operation or message delivery) so that the thread may continue its execution.

In a typical operating system, events are represented by some kind of **event** data structure. A thread that wishes to block itself, or, more generally, to be notified about the completion of an event, executes a suspend() operation on that event, which places the thread on the event's **waiting queue**. The event "happens" when some other thread (a user or a system thread, depending on the type of the event) announces that the event has taken place. For example, in the case of an I/O operation, a disk interrupt will cause the disk-interrupt handler to execute and the handler eventually will announce the completion of the I/O event. In *OSP ²*, an event is an object and such an announcement is made by executing the notifyThreads() method associated with the event. As a result, threads waiting on the event are unblocked by the operating system and can continue their execution.

In *OSP* 2, events are represented by the Event class. A basic event has an id, which serves to distinguish this event from other events and a **waiting queue**. Thus, an event provides the means for suspending threads when they have to wait, and subsequently locating them when they are to be resumed.

In practice, the Event class is almost always subclassed before it is used. This is because threads are usually interested in very specific kinds of events rather than just generic events. For example, a thread is suspended because it has to wait for an I/O operation to complete or a page to be swapped in, or because it is suspended on a communication port until a message arrives. Thus, *OSP ²* treats memory pages, I/O request blocks (IORBs), and communication ports as events in the sense that all these classes extend the class Event.

The Event class provides the methods necessary for maintaining the waiting queue, and these methods can be used on pages, ports, and IORBs when these are used in their capacity as events. The methods provided by class Event are as follows:

```
\diamond public void addThread(ThreadCB thread)
```
Add the specified thread to the waiting queue of the event. No checks are performed to ensure that the thread is not already on the queue.

- public void removeThread(ThreadCB thread) Remove the specified thread from the queue. If the thread is not found, return silently.
- \diamond public boolean contains(ThreadCB thread) Return true if the thread is on the waiting queue for this event, false otherwise.
- \diamond public int getNumberOfThreadsWaiting() Returns the length of the waiting queue.
- \diamond public GenericList getThreadList() Returns the waiting queue itself.

```
\diamond public ThreadCB getHead()
  Returns the thread at the head of the waiting queue or the null object.
```

```
\diamond public void notifyThreads()
```
Resumes all threads on the waiting queue (i.e., executes resume() on each one of them) and empties the queue. It is quite possible that some threads on the waiting queue have been destroyed while waiting. In this case, notifyThreads() simply removes the destroyed threads from the queue as executing resume() on such a thread would be an error.

Several projects in *OSP ²* make extensive use of events and we will refer back to this section when necessary.

1.7 *OSP 2* **Daemons**

The implementation of certain functions of an OS can be facilitated through the use of daemons: special system threads that run periodically and perform "work" specified by the user. In $\mathcal{OSP}2$, such work might include proactive swapping out of dirty memory pages, as required by some memory-management algorithms, and deadlock detection.

Daemon support in \mathcal{OSP} *2* is provided by the Daemon class and the interface DaemonInterface. To use a daemon, one creates an object in a class that implements DaemonInterface and then registers this object with the system. The following statements declare a class of daemons whose only job is to insert a notice in the system log:

```
class MyDaemon implements DaemonInterface
{
    public void unleash(ThreadCB thread)
    {
        MyOut.print(this, "My daemon executed at time: "
                          + HClock.get());
    }
}
```
The only mandatory method in this class is unleash, which should contain the code you want the daemon to execute. For instance, in case of a deadlockdetection daemon, a method should be provided that executes the appropriate deadlock-detection algorithm. This method is called by *OSP ²* when it wakes up the daemon.

Defining a daemon is your responsibility. You also need to register it with the system and provide three things: the name of the daemon (for easy identification of the daemon in a system trace), a concrete daemon object to call, and the amount of time that should pass between invocations of the daemon. This is typically done when *OSP ²* begins executing, inside the init() method that exists in the main class of each student package. Here is an example of registering a daemon:

```
Daemon.create("My own daemon", new MyDaemon(), 20000);
```
The first argument can be an arbitrary string. The second is an object of the daemon class defined earlier. The third argument tells *OSP ²* that the daemon should be periodically woken up after every [2](#page-29-0)0,000 ticks. You can create several

² *OSP ²* does not guarantee that it will wake up the daemon exactly after the specified number of ticks, but it will try to wake it up as soon as possible after the specified interval.

daemons if several periodic jobs need to be performed by the module that you are implementing. Typically the requirement to use daemons would be part of the assignment given out by your instructor, but you might also decide to use them on your own, based on your understanding of the problem.

1.8 Compiling and Running Projects

A student project assignment consists of several files:

- 1. Demo.jar, which contains a demo version of *OSP ²* . It can be used to get a general idea of how *OSP ²* works, to familiarize yourself with the graphical interface and command-line options of the system, and to create configuration files for running *OSP ²* with different parameters.
- 2. Template files, each of which contains the necessary import statements, the class header of the public class to be implemented, and the headers of the public methods that must be implemented by the student. For instance, for the THREADS project, the template files would be
	- a) ThreadCB.java
	- b) TimerInterruptHandler.java
- 3. OSP.jar, which contains the compiled classes of the *OSP ²* simulator that drive the execution of the classes in the student project. When your implementation of the classes in the project is complete, they should be compiled and linked with the OSP.jar file.
- 4. A Makefile that simplifies the compilation process under Unix-based systems (Solaris, Linux, Free BSD, etc.).
- 5. The Misc subdirectory, which includes two files:
	- a) params.osp
	- b) wgui.rdl

The first file contains the parameters that will drive the simulation and the second file is a configuration file for the GUI. You should not edit either of these files manually. In fact, there is no reason to touch wgui.rdl at all, unless you are not satisfied with the overall look of the graphical interface :-). However, you might want to run *OSP ²* with different parameters and create a new configuration file derived from params.osp. The only recommended way of doing this is to change the parameters through the GUI of the demo version of *OSP ²* and then save the new parameters in a

new file. A GUI panel that lets the user change the simulation parameters is shown in Figure 1.2 .

Figure 1.2 Panel for changing *OSP ²* simulation parameters.

Java settings. *OSP 2* requires JDK 1.5 or a later version. To run and compile *OSP ²* you must first make sure that Java is properly set up on your machine and that your personal configuration files are set appropriately. This simply means that the environment variable PATH is set appropriately. For Windows, this variable should be set in the autoexec.bat file or through the control panel as follows:

set PATH=%PATH%;C:\jdk\bin

The second component in this setting should, of course, point to the place where the Java executables are installed and our choice of $C:\idk\binom{in}{i}$ is merely an example.

For Unix-based systems, the setting depends on the type of the shell used. We show the settings for the two most popular shells: bash and csh. Settings for other shells (such as ksh, sh, tcsh) would be similar to either bash or csh, the only difference being the name of the configuration file.

To set the PATH variable for bash, place the following in the .bashrc file in your home directory:

PATH=/usr/local/bin/jdk:\$PATHexport PATH

As before, /usr/local/jdk/bin is just an example. The actual location of the Java executables can vary.

For csh, the PATH variable should be set in the file .cshrc in your home directory:

setenv PATH /usr/local/bin/jdk:\$PATH

Running the demo program. To run the demo version of *OSP ²*, simply type:

java -classpath .:Demo.jar osp.OSP

(use .;Demo.jar on Windows).

Some installations of JDK might require that you set the CLASSPATH environment variable (this requirement would then be part of the Java installation instructions). In this case, you might need to run *OSP ²* as follows:

java -classpath .:Demo.jar:\${CLASSPATH} osp.OSP

for Unix-based systems and

java -classpath .;Demo.jar;%CLASSPATH% osp.OSP

for Windows.

Compiling and running the project. Once your implementation of the project is finished, you are ready to compile and run the system. Here is how to do this.

On Unix-based systems, simply type make, and the project will be compiled. To run it without the GUI, type make run; with the GUI, type make gui; and to run with the debugger type make debug. Sometimes make clean; make can be helpful if you need to get rid of stale .class files and force recompilation of the entire project. That's all! The only caveat is that this must be a version of *GNU make*, which is available on most Unix-based systems, albeit sometimes under different names, such as gnumake or gmake. To find out it your makeprogram is a GNU make, type

make --version

If it does not say that this is GNU make or if it does not understand the --version argument, then it is *not* GNU make, and you should ask the system administrator if this version of the make-program is installed (and under which name). If you cannot locate the appropriate make-program, read on.

Figure [1.3](#page-33-0) shows what you can expect when running $\mathcal{OSP2}$ with a GUI and Figure [1.4](#page-34-0) shows a run without the GUI.

	OSP Run	$ \Box$

Elapsed time: 5 seconds Details are in the log file OSP.log kifer@kiferlap:~/0SP/osp2/ > \Box

Figure 1.4 An *OSP ²* run without the GUI.

The only difference under Windows is that one has to replace ":" with ";". The first command compiles the project, the second runs it, and the third runs it under the Java debugger.^{[3](#page-34-1)} Running \mathcal{OSP} *2* with the Java debugger can be excruciatingly slow, so you should try this only if you need to trace the execution of your program or examine it in some other way that the debugger provides.

Again, some installations of JDK might insists that you set the CLASSPATH environment variable and attach it to the -classpath argument as explained earlier.

OSP ² **command-line options.** You can run *OSP ²* with certain commandline options. Here is the full list of options:

-help - lists all command-line options -noGUI - runs the simulator without the GUI -paramFile - use the next argument as the parameter file -guiFile - use the next argument as GUI configuration file

³ Some Java distributions for Linux have problems with running the debugger due to broken shell scripts. When run, the debugger will complain that it cannot load certain libraries. To fix this, you must set the environment variable LD LIBRARY PATH to something like /usr/local/jdk/lib/i386:\$LD LIBRARY PATH. You might have to do some experimentation to find out the exact path.

```
-userOption - use the next argument to set the global
              variable userOption
   -debugOn - includes debugging messages in the OSP system log
```
Among these, only -userOption, -noGUI, and -paramFile are useful for student projects. The first option, -userOption, allows you to pass a string argument to the student program from the command line. As a result, the string argument specified on the command line becomes the value of the global variable userOption. This can be used, for example, when experimenting with different project implementations, based, perhaps, on different algorithms, and a command-line option is needed to indicate which algorithm to execute. This option can also be used to invoke debugging code that is normally hidden. The second option, $-noGUI$, runs $OSP2$ without the GUI, which saves time. *OSP ²* 's GUI is very useful as a tool for setting the simulation parameters, but apart from that it is just a very fancy progress bar and, as such, is intended to distract serious people from doing work.

The second useful option, -paramFile, can be used to run *OSP ²* with alternative parameter files, which can be helpful for debugging. The use of -debugOn option is not recommended for student projects. It is mainly a tool for debugging *OSP ²* itself, and the messages it produces can be confusing to someone who is not familiar with the source code of the system. Apart from that, with this option turned on, the OSP system log can be in excess of 30M, which might be a problem on shared file systems.

Here is an example of how to specify command-line arguments to the make command under Unix:

```
make run OPTS="-paramFile my-other-param-file.osp -noGUI"
```
For Windows and for those Unix users who do not trust makefiles, the same effect can be achieved as follows:

```
java -classpath .:OSP.jar osp.OSP
     -paramFile my-other-param-file -noGUI
```
(This command should be typed on one line.)

1.9 General Rules of Engagement

This section describes important general conventions about writing code for student projects.
1.9.1 A Day in the Life of an *OSP 2* **Thread**

A key concept in *OSP ²* is the *thread*, the schedulable and dispatchable unit of execution in *OSP ²*. Threads are simulated in *OSP ²* by the event engine. That is, the event engine, using a certain "stochastic model", semi-randomly decides how many threads to create, how long each of them will live, and what services they will request of the OS while they are alive. A request-of-service by a thread is represented in the event engine by an event corresponding to a call to a method in one of the *OSP ²* modules. For example, if *OSP ²* wants to simulate a request by a thread to read a certain file, an event is created that will eventually result in a call to method do read() of class OpenFile of package FileSys.

A key point that we will emphasize numerous times in this book is that the threads that *OSP ²* simulates represent the behavior of user programs or applications. In a typical computing environment, an application program performs some useful work for a user. To do so, the application requests services from the operating system, such as memory allocation, the use of the CPU, management of files, etc. The user sees the results of the work performed by the application, but the details of how the services are implemented by the operating system are normally hidden from the user.

In *OSP* 2 you have to take the opposite view: your concern is the operating system itself, and the user applications are faceless programs that you know nothing about. The only time you become aware of these programs is when they—or more precisely the simulated \mathcal{OSP} *2* threads representing the behavior of these programs—request services from you, the operating system. The aim of each of student project is to implement a well-defined service, such as memory or thread management, that might be requested by a typical application. When a simulated *OSP ²* thread requests a service from the OS, it suddenly becomes "real": a call is made to one of the methods in your project and the simulated computation becomes live computation of one of the methods that you implemented.

OSP ² has a modular, object-oriented design with clear interfaces. Every student project implements a particular service. The implementation of the classes needed to complete each project is under the student's control. For each class, the student is required to implement certain methods and in doing so can augment the class with any number of auxiliary methods or variables. The student is also provided with a set of methods to operate on the "built-in" data structures of the class (which are represented as private fields in the IFL layer). In some cases, it becomes necessary to obtain services from other parts of the system, which is also done through the published interfaces.

It is important to keep in mind that if you are assigned, say, the

memory-management project, Memory, then you are responsible for implementing all the necessary functionality as defined by the project description. *OSP ²* will not attempt to provide any memory-related service, leaving everything to you. However, like a Big Brother, it is watching and is very keen on reporting errors.

When implementing a project, only the interfaces described in that project's description can be used. Method calls and classes that you might find in the description of other projects will not work and are likely to result in a compilation error. This is the result of the method-name obfuscation described in Section $1.9.4$, which is performed to prevent corruption of the internal system state.

1.9.2 Convention for Calling Student Methods

One of the most important tasks of the *OSP ²* simulator is to verify the actions performed by student code for semantic correctness and to provide meaningful error messages and warnings. This error checking is performed by the **interface layer** of *OSP ²* (or IFL). The IFL contains wrapper methods that validate the state of the system before and after student code is executed. Because of these wrappers, a special convention for naming and invoking methods must be followed when implementing an *OSP ²* project. To make the discussion concrete, consider the THREADS package, which is responsible for thread-management tasks such as thread creation. There is both a Java class for threads in the IFL, called IflThreadCB (the CB stands for "control block"), and a Java class for threads in the student package, simply named ThreadCB (i.e. without the Ifl prefix). Moreover, ThreadCB is a *subclass* of IflThreadCB and both of these classes implement methods for thread creation (among others), with the IFL method serving as a protective "wrapper" for the student-layer method.

To distinguish these thread-creation methods, the one defined in the superclass is simply called create(), while the one in the subclass is called do create(), i.e. the corresponding method name in the student package is prepended with the prefix do_. In general, we have the following naming convention.

Methods in the OSP ² API that are to be implemented by the student have the naming schema do_name*, where* name *is the name of the wrapper in the IFL.*

There is an exception to this rule, namely the methods atError() and atWarning(), which are introduced below.

This convention has several ramifications that the student must be aware of when implementing a project. These are best understood by considering the flow of execution in *OSP ²* when an event is generated by the event engine and subsequently "handled" by the appropriate classes in the IFL layer and student package. Five main points of control can be identified within this execution flow; see also Figure $\overline{1.5}$.

Figure 1.5 Execution flow for handling an event.

- 1. The event engine selects the event at the head of the "event queue" for execution. The event is actually a call to one of the student methods although control must go through the IFL. Assume, for the sake of discussion, that the selected event is a call to the create() thread method. In this case, the event engine calls create() in the IFL.
- 2. The IFL performs some bookkeeping for the purpose of detecting possible errors in, and for monitoring the performance of, the student's implementation of create() and then calls do create() in the student layer.
- 3. The student implementation of do create() performs the requested action.
- 4. Control returns to create(), which verifies that the actions taken by the student code were correct. If the student code executed incorrectly, an error message is written to the simulation log and simulation halts.
- 5. Assuming the student code executed correctly, simulation proceeds to the next scheduled event on the event queue.

Students should therefore adhere to the following additional naming convention:

When calling *a method named* name *in this or another package, call the method* name*, i.e. without the "do " prefix.*

In contrast, as noted above, when *implementing* a method named name, students will actually implement the method do_name.

Note also that *the student implementation should never directly refer to the classes defined in the IFL layer*. For instance, even though the method dispatch() is defined in the class IflThreadCB, it is inherited by Thread-CB and it should be called as ThreadCB.dispatch() rather than IflThread-CB.dispatch().

1.9.3 Static vs. Instance Methods

When you receive a project assignment that contains the templates of the methods to be implemented, you will notice that some methods are static (i.e., they apply to class objects) and some methods (those that do not have the static keyword attached) work on instance objects.

This division of the project methods into static and instance methods comes from the differences in their function. For example, the method do_dispatch() is static in class ThreadCB, because it makes no sense to call it on any particular thread: the thread to be dispatched is not known at the time of the call and, in fact, it is the job of the do dispatch() method to find such a thread and give it control of the CPU, as described in Chapter $\mathbf{\mathcal{D}}$.

On the other hand, methods do_resume() and do_suspend() in ThreadCB are *not* static: they are called on specific thread objects, because the job of these methods is to resume or suspend the threads on which the methods are called. As usual in Java, the context object of a non-static method is accessible through the variable this.

Therefore, when reading the description of each method in the project, it is important to be aware of whether this method is static or an instance method.

1.9.4 Obfuscation of Method and Class Names

Chapters \mathbb{S} through \mathbb{S} describe the classes and methods that comprise the various student projects. For each project, the student implementation may require services implemented in other parts of *OSP ²* and must call the appropriate methods to obtain these services. Methods needed for one project, however, are not necessarily needed for another. In some cases, incorrect use of methods that belong to other packages might even corrupt the internal state of the system.

To prevent the student implementation from incorrectly using public methods that are not required for the given project, the names of these methods are changed in that project by a special "obfuscater" program. For example, the method isFree() of class FrameTableEntry is available in project Memory, but it is obfuscated away and will cause a compilation error if it is used by methods in project THREADS.

1.9.5 Possible Hanging After Errors

When *OSP* 2 detects an error in a student program, it prints information about the error and then tries to terminate. Graceful termination, however, is not always possible because *OSP ²* is a multi-threaded application and termination of some of the active threads might depend on student code (whose behavior cannot be predicted). It is therefore possible that, after printing an error message, *OSP ²* may hang; in this case the system must be terminated by the user.

1.9.6 Possible Exceptions After the End of Execution

On very rare occasions you might see exceptions that occur after the end of a run of the simulator. This is nothing to worry about, however, as it does *not* indicate a problem with your program. The reason for these exceptions is that when the designated simulation time runs out, *OSP ²* tries hard to stop all the currently active Java threads. Unfortunately, it is not possible to terminate threads immediately, so a thread may continue to run for a short while even though some of the vital system objects may have already been destroyed. In such situations, NullPointerException and other exceptions can occur.

1.9.7 General Advice: How to Figure it Out

When you begin an $\mathcal{OSP2}$ project, it is important to understand the specifications of the various student projects contained in the following chapters, and how your implementation fits into the big picture. Perhaps, it is best to state what this manual is *not*:

- 1. It is *not* intended to replace the textbook.
- 2. It is *not* intended to teach you the basic concepts in operating systems.
- 3. It is *not* intended to guide you every step of the way to the completion of

your project.

Instead, the description of a student project provides a complete description of the API that you can use to implement the project and a description of the functionality of each method in the project. The manual does not explain how to put the pieces of the puzzle together—this is for you to figure out based on your understanding of the subject.

The best advice is: think logically. In these projects *you are implementing parts of an operating system*, which is probably very different from the kind of programming you have done in the past. If you are in doubt about whether or not it is appropriate for your implementation to take a certain action, consider whether you would like it if the OS on your desktop behaved this way. For example, suppose you are implementing a thread scheduler and at certain point in the program you have to deal with the situation where no threads are left to schedule. Should you leave the CPU idle or create and run a dummy thread, thereby wasting computing resources? The answer should become obvious if you just ask yourself the simple question: "Would I want my home computer to behave this way?"

1.10 System Log, Snapshots, and Statistics

During a run, *OSP ²* prints messages in the system log. Each message describes a specific event that occurred during execution. Messages that come from the simulator are prefixed with Sim:; those that come from student packages other than the project-assignment module(s) are prefixed with Mod :; and those that come from the project you are currently implementing are prefixed with My:.

Periodically *OSP ²* dumps **snapshots** of the system state into the log file. These snapshots are primarily intended for performance checking and debugging. A snapshot contains a complete dump of main memory, the status of all page tables, the status of all threads, including the queues they are in, and the status of all communication ports.

In addition, the snapshot provides statistics such as CPU utilization, **average service time** (also known as **average turnaround time**) of an I/O request and a thread, the average number of tracks swept on each device per I/O request, and the **average normalized service time**. The last of these describes the average relative delay suffered by each thread, and is determined by the following formula:

> Σ_i $\frac{\text{CPU time used}(\text{thread}_i)}{\text{turnaround time}(\text{thread}_i)}$ total number of threads

where the sum is over all threads (dead or alive). This is a better measure of performance than the average turnaround time, and this statistic should be kept as high as possible (but, of course, it cannot exceed 1).

It should be noted that some entries in the system log can have fairly long lines, so to view the log it may be necessary to use a viewer with horizontal scroll capability. For example, if you are running *OSP ²* with a parameter file that specifies long page tables (say, more than 64 pages), then you can expect to need to use a scrollable viewer. Most text editors provide this capability.

1.11 Debugging

There is no special-purpose debugger for *OSP ²* , but there are a few things that can help. Generally, errors in student code can be divided in two categories:

- 1. Errors that cause Java exceptions.
- 2. Semantic errors, such as an incorrect action taken in response to a simulator request. Examples include the failure to maintain the correct status of a thread (e.g., ThreadWaiting instead of ThreadRunning) or replacing a dirty page without first swapping it out to the swap device.

Errors of the first kind are much easier to fix since they can be identified with the help of a Java debugger, such as jdb. For example, a Java debugger can be used to determine where the exception NullPointerException has occurred. In all likelihood, Java exceptions are due to errors in student code. If an exception takes place in *OSP ²* code, it does not necessarily mean that the student code is correct; rather, it likely means that *OSP ²* has failed to catch the problem early enough to generate a meaningful error message to guide you to the real problem.

Apart from tracking down exceptions, Java debuggers are not very useful for debugging *OSP ²* projects, especially for finding semantic mistakes in student code. This is because such an error might be detected by *OSP ²* thousands of instructions after the erroneous action was performed by the student program and using the debugger trace facility to track down the source of the error might wear you down before the first signs of a problem begin to show up. Therefore, the following procedure is recommended for finding and fixing semantic problems.

System log. When $\mathcal{OSP}2$ detects a semantic error, it tries to come up with as clear an explanation as possible. When an error or a warning is issued,

the log file (OSP.log, unless specified differently in the configuration file) will contain a message of the form <<Error>>, <<Assertion>>, or <<Warning>>, which are easy to find with an editor. When $\mathcal{OSP2}$ terminates, it tells you if one of these conditions was encountered or if it terminated successfully.

In case of a problem, the best way to understand what might have happened is to trace back the messages in the system log. For instance, if an error message says that you are trying to dispatch a thread that is waiting on some event that has not occurred yet, you should trace back and see when the thread was suspended on that event and what was the sequence of events that happened since. You might discover, for example, that your program is placing threads on the ready queue that, in reality, are not ready to execute. Likewise, if *OSP ²* complains that there is a discrepancy between what it perceives to be the dirty/clean status of a page and the value of the dirty bit set for this page by the student program, tracing the system log might reveal that, say, this page has just been swapped in but your program did not reset the dirty bit to *false*.

OSP ² generates a log by default, unless tracing is turned off. However, the log messages thus generated are typically not sufficient by themselves to debug errors in your code. This is because *OSP ²* cannot know what is actually happening inside student code and it is therefore necessary to put the execution of your program in the context of the overall execution of *OSP ²* . This can be achieved with the help of the methods in the class MyOut, which were discussed earlier. Moreover, it is useful to keep in mind that the toString() method of all major classes in \mathcal{OSP} *2* is set up in a printer-friendly manner. For example, executing

```
MyOut.print(this,
            "The " + thread + " is suspended on " + event);
```
where thread is an object of class ThreadCB and event is an object of class Event will produce output that looks like this:

My: 2534.5533 [Threads.ThreadCB] The Thread(15:32/RU) is suspended on Event(3)

Thus, no special care is needed to produce a readable representation of *OSP ²* objects. The header of the *OSP ²* system log provides a brief explanation of the printable representation of various objects. For instance, in the above representation for a thread, Thread(15:32/RU), the first number (15) is the thread id, the second (32) is the Id of the task the thread belongs to, and RU is the code that represents the current status of the thread (ThreadRunning in this case).

Error and warning hooks. In addition to MyOut, the main class of every student project has the following pair of methods:

```
\diamond public static void atError()
```
\diamond public static void atWarning()

The first method is called when an error or a condition violation is detected by *OSP ²*, and the second is called right after *OSP ²* issues a warning message. Normally, the bodies of these methods are empty, *and this is how you should leave them when you submit your program*. However, during debugging you can put arbitrary code there. Most useful would be code that prints the status of the relevant variables in your program. Note that whenever a condition violation, error, or warning occurs, \mathcal{OSP} *2* prints the full stack trace that indicates the sequence of method calls that led to the problem.

System snapshot. *OSP ²* also produces a **system snapshot** when a condition violation or error occurs. The snapshot conveys the status of memory allocation, the status of each task and thread in the system, etc. This information can be compared with the status of the system per your implementation and the system log can be consulted to determine where the discrepancy arises. When \mathcal{OSP} *2* prints out a warning, no snapshot is added to the log by default. This is because warnings tend to come in large numbers and this can lead to an unmanageably large number of snapshots in the log. However, you can include the snapshot() method of class MyOut in the body of the atWarning() method of the main class of your project and produce a snapshot in this way. (It is recommended to print a snapshot only on the first warning, since subsequent snapshots are not likely to shed any more light on the problem.)

Execution stack trace. Another important resource for debugging *OSP ²* projects is the execution stack trace provided by the Java virtual machine when a Java exception occurs. Here is an example of such a trace:

```
java.lang.NullPointerException
```
- at osp.Threads.ThreadCB.do_kill(ThreadCB.java:195)
- at osp.IFLModules.IflThreadCB.kill(IflThreadCB.java:634)
- at osp.IFLModules.IflThreadCB.killOldThreads(IflThreadCB.java, Compiled Code)
- at osp.IFLModules.CallbackThreadKill.voidCallback(IflThreadCB.java, Compiled Code)
- at osp.EventEngine.EventCallback.Activate(EventCallback.java, Compiled Code)
- at osp.EventEngine.EventEngObj.ActivateChildren(EventEngObj.java, Compiled Code)
- at osp.EventEngine.EventEngObj.Activate(EventEngObj.java, Compiled Code)
- at osp.EventEngine.EventDriver.go(EventDriver.java:114)
- at osp.EventEngine.EngineThread.run(EngineThread.java:61)

The trace says that a NullPointerException has occurred in method

do kill() of class ThreadCB at source code line 195. Going down the trace, we can see the sequence of method calls that led to the error: d o $\&$ ill() was called by kill() of IflThreadCB, etc. The most important information here is the line number where the error occurred.^{[4](#page-45-0)}

OSP ² prints a similar trace in the system log when an error or a warning is issued. For instance,

```
Sys: 36360 <<Warning!>> [Threads.ThreadCB]
 After do_kill(Thread(36:1/KL)): CPU is idle,
 but there are ready threads
 ready queue = (89:3,115:2,130:2,141:3,142:5)
 at osp.IFLModules.IflThreadCB.idleCPUwarning(IflThreadCB.java,
     Compiled Code)
 at osp.IFLModules.IflThreadCB.kill(IflThreadCB.java, Compiled Code)
 at osp.Tasks.TaskCB.do_kill(TaskCB.java, Compiled Code)
 at osp.IFLModules.IflTaskCB.kill(IflTaskCB.java, Compiled Code)
 at osp.IFLModules.IflTaskCB.killOldTasks(IflTaskCB.java, Compiled Code)
 at osp.IFLModules.CallbackTaskKill.voidCallback(IflTaskCB.java,
     Compiled Code)
 at osp.EventEngine.EventCallback.Activate(EventCallback.java,
     Compiled Code)
 at osp.EventEngine.EventEngObj.ActivateChildren(EventEngObj.java,
    Compiled Code)
 at osp.EventEngine.EventEngObj.Activate(EventEngObj.java, Compiled Code)
 at osp.EventEngine.EventDriver.go(EventDriver.java:114)
 at osp.EventEngine.EngineThread.run(EngineThread.java:61)
```
The trace appears after the warning message. In this case, we must look deeper in the trace to find out what happened. The top line of the trace says that the warning was issued by method idleCPUwarning() of class IflThreadCB, which was called by kill(), the system wrapper for the do kill() method, which is part of a student project (refer back to Section $1.9.2$ for the information about the naming conventions for methods that are implemented as part of student projects). The trace further says that the method IflThreadCB.kill() was in turn called by the method do kill() of class TaskCB, which was called by IflTaskCB.kill(). It takes a little bit of analysis and understanding of the functionality of the different system calls to realize what happened: the task $Task(1/L)$ has been destroyed by the system call TaskCB.kill(), which caused the destruction of all the threads that belong to that task. In particular, just after thread Thread(36:1/KL) was killed, the system detected that the CPU was idle even though some ready-to-run threads were present in the system. Thus, the cause of the warning is most probably the failure of the student implementation to call the dispatch() method at the end of d o $_k$ ill $()$.

⁴ Line-number information is not always provided, unless you run the system using the debugger.

Obfuscation and stack traces. Unfortunately, the obfuscation that *OSP ²* employs to prevent inappropriate calls to certain methods diminishes the value of execution stack traces, because the names of some method calls listed in a trace might be unintelligible. However, even with name obfuscation, the trace often contains enough information to be useful. Here is an example of an obfuscated trace:

```
java.lang.NullPointerException
```

```
at osp.IFLModules.IflDevice.enqueueIORB(IflDevice.java:283)
at osp.FileSys.OpenFile.do_read(OpenFile.java:421)
at osp.IFLModules.IflOpenFile.read(IflOpenFile.java:415)
at osp.Memory.PageFaultHandler.a(PageFaultHandler.java:395)
...
```
In the last line, the real name of the method osp.Memory.PageFaultHandler.a was obfuscated and became unrecognizable (there is no method called a in the source code). However, it is still clear that the error occurred while a call to the method enqueueIORB was made from within the read method, which was executed on a file.

1.12 Project Submission

The manner by which you submit your *OSP ²* projects is determined by the instructor. The following instructions apply if your instructor chooses to use the automatic project submission system of *OSP ²*.

First, you will have to supply your email address to the instructor, who will prepare an account for you. The email address identifies you to the system. You must use the same address in all your interactions with the submission system.

The submission system provides three functions, which are available as links from the project submission page. The URL of this page will be supplied to you by your instructor. The functions are as follows:

1. *Change of password.*

Clicking on this link will let you change your password. Your initial password will be mailed to you when the instructor sets up your account.

After you change your password and then try to submit a project, you might see the "authorization has failed" dialog box. This happens when the browser tries to use your old password. It is not a problem, however, because clicking "OK" in the dialog box lets you re-enter the correct password.

2. *Password reminder.*

If you forget your password or if you did not receive the initial password for some reason, you should click on this link. First, you will get email with a link to a servlet. Clicking on this link will have the following effect:

- Your password will be changed to some random string.
- You will get your new password by email.

If the new password is hard to remember, you can use the "Change of password" function to change your password.

If you do not click on the aforesaid servlet link, your password will not be changed. It should be noted that the password-reminder function can be used only within intervals of at least four hours.

3. *Project submission.*

When you are ready to submit your project assignment, click on the "Submit assignment" link on the project submission page. After authentication, you will be presented with a form where you will be asked to enter the project name and the *.java files that comprise your program. The system then copies the sources over to the server and compiles them. If successful, the sources stay on the server (so that they can be checked by the instructor and his or her teaching assistants) and the compiled class files are sent back to your browser as an applet. Next, you will have to run this applet (by clicking on appropriate buttons). If you are happy with the results, click on the submission button. The simulation run will then be sent to the server (again, so that the instructor can check it for errors).

Note that some browsers do not give a warning when a non-existing file is being sent to the server. In some cases (e.g. when the file is actually a directory name) the browser might even hang. Therefore, it is important to make sure that you send the correct *.java files to the server.

You should keep in mind that the instructor might set up the submission process in such a way that your project would have to be run with several parameter files. When the first run is finished, you should press the *Submit* button and then the *Next* button. If there are more parameter files to be considered, a new applet will start. When this is finished, submit the output and hit *Next* again. When your project has been run with all the parameter files, you will receive a confirmation and the main project-submission page will be displayed.

Finally, some browsers might issue a security exception when you try to run the submission applet. You will see this exception in the Java console of the browser (we recommend that you always run the submission applet with the Java console open). If this happens, you should place the file .java.policy in your home directory. This file should contain the entry

```
grant {
    permission java.security.AllPermission;
};
```
2 Putting it All Together: An Example Session with OSP *2*

2.1 Chapter Objective

Your instructor has assigned you the THREADS project to implement; see Chapter $\mathbf{\mathbb{I}}$. You are new to \mathcal{OSP} *2*. What do you do? In this chapter, we present an example session with $\mathcal{OSP2}$ that is intended to give you the guidance and confidence you need to successfully complete your assignment.

2.2 Overview of Thread Management in *OSP 2*

The THREADS project, as the name implies, deals with thread management and scheduling, where threads are the executable and dispatchable units in *OSP ²*. Our example will focus on thread management, in particular, the resumption of a thread from a waiting state. This activity is the responsibility of the method ϕ -resume(), one of the methods you are to implement as part of your implementation of the class ThreadCB.

Thread management involves the notions of thread creation, destruction, suspension, resumption and dispatching; maintaining thread status; and moving threads between different (ready and waiting) queues. Underlying all of this is the notion of a thread *state*, which can be one of ThreadReady, ThreadWaiting, ThreadKill, etc.

An *OSP ²* thread assumes the ThreadWaiting state when it enters the pagefault handler or when it executes a blocking system call (e.g., write()). The ThreadWaiting state is also known as the "level-0 waiting state". While in this state, a thread can again enter the pagefault handler or execute a blocking system call, causing it to enter the level-1 waiting state, represented by the constant ThreadWaiting+1. This process can continue indefinitely, leading to arbitrarily nested depths of waiting.

When a thread completes the execution of the pagefault handler or blocking system call, it should be moved up to the next highest waiting level by decrementing its waiting status; in the case of level 0 (ThreadWaiting, it should transit to the ThreadReady state.

2.3 The Student Method do_resume()

As mentioned previously, we will focus our attention during this example session on the method ϕ -resume() of class ThreadCB. Its code is given in Figure $\boxed{2.1}$. Notice the use of the MyOut utility to insert student output in the file OSP. log. For example, the statement

```
MyOut.print(this, "Resuming " + this);
```
will result in output such as

```
Mod: 63 [Threads.ThreadCB]
        Resuming Thread(0:1/W2)
```
appearing in the log file, indicating that at simulation time 63, thread 0 of task 1 is at waiting-level 2 (W2). The tag "Mod:" identifies this output as being from a student module, making it easy for you to distinguish your output from *OSP ²* 's in the log file.

Do resume() is one of the simplest methods in *OSP ²*. All it needs to do is decrement the thread's waiting-level, place it on the ready queue if its new status is ThreadReady, and call dispatch() so that some thread can be dispatched onto the CPU for execution.

Assuming that you have completed your design and coding of the THREADS project, let us proceed in a step-by-step fashion with the example session.

```
/** Resumes the thread.
Only a thread with status ThreadWaiting or higher can
be resumed. The status must be set to ThreadReady or
decremented, respectively. A ready thread should be
    placed on the ready queue.
@OSPProject Threads
*/
public void do_resume()
{
    if(getStatus() < ThreadWaiting) {
    MyOut.print(this,
        "Attempt to resume "
        + this + ", which wasn't waiting");
   return;
}
    MyOut.print(this, "Resuming " + this);
    // Set thread's status.
if (getStatus() == ThreadWaiting) {
    setStatus(ThreadReady);
} else if (getStatus() > ThreadWaiting)
    setStatus(getStatus()-1);
    // Put the thread on the ready queue, if appropriate
if (getStatus() == ThreadReady)
    readyQueue.append(this);
dispatch();
}
```
Figure 2.1 Code for student method do resume().

2.4 Step 1: Compiling and Running the Project

- \diamond You have a directory with all the necessary files in it for the THREADS project: ThreadCB.java, TimerInterruptHandler.java, OSP.jar, Makefile, etc.
- You have set the environment variable PATH appropriately so that the proper version of JDK (1.5 or newer) will be invoked.
- On Unix-based systems, you can use the make command to compile the project. For this example session, we will compile *OSP ²* to run without the GUI by issuing the command:

make runnogui

- Problems in compiling? If you think this could be due to stale .class files,

type make clean and then make to force recompilation of the entire project.

- To now run the project, type:

```
java -classpath .: osp.OSP -noGUI
```
2.5 Step 2: Examining the OSP.log **File**

Assuming for the moment that you have correctly implemented the THREADS project and *OSP ²* ran successfully to completion without errors, let us now take a look at a relevant snippet from the OSP.log file:

```
Sim: 63 [Memory.PageTableEntry]
        Unlocking Page(12:1/0). New lock count: 0
Sim: 63 [Threads.ThreadCB]
        Entering resume(Thread(0:1/W2))
Mod: 63 [Threads.ThreadCB]
        Resuming Thread(0:1/W2)
Sim: 63 [Threads.ThreadCB]
        Leaving resume(Thread(0:1/W1))
Mod: 63 [Hardware.Disk]
        Device(0) has no pending IORBs to dequeue
```
At simulation time 63, thread 0 of task 1 has exited the pagefault handler and is "resumed" by the student method do resume(). In this case, this means the thread moves from waiting-level 2 to waiting-level 1.

The log file also contains statistics about tasks and threads generated during our successful run of the THREADS project. It is a good idea to have a look at these too, both to see how well your implementation is performing and to simply get a better understanding of how threads behave in *OSP ²*.

```
TASKS and THREADS:
```

```
CPU Utilization: 61.382%
Average service time per thread: 36180.812
Average normalized service time per thread: 0.047044374
Total number of tasks: 4
Running thread(s): none
Threads summary: 18 alive
Among live threads: 0 running
                    6 suspended
                    0 ready
```

```
ready queue = ()running thread(s) = ()waiting thread(s) = (97:12,107:13,110:15,111:15,112:15,113:15)
thread(s) in pagefault = (110:15, 115:13, 124:13)killed thread(s) = (7:1,15:1,13:1,12:1,10:1,9:1)
```
2.6 Step 3: Introducing an Error into do resume()

Unfortunately, not all of your runs of *OSP ²* will be as successful as the one above: we all make programming mistakes, whether they be logical errors or simply typographical errors. Let us consider what happens when the latter occurs. In particular, suppose that in do resume(), instead of typing:

```
} else if (getStatus() > ThreadWaiting)
    setStatus(getStatus()-1);
```
you type:

} else if (getStatus() > ThreadWaiting) setStatus(getStatus()+1);

This is not an uncommon mistake: typing a plus sign when indeed you meant to type a minus sign. What are the consequences of this typo? Well, for one, *OSP ²* will terminate unsuccessfully at simulation time 63 and place the following output in the log file:

```
Sim: 63
[Threads.ThreadCB]
        Entering resume(Thread(0:1/W2))
Mod: 63 [Threads.ThreadCB]
        Resuming Thread(0:1/W2)
Sim: 63 <<Error!>> [Threads.ThreadCB]
        After do_resume(Thread(0:1/W3)): Thread status is
        ThreadWaiting3; should be ThreadWaiting1
        at osp.IFLModules.IflThreadCB.resume(IflThreadCB.java:1101)
        at osp.IFLModules.Event.notifyThreads(Event.java:130)
        at osp.Devices.DiskInterruptHandler.do_handleInterrupt
           (DiskInterruptHandler.java:114)
        at osp.IFLModules.IflDiskInterruptHandler.handleInterrupt
           (IflDiskInterruptHandler.java:107)
```

```
at osp.Interrupts.Interrupts.interrupt(Interrupts.java:48)
at osp.Hardware.CPU.interrupt(CPU.java:54)
at osp.IFLModules.IflIORB.voidCallback(IflIORB.java:238)
at osp.IFLModules.CallbackDiskInterrupt.voidCallback
   (IflDevice.java:604)
at osp.EventEngine.EventCallback.Activate(EventCallback.
   java:48)
at osp.EventEngine.EventDriver.go(EventDriver.java:119)
```

```
at osp.EventEngine.EngineThread.run(EngineThread.java:60)
```
As you can see, the simulator has detected our error! What follows the error message is a dump of the system-call stack which indicates the sequence of method calls that led to the problem. Not surprisingly, *OSP ²*'s IFL version of do resume is at the top of the stack, as it was in this "wrapper method" where the error was detected. In an actual debugging situation, you would use this information to isolate and repair the problem in your implementation of the do_resume() method.

To complete our example session, here are the statistics for tasks and threads that can be found in the log file at the end of our unsuccessful run.

```
TASKS and THREADS:
```

```
CPU Utilization: 28.57143%
Average service time per thread: 63.0
Average normalized service time per thread: 0.28125
Total number of tasks: 1
Running thread(s): none
Threads summary: 1 alive
Among live threads: 0 running
                    1 suspended
                    0 ready
ready queue = ()
running thread(s) = ()waiting thread(s) = (0:1)thread(s) in pagefault = (0:1)killed thread(s) = ()
```
3 Tasks*: Management of Tasks (a.k.a. Processes)*

3.1 Chapter Objective

The objective of the Tasks project is to teach students about task management in a modern-day operating system and to provide them with a wellstructured programming environment in which to implement task-management techniques. To this end, students will be asked to implement the *OSP ²* class TaskCB, the only class of package Tasks. TaskCB stands for *Task Control Block*, the *OSP ²* object used to represent tasks.

3.2 Conceptual Background

Like other modern operating systems, $\mathcal{OSP}2$ distinguishes between program execution and resource ownership. The former is captured through the concept of a **thread**, which represents a running program, and the latter is captured using the concept of a **task**. In older operating systems, like traditional Unix, the **process** filled both of these roles; actually, we sometimes use the term "process" as a synonym for task. In *OSP ²* , a task serves as a "container" for one or more threads, all executing the same code and sharing the same memory address space. Also associated with a task is a swap file containing an image of the task's address space, other files opened by the task's constituent threads, and the communication ports created by these threads. We say that these resources (memory, ports, files, etc.) are *owned* by the task and *shared* by the task's threads; this explains how the issue of resource ownership is organized around the concept of a task.

Threads are the schedulable and dispatchable units of execution in *OSP ²*. They are sometimes referred to as "lightweight processes" for it is much easier in a multiprogramming OS to switch the CPU from one thread to another than from one process to another, due to above-explained separation of program execution and resource ownership in an OS supporting the task/thread doctrine. We will have more to say about threads in the next chapter.

A task can be created or destroyed, newly created threads can be added to a task, and threads are deleted from the owner task's thread list after they are destroyed. There is also a system-wide notion of the **current task**, which is the task that owns the currently running thread. This thread is known as the **current thread** of the task.

In the rest of this chapter we describe TaskCB, the only class in the Tasks package. The class diagram of Figure [3.1](#page-57-0) puts TaskCB in context with related classes.

3.3 Class TaskCB

Tasks are represented by the class TaskCB, which is the only class to be implemented in the Tasks project. It is defined as follows:

```
\diamond public class TaskCB extends IflTaskCB
```
The following methods are to be implemented as part of this project:

```
\diamond public static void init()
```
This method is called at the very beginning of simulation and can be used to initialize static variables of the class, if necessary.

```
-
 public static TaskCB do create()
```
This method creates a new task object and then initializes it properly.

In *OSP ²*, creation of a task involves the creation of a task object, allocation of resources to the task, and various initializations. The task object is created using the default task constructor TaskCB(). First, a page table must be created using the PageTable() constructor, and associated with the task using the method setPageTable(). Second, a task must keep track of its threads (objects of type ThreadCB), communication ports (objects of type PortCB),

Figure 3.1 Overview of the package TASKS.

and files (objects of type OpenFile), which means that the appropriate structures have to be created. *OSP ²* does not have any specific requirements for these data structures, except that they must correctly maintain the inventory of threads, ports, and files attached to the task. Lists or variable-size arrays are good candidates.

Next, the task-creation time should be set equal to the current

simulation time (available through the class HClock), the status should be set to TaskLive, and the task priority should be set to some integer value. *OSP ²* does not prescribe what this value should be; it is determined by the requirements of the project and might be specified by the instructor (if, for example, the scheduling strategy implemented in the THREADS project uses task priorities).

The next important step is the creation of the swap file for the task. A swap file contains the image of the task's virtual memory space and thus is equal to the maximal number of bytes in the virtual address space of the task. In *OSP ²* this number is determined by the number of bits needed to specify an address in the virtual address space of a task, and is obtained using the following method: MMU.getVirtualAddressBits(). The name of the swap file is, by convention, the same as the task ID number, and the file itself resides in the directory specified by the global constant SwapDeviceMountPoint. To create the swap file, you should use the static method create() of class FileSys. Then the file has to be opened using the static method open() of OpenFile. The open() method takes a string that represents a full path name of a file and returns a run-time file handle that is used in the read, write, and close file operations. The resulting open-file handle should be saved in the task data structure using the method setSwapFile().

An open() operation can fail due to lack of space on the swap device. In this case the do create() method of TaskCB should dispatch a new thread and return null.

A task in *OSP ²* must have at least one live thread, so you need to create the first thread for the task using the static method create() of class Thread-CB. Finally, the TaskCB object created and initialized by your do create() method should be returned.^{[1](#page-58-0)4}

This method is called to destroy a task. First, it should iterate through the list of all live threads of the task and kill() them. (Recall that maintenance of this list is entirely the responsibility of your implementation.) Each time a thread is killed, the do_removeThread() method is called by the THREADS package. The do kill() method should then iterate over the ports attached to the task and destroy() them as well. Each request to destroy a port will eventually result in a call to your **do_removePort()** method. The status

⁻ public void do kill()

 1 There is no need to invoke the dispatch() method of ThreadCB in order to schedule a thread to run after the do create() system call is complete. Since a new thread is created as part of the process of task creation, dispatch() will be called by the create() method of ThreadCB. However, calling dispatch() before leaving do create() is harmless.

of the task should be set to TaskTerm (terminated task) and the memory previously allocated to the task should be released. The latter is accomplished by invoking the method deallocateMemory() of class PageTable on the page table of the task.

The last resource left to be released by the task is the set of files opened by the various threads of the task and the swap file of the task. The **open files table** of a task is a data structure that should be maintained as part of the implementation of class TaskCB and should include all files opened by the threads of the task (which are objects of class OpenFile); *OSP ²* does not prescribe how this should be done. To free up this resource, you must close() every file in the open files table.

You should keep in mind that each call to close() eventually results in a call to your method do_removeFile(). However, this might not happen immediately. When you close a file that is the target of an active I/O operation, i.e., an operation that is currently being processed by an external device such as a disk, the file is not closed immediately. Rather, the system will remember that the file needs to be closed and will re-issue the close() command when the I/O operation completes. Because of this possible delay, some files of the task can remain open for a period of time even after you perform the close() operation on every open file. This means, of course, that calls to your method do removeFile() might be similarly delayed.

Finally, the swap file of the task must be destroyed using method delete() of FileSys β The argument to this method is the name of the swap file (see the discussion of do create()).

```
\diamond public int do_getThreadCount()
```
This method must return a correct thread count, which must be maintained as part of the implementation of the do_create() and do_kill() methods.

```
\diamond public int do_addThread(ThreadCB thread)
```
This method is called by other parts of *OSP ²* whenever a new thread is created. The purpose of these calls is to notify TaskCB of the creation of a new thread so that the inventory of threads owned by the task can be properly updated. SUCCESS is to be returned unless the maximum number of threads for this task has been reached, in which case, FAILURE should be returned.

```
\diamond public int do_removeThread(ThreadCB thread)
```
This method is called when a thread is destroyed. The thread should be

² Closing a file does not deallocate the space; it merely removes the file handle and flushes the data on disk. Deleting a file removes a hard link to the file, and when the number of such links becomes zero, the file space is freed.

removed from the list of threads owned by the task. SUCCESS should be returned if the thread belongs to the task and FAILURE otherwise.

```
-
 public int do getPortCount()
```
Returns the number of ports owned by the task.

```
-
 public int do addPort(PortCB newPort)
```
This method is called when a new communication port is created by one of the task's constituent threads. It enables TaskCB to maintain the inventory of ports that belong to the task. If the maximum number of ports for this task has been reached, FAILURE should be returned. Otherwise, SUCCESS is returned.

```
-
 public int do removePort(PortCB oldPort)
```
This method is called when one of the task's communication ports is destroyed. The method should remove the port from the list of ports maintained by TaskCB. SUCCESS is to be returned if the port belongs to the task; FAILURE otherwise.

```
\diamond public void do_addFile(OpenFile file)
```
Adds file to the table of open files of the task. The implementation of the table is entirely up to the student. This method is typically called by the method open() of class OpenFile (indirectly, through the wrapper addFile()).

```
-
 public int do removeFile(OpenFile file)
```
Removes file from the table of open files of the task. This method is typically called by the method close() of class OpenFile. It returns SUCCESS if the file belongs to the task; FAILURE otherwise.

Relevant methods and fields defined in this and other packages.

The following public methods and fields of other classes are useful for implementing the methods of the Tasks project.

 \diamond final public void kill() $\qquad \qquad$ ThreadCB

Destroys the thread. Notice that this method calls your implementation of do removeThread() to disassociate the thread from the task.

Summary of Class TaskCB

The following table summarizes the attributes of class TaskCB and the methods for manipulating them. These attributes and methods are provided by the class IflTaskCB and are inherited. The methods appearing in the table are more fully described in Section [3.4.](#page-63-0)

- Identity: The identity of a task is set by the system, but it can be queried with the method getID().
- Page table: The page table of a task is set with the method $setPageTable()$ and can be retrieved using getPageTable().
- Status: The status of a task is handled using the methods setStatus() and getStatus().
- Priority: The status of a task is handled using the methods $setPriority()$ and getPriority().
- Current thread: Indicates which thread of a task is currently running. The methods to query and modify this attribute are getCurrentThread() and setCurrentThread().
- Creation time: The creation time of a task is handled using the methods getCreationTime() and setCreationTime().
- Swap file: A task's swap file is set and retrieved using the methods getSwapFile() and setSwapFile().
- Table of open files: Keeps track of all of the open files of a task, which are instances of class OpenFile. *OSP ²* does not impose any requirements to how this table is maintained as long as it properly keeps inventory of a task's open files. Two methods are used in conjunction with this table: addFile() and removeFile(). Calls to these methods by other packages are intended to notify a task as to which files it owns. In addition, when a task is destroyed, all its files must be closed. This is performed as part of the do kill() method, which must iterate through this table and close all the files in it. The do-versions of the $addFile()$ and $removeFile()$ methods are part of the Tasks project. Note that TaskCB never calls these methods—it *implements* them.
- Table of ports: Keeps track of all of the communication ports owned by a task. *OSP ²* does not define a specific variable by which to refer to this table, and the internal data structure used to implement it is entirely up to the student. However, the following methods are defined to manipulate this table: getPortCount(), addPort(), and removePort(). The first indicates how many open ports the task has; the second is used to attach a new port to the task; and the last is used to remove destroyed ports. The do-versions of these methods are part of the Tasks project. TaskCB *implements* these methods—it never calls them.
- Table of live threads: As with ports, *OSP ²* does not prescribe how this table is to be implemented. However, the following methods are defined to manipulate this table: getThreadCount(), addThread(), and removeThread() . The first method counts the number of live threads owned by the task, the second adds newly created threads to tasks, and the third method removes killed threads. The do-versions of these methods are implemented by the student. These methods are *implemented* by TaskCB— they are never called by this class.

3.4 Methods Exported by the Tasks **Package**

The following is a summary of the public methods defined in the classes of the Tasks package or in its superclasses. These methods can be used in the implementation of this or other student packages. To the right of each method we list the class of the objects to which the method applies. In the case of the Tasks package, all exported methods belong to a single class, TaskCB, which inherits them from the superclass IflTaskCB. In general, the public methods exported by a student package may belong to more than one class; see, for example, package MEMORY (Section [5.8\)](#page-108-0).

- final public int getPortCount() TaskCB Returns the number of ports owned by the task.

4 Threads*: Management and Scheduling of Threads*

4.1 Chapter Objective

Threads are the schedulable and dispatchable units of execution in *OSP ²* . The objective of the THREADS project is to teach students about thread management and scheduling in a modern-day operating system and to provide them with a well-structured programming environment in which to implement thread-management and scheduling techniques. To this end, students will be asked to implement the two public classes of the THREADS package: ThreadCB and TimerInterruptHandler. The former implements the most common operations on a thread, while the latter is a timer interrupt handler that can be used to implement time-quantum-based scheduling algorithms for threads. We begin this chapter with an overview of thread basics.

4.2 Overview of Threads

Multi-threading refers to the ability of an OS to support multiple threads of execution within a single task. There are at least four reasons why it is desirable to structure applications as multi-threaded ones:

Parallel Processing: A multi-threaded application can process one batch of

data while another is being input from a device. On a multiprocessor architecture, threads may be able to execute in parallel, leading to more work getting done in less time.

- Program Structuring: Threads represent a modular means of structuring an application that needs to perform multiple, independent activities.
- Interactive Applications: In an interactive application, one thread can be used to carry out the current command while, at the same time, another thread prompts the user for the next command. This pipelining effect can lead to a perceived increase in the speed of the application.
- Asynchronous Activity: A thread can be created whose sole job is to schedule itself to perform periodic backups in support of the main thread of control in a given application.
- Concurrency: Threads can execute concurrently. Thus, for example, a server process can service a number of clients concurrently: each client request triggers the creation of a new thread within the server.

We thus see that there is considerable incentive from an application programming perspective for an OS to support multi-threading.

Threads as Independent Entities. As explained in Chapter \mathbb{Z} , the resources available to a thread, such as memory, open files and communication ports, are those belonging to the task to which the thread is affiliated. That is, a task is a container for one or more threads and each of these threads has shared access to the resources owned by the task. There is, however, certain information associated with a thread that allows it to execute as a more or less independent entity:

- A thread execution state (Running, Ready, Blocked, etc.).
- \Diamond A saved thread context when not running. This context includes the contents of the machine registers when it was last running; in particular, every thread has its own, independent program counter.
- An execution stack.
- \Diamond A certain amount of per-thread static storage for local variables.
- Access to the memory and resources of its container task; it shares these resources with the other threads in that task.

 1 Not to be confused with the Java keyword static used to define a variable as a class variable or a method as a class method.

It is worth taking time to emphasize the implications of this last item. All the threads of a given task reside in the same address space and have access to the same data. Consequently, when one thread modifies a piece of data, the effect of this change is visible to the other threads should they subsequently decide to read this data item. If one thread opens a file with read access, the other threads in the same task will also be able to read from this file. It is thus imperative that when programming a multi-threaded application, the actions of the threads be carefully coordinated; otherwise conflicts could easily arise that could hinder the threads from performing their desired computation.

Scheduling Algorithms for Threads. As previously noted, threads are the schedulable units of execution in *OSP ²* and any other OS that supports threads. This represents a shift from older operating systems like traditional Unix in which processes played this role.^{[2](#page-68-0)} Thread scheduling is an integral part of multiprogramming: when the currently executing thread becomes blocked waiting for some event to occur, this represents a golden opportunity for the OS to perform a context switch so that a ready-to-run thread can be given control of the CPU. In this way, the CPU is kept busy most of the time, thereby increasing its utilization.

So what are the kinds of events that threads may block on? These include I/O interrupts and software signals. It should be noted, however, that an OS can decide to perform a context switch any time it is convenient, again for the purpose of improving system performance. Convenient in this case means any time control resides within the OS, and include occasions such as timer interrupts and system call invocations.

The question you must now ask yourself is which thread should the OS schedule next when a context switch is to take place? The decision taken here is critical; it can significantly impact a variety of performance-related measures, such as:

CPU utilization: the percentage of time the CPU is kept busy (not idle).

Throughput: the number of jobs or tasks processed per unit of time.

Response time: the amount of time needed to process an interactive command. Typically one is interested in the average response time over all commands.

Turnaround time: The amount of time needed to process a given task. Includes actual execution time plus time spent waiting for resources, including the CPU.

² Modern Unix implementations, like SUN's Solaris, IBM's AIX, and Linux, do, of course, support threads.

The answer to the question as to which thread to schedule next lies in the **CPU scheduling algorithm** the OS implements. A variety of scheduling algorithms have been proposed in the literature and they can be classified along the following lines:

- Emphasis on response time vs. CPU utilization. Algorithms of the former kind can be thought of as user-oriented and those of the latter kind as systemoriented.
- Preemptive vs. nonpreemptive. A preemptive algorithm may interrupt a thread and move it to the ready-to-run queue, while in the nonpreemptive case, a thread continues to execute until it terminates or blocks on some event. Several preemptive algorithms preempt a thread after it has finished up its "slice" or quantum of CPU time.
- Fair vs. unfair. In a fair algorithm, every thread that requires access to the CPU eventually gets time on the CPU. In the absence of fairness, **starvation** is possible and the algorithm is said to be unfair in this case.
- Choice of selection function. The selection function determines which thread, among the ready-to-run threads, is selected next for execution. The choice can be based on priority, resource requirements, or execution characteristics of the thread such as the amount of elapsed time since the thread last got to execute on the CPU.

We now briefly describe some of the more common scheduling algorithms that have been proposed. In describing these algorithms, we assume the existence of a **ready queue** where ready-to-run threads lie in wait for the CPU.

- First-Come-First-Served (FCFS) As the name indicates, threads are serviced in the order they entered the ready queue. This is probably the simplest scheduling algorithm that has been proposed and has the tendency to favor long, CPU-intensive threads over short, I/O-bound threads.
- Round Robin. Like FCFS but each thread gets to execute for a length of time known as the **time slice** or **time quantum** before it is preempted and placed back on the ready queue. Time slicing can be used to allow shortlived threads, corresponding to interactive commands, to get through the system quickly, thereby improving the system's response time.
- Shortest Thread Next (STN). This is a nonpreemptive policy in which the thread with the shortest expected processing time is selected next. Like round robin, it tends to favor I/O -bound threads. The scheduler must have an estimate of processing time to perform the selection function.
- Shortest Remaining Time (SRT). This is a preemptive version of STN in which the thread with the shortest expected remaining processing time is selected next. SRT tends to yield superior turnaround time performance compared with STN.
- Highest Response Ratio Next (HRRN). A nonpreemptive algorithm that chooses the thread with the highest value of the ratio of $R = \frac{w+s}{s}$, where R is called the response ratio, w is the time spent waiting for the CPU, and s is the expected service time. Favors short threads but also gives priority to aging threads with high values for w.
- Feedback. This algorithm, sometimes referred to as "multi-level round robin" utilizes a series of queues, each with their own time quantum. Threads enter the system at the top-level queue. If a thread gains control of the CPU and exhausts its time quantum, it is demoted to the next lower queue. The lowest queue implements pure round robin. The selection function chooses the thread at the head of the highest non-empty queue. Thus this algorithm penalizes long-running threads since each time they use up their time quantum, they are demoted to the next lower queue.
- Priority-Driven Preemptive Scheduling. The basic idea of this scheme is that when a thread becomes ready to execute whose priority is higher than the currently executing thread, the lower-priority thread is preempted and the processor is given to the higher-priority thread. Thread priorities may be computed statically (threads have a fixed priority that never changes) or adjusted dynamically (a thread's priority begins at some initial assigned value and then may change, up or down, during the thread's lifetime). The priority-driven preemptive approach to thread scheduling is especially important in operating systems that support **real-time** threads or processes, such as Linux, Unix SVR4, and Windows 2000/XP/Vista.

The rest of this chapter describes each class in the package THREADS in detail. These classes are placed in a larger context in the class diagram given in Figure 4.1 .

4.3 The Class ThreadCB

ThreadCB stands for **thread control block**; it is a class that contains all the structures necessary for maintaining the information about each particular thread. This class is defined as follows:

\diamond public class ThreadCB extends If1ThreadCB

Figure 4.1 Overview of the package THREADS.

Like other classes that belong to student projects, this class defines methods that start with do_ and that are wrapped with similarly named methods in class IflThreadCB. Before discussing the required functionality of the methods in ThreadCB we need to look deeper into the nature of *OSP ²* threads.

Figure 4.2 The state transition diagram for *OSP ²* threads.

State transitions. Thread management is concerned with two main issues: the life cycle of a thread (i.e., **creation** and **destruction** of threads) and maintaining thread status and moving threads between different queues and CPU (**suspension**, **resumption**, and **dispatching**). Therefore, to understand thread management in *OSP ²* it is important to understand the different states a thread can be in and how state transitions take place. Figure [4.2](#page-72-0) illustrates this issue.

When a thread is first created, it enters the ready state (ThreadReady), which means it must be placed on the queue of ready-to-run threads. *OSP ²* does not prescribe how this queue is supposed to be organized and it is entirely up to the student implementation, unless the instructor has specific requirements.

From then on, two things can happen: a ready-to-run thread can be **scheduled to run** (and **dispatched**) and gain control of the CPU (and thus change its status to ThreadRunning), or it can be **destroyed** (or **killed**) and change its status to ThreadKill.

A thread can be dispatched only if it has the status ThreadReady, but a live thread (i.e., one that has status *other than* ThreadKill) can be killed in any state, not only in the ready state. One sad thing about *OSP ²* threads is that they never die of natural causes: they either get destroyed by somebody else or self-destroy. In other words, there is no separate system call to terminate a thread normally and there is no special state to denote normal thread termination.

A running thread can be preempted and placed back into the **ready queue** or it can be suspended to the **waiting state**. The latter can happen due to a pagefault or when the thread executes a blocking system call, such as an I/O operation or a communication (sending or receiving a message). *OSP ²* does not place any restrictions on the way the ready queue is implemented, so you should use your own design. However, your instructor may have specific requirements to how scheduling is to be done. In this case, some designs might be much better than others.

An *OSP* 2 thread can be at several levels of waiting. When a running thread enters the pagefault handler or when it executes a blocking system call (e.g., $write()$, it enters the level 0 waiting state represented by the integer constant ThreadWaiting. Level 1 waiting state is represented by the constant ThreadWaiting+1, etc.

A thread is not always blocked when it enters a waiting state. For instance, when a thread causes a pagefault or executes a write() operation on a file, its waiting state signifies that in order to continue execution of the user program the thread needs to wait until the pagefault or the system call is finished. In other words, the thread switches hats: it leaves the user program and becomes a system thread. A system thread might do some work needed to process the request and then it might execute another system call. At this point, it would enter the waiting state at level 1, which signifies that the original thread has to wait for two system calls to complete. If the second system call is blocking $(e.g.,$ involves I/O , the execution of the thread will block until the appropriate event happens (e.g., the I/O completes).

To illustrate this process, consider processing of a pagefault (Chapter $\mathbb{5}$). When a pagefault occurs, the thread enters the level 0 waiting state, executes a page replacement algorithm and then makes a system call to write(). When the write() call starts execution, the thread's waiting level is bumped up to 1. After assembling a proper I/O request to the swap device, the thread will suspend itself on a blocking event, to wait for the I/O . At this point, the thread will be in state ThreadWaiting+2. When the I/O is finished, the resume() method is executed on the thread and it drops into the level 1 waiting state. When the write() system call is about to exit, another resume() is executed and the thread's wait level drops to 0 (i.e., its state becomes ThreadWaiting again). Next, while still in the pagefault handler, the thread would execute the read() system call and go into the waiting state at levels 1 and 2, similar to the write() call. When the read() operation is finished, the ensuing resume() operations will drop the thread to level 0 again. At this point, the pagefault handler performs some record-keeping operations (see Chapter [5\)](#page-83-0), executes a resume() operation and exits. This causes the thread to change its status from ThreadWaiting to ThreadReady.

In sum, an \mathcal{OSP} *2* thread can be suspended to several levels of depth by executing a sequence of nested suspend() operations. When all the corresponding events happen, the resume() method is called on the thread, which decreases the wait level by 1. When all the events on which the thread is suspended occur, the thread goes back into the ThreadReady state.

Context switching. Passing control of the CPU from one thread to another is called **context switching**. This has two distinct phases: **preempting** the currently running thread and **dispatching** another thread. Preempting a thread involves the following steps:

1. Changing of the state of the currently running thread from ThreadRunning to whatever is appropriate in the particular case. For instance, if a thread loses control of the CPU because it has to wait for I/O, then its status might become ThreadWaiting. If the thread has used up its time quantum, then the new status should become ThreadReady. Changing the status is done using the method setStatus() described later.

This step requires knowing the currently running thread. The call MMU. getPTBR() (described below) lets you find the page table of the currently scheduled task. The task itself can be obtained by applying the method getTask() to this page table. The currently running thread is then determined using the method getCurrentThread().

- 2. Setting the **page table base register** (PTBR) to null. PTBR is a register of the memory management unit (a piece of hardware that controls memory access), or MMU, which always points to the page table of the running thread. This is how MMU knows which page table to use for address translation. In \mathcal{OSP} 2, PTBR can be accessed using the static methods getPTBR() and setPTBR() of class MMU.
- 3. Changing the current thread of the previously running task to null. The current thread of a task can be set using the method setCurrentThread().

When a thread, t , is selected to run, it must be given control of the CPU. This is called **dispatching** a thread and involves a sequence of steps similar to the steps for preempting threads:

- 1. The status of t is changed from ThreadReady to ThreadRunning.
- 2. PTBR is set to point to the page table of the task that owns t . The page table of a task can be obtained via the method getPageTable(), and the PTBR is set using the method setPTBR() of class MMU.

3. The current thread of the above task must be set to t using the method setCurrentThread().

In practice, context switch is performed as part of the dispatch() operation, and steps 2 and 3 in the first list above can be combined with steps 2 and 3 of the second list.

In the degenerate case, when the running thread t is suspended and no other thread takes control of the CPU, consider it as a context switch from t to the imaginary "null thread". Likewise, if no process is running and the dispatcher chooses some ready-to-run thread for execution, you can view it as a context switch from the null thread to t.

Events. Before going on you must revisit Section $\overline{1.6}$, which describes the Event class.

The state transition diagram shows that to a large extent thread management is driven by two operations: suspend() and resume(). The suspend operation places a thread into a waiting queue of the event passed as an argument (and increases the wait level) and the resume operation decreases the wait level and, if appropriate, places it into the queue of ready-to-run threads (in which all threads are in the ThreadReady state). All this is accomplished using the Event class discussed in Section $\overline{1.6}$. Note that, as described earlier, a thread can execute several suspend operations on different events, so it might find itself in different waiting queues. The thread will be notified about the completion of these events in the order opposite to that in which the suspend() operations were performed. After all the relevant events have occurred, the thread is free to execute again and is placed on the ready queue.

Only the first method in class Event, addThread(), is really necessary for the Threads project, but other methods might be useful for debugging (and, of course, they are necessary for other *OSP ²* projects).

Methods of class ThreadCB**.** These are the methods that have to be implemented as part of the project. Their implementation requires support from other parts of OSP in the form of the methods that can be called from within ThreadCB to accomplish a specific objective. We discuss these methods as part of the required functionality and then give a summary of these methods in a separate section.

\diamond public static void init()

This method is called once at the beginning of the simulation. You can use it to set up static variables that are used in your implementation, if necessary. If you find no use for this feature, leave the body of the method empty.

\diamond public static ThreadCB do_create(TaskCB task)

The job of this method is to create a thread object using the default constructor ThreadCB() and associate this newly created thread with a task (provided as an argument to the do create() method). To link a thread to its task, the method addThread() of class IflTaskCB should be used and the thread's task must be set using the method setTask() of IflThreadCB.

There is a global constant (in IflThreadCB), called MaxThreadsPerTask. If this number of threads per task is exceeded, no new thread should be created for that task, and null should be returned. null should also be returned if addThread() returns FAILURE. You can find out the number of threads a task currently has by calling the method getThreadCount() on that task.

If priority scheduling needs to be implemented, the do create() method must correctly assign the thread's initial priority. The actual value of the priority depends on the particular scheduling policy used. *OSP ²* provides methods for setting and querying the priority of both tasks and threads. The methods are setPriority() and getPriority() in classes TaskCB and ThreadCB, respectively.

Finally, the status of the new thread should be set to ThreadReady and it should be placed in the ready queue.

If all is well, the thread object created by this method should be returned.

It is important to keep in mind that each time control is transferred to the operating system, it is seen as an opportunity to schedule a thread to run. Therefore, regardless of whether the new thread was created successfully, the dispatcher must be called (or else a warning will be issued).

```
\diamond public void do_kill()
```
This method destroys threads. To destroy a thread, its status must be set to ThreadKill and a number of other actions must be performed depending on the current status of the thread. (The status of a thread can be obtained via the method getStatus().)

If the thread is ready, then it must be removed from the ready queue. If a running thread is being destroyed, then it must be removed from controlling the CPU, as described earlier.

There is nothing special to do if the killed thread has status ThreadWaiting (at any level). However, you are not done yet. First, the thread being destroyed might have initiated an I/O operation and thus is suspended on the corresponding IORB. The I/O request might have been enqueued to some device and has not been processed because the device may be busy with other work. What should now happen to the IORB? Should you just let the

device work on a request that came from a dead thread?

The answer is that you should cancel the I/O request by removing the corresponding IORB from its device queue. This can be done by scanning all devices in the device table and executing the method cancelPendingIO() on each device. The device table is an array of size Device.getTableSize() (starting with device 0), where device i can be obtained with a call to Device.get().

During the run, threads may acquire and release shared resources that are needed for the execution. Therefore, when a thread is killed, those resources must be released into the common pool so that other threads could use them. This is done using the static method giveupResources() of class Resource-CB, which accepts the thread be killed as a parameter.

Two things remain to be done now. First, you must dispatch a new thread, since you should use every interrupt or a system call as an opportunity to optimize CPU usage. Second, since you have just killed a thread, you must check if the corresponding task still has any threads left. A task with no threads is considered dead and must be destroyed with the kill() method of class TaskCB. To find out the number of threads a task has, use the method getThreadCount() of TaskCB.

\diamond public void do_suspend(Event event)

To suspend a thread, you must first figure out which state to suspend it to. As can be seen from Figure $\boxed{4.2}$, there are two candidates: If the thread is running, then it is suspended to ThreadWaiting. If it is already waiting, then the status is incremented by 1. For instance, if the current status of the thread is ThreadWaiting then it should become ThreadWaiting+1. You now must set the new thread status using the method setStatus() and place it on the waiting queue to the event.

If suspend() is called to suspend the running thread, then the thread must lose control of the CPU. Switching control of the CPU can also be done in the dispatcher (as part of the context switch), but it has to be done somewhere to avert an error.

Finally, a new thread must be dispatched using a call to dispatch().

 \diamond public void do_resume()

A waiting thread can be resumed to a waiting state at a lower level (e.g., ThreadWaiting+2 to ThreadWaiting+1 to ThreadWaiting or from ThreadWaiting to the status ThreadReady). If the thread becomes ready, it should be placed on the ready queue for future scheduling. Finally, a new thread should be dispatched.

has no "holes".

Note that there is no need to take the resumed thread out of the waiting queue to any event. A typical sequence of actions that leads to a call to resume() is as follows: When an event happens, the method notifyThreads() is invoked on the appropriate Event object. This method examines the waiting queue of the event, removes the threads blocked on this event one by one, and calls resume() on each such thread. So, by the time $d\rho$ -resume() is called, the corresponding thread is no longer on the waiting queue of the event.

\diamond public static int do_dispatch()

This method is where thread scheduling takes place. Scheduling can be as simple as plain round-robin or as complex as multi-queue scheduling with feedback. *OSP ²* does not impose any restrictions on how scheduling is to be done, provided that the following conventions are followed.

First, some thread should be chosen from the ready queue (or the currently running thread can be allowed to continue). If a new thread is chosen, *context switch* must be performed, as described earlier, and SUCCESS returned. If no ready-to-run thread can be found, FAILURE must be returned.

Relevant methods defined in other packages. Apart from the methods of the Event class listed above, the following methods of other classes should or can be used to implement the methods in class ThreadCB as described above:

 \diamond public void cancelPendingIO(ThreadCB th) \hfill Device The context for this method is a device object, and the method cancels pending IORBs of the thread th on that device. This is done when th is killed to prevent the servicing of pending I/O 's requested by killed threads. However, this method does not cancel the IORB that is currently being serviced by the device. The device is just allowed to finish.

 \diamond final static public PageTable getPTBR() $\qquad \qquad \mathsf{MMU}$ This method returns the value of the page table base register (PTBR) of the MMU. PTBR holds a reference to the page table of the currently running task.

- public int addThread(ThreadCB thread) TaskCB Attaches a newly created thread to task. Returns SUCCESS or FAILURE.
- \diamond public int removeThread(ThreadCB thread) \hfill TaskCB Removes killed thread to task. \diamond public ThreadCB getCurrentThread() \hfill TaskCB
- Returns the current thread object of the task. \diamond public void setCurrentThread(ThreadCB t) \hfill TaskCB Sets the current thread of the task to the given thread.
- final public int getPriority() TaskCB Tells the priority of the task.
- \diamond final public void setPriority(int p) \hfill TaskCB Sets the priority of the task. The setPriority()/getPriority() methods are provided for convenience, in case priority scheduling is used and dispatching takes into account the priority of both the task and the thread.
- final public PageTable getPageTable() TaskCB Returns the page table of the task.

 \diamond public static void giveupResources(ThreadCB thread) $\;$ ResourceCB $\;$ Releases all abstract shared resources held by the thread. Note: these resources do not include concrete resources such as memory or CPU.

Summary of Class ThreadCB

The following table summarizes the attributes of class ThreadCB and the methods for manipulating them. These attributes and methods are provided by the class IflThreadCB and are inherited. The methods appearing in the table are more fully described in Section [4.5.](#page-81-0)

- Task: The task that owns the thread. This property can be set and queried via the methods setTask() and getTask().
- Identity: The identity of a thread can be obtained using the method getID(). This property is set by the system.
- Status: The status of the thread. The relevant methods are setStatus() and getStatus().
- Priority: The priority of the thread. The methods to query and change thread's priority are setPriority() and getPriority().
- Creation time: The value of this property can be obtained using the method getCreationTime().
- CPU time used: The total CPU time used by the thread can be obtained via the method getTimeOnCPU().

4.4 The Class TimerInterruptHandler

This class is much simpler than ThreadCB. It is defined as

public class TimerInterruptHandler extends IflTimerInterruptHandler

and contains only one method:

 \diamond public void do_handleInterrupt()

This method is called by the general interrupt handler when the system timer expires. The timer interrupt handler is the simplest of all interrupt handlers in \mathcal{OSP} *2*. Its main purpose is to schedule the next thread to run and, possibly, to set the timer to cause an interrupt again after a certain time interval. Resetting the times can also be done in the dispatch() method of ThreadCB instead, because the dispatcher might want to have full control over CPU time slices allocated to threads.

Relevant methods defined in other packages. The following is a list of methods that belong to other classes and might be useful for implementing do handleInterrupt():

- \Diamond final static public void set(int time) $\qquad \qquad \text{HTimer}$ Sets the hardware timer to time ticks from now. Cancels the previously set timer, if any.
- \diamond final static public int get() $\qquad \qquad \text{HTimer}$ Returns the time left to the next timer interrupt.

4.5 Methods Exported by the Threads **Package**

The following is a summary of the public methods defined in the classes of the Threads package or in the corresponding superclasses, which can be used to implement this and other student packages. To the right of each method we list the class of the objects to which the method applies. In the case of the Threads package, all exported methods belong to the class TaskCB, which inherits them from the superclass IflTaskCB.

- \diamond final public static ThreadCB create() $\hspace{1cm}$ ThreadCB This method is a wrapper around the method do create() described in this chapter. It is provided by IflThreadCB and is inherited by ThreadCB. Returns the created thread.
- \diamond final public static void dispatch() \hfill ThreadCB This is a wrapper around the method do dispatch() described in this chapter. This method is provided by IflThreadCB and is inherited by ThreadCB.
- \diamond final public void suspend(Event event) \hfill ThreadCB This is a wrapper around the method **do_suspend** () described in this chapter. This method is provided by IflThreadCB and is inherited by ThreadCB.

for convenience, in case the assignment calls for priority scheduling. *OSP ²* does not actually care how priority is used, if at all.

5 Memory*: Virtual Memory Management*

5.1 Chapter Objective

The objective of project Memory is to teach students about virtual memory and other modern memory-management techniques and to provide them with a well-structured programming environment in which to implement these techniques. To this end, students will be asked to implement the five public classes of the Memory package. The main class, MMU, represents the memorymanagement unit, the piece of hardware that is responsible for memory access in a computer. The other classes are FrameTableEntry, PageFaultHandler, PageTableEntry, and PageTable. All of these classes are described in detail later on in the chapter, each in its own subsection. We begin with an overview of memory-management basics.

5.2 Overview of Memory Management

In a modern computer, the portion of the circuitry called the **memory management unit** (abbr. MMU) is responsible for providing access to main memory. In *OSP ²*, memory access is simulated by calling the method refer() of the class MMU, which is one of the key methods to be implemented in this project. It may seem strange at first that you are being asked to implement a piece of hardware as part of an operating systems programming project. However, the

MMU is the gateway to memory for executing threads, and it provides you with a golden opportunity to implement the memory-management technique your Memory assignment calls for.

Memory management and multiprogramming. Modern memorymanagement techniques are aimed at supporting multiprogramming and must therefore allow multiple processes or threads to be memory-resident simultaneously. In this way, when the currently executed thread becomes blocked, e.g. waiting for an I/O request to complete, control of the CPU can be easily switched to another memory-resident thread, albeit one that is in the ready state waiting to resume execution.

Partitioning memory. The basic memory-management technique in support of multiprogramming is to partition main memory into, shall we say, partitions or chunks of memory that different processes can occupy. Partitions can be either fixed-size or variable-size. The former results in internal fragmentation, which occurs when a process does not utilize the entirety of a partition. The latter results in external fragmentation, which occurs when a partition is too small to be of use to any process. We shall focus the remainder of our overview of memory-management basics on the fixed-sized partitions utilized by a technique known as paging. Segmentation is an alternative to paging that uses variable-size partitions.

Logical memory. The big advance in memory management came with the realization that the memory allocated to a process need not be contiguous! In the case of paging, a partition is called a page and a process's pages collectively make up its logical address space. Physical memory is divided into page frames, each the size of a page so the fit of a page in a page frame is exact. Thus, in theory, a page of a process can be placed in any available page frame. The point is that the pages of a process's logical address space may be dispersed noncontiguously among the page frames of main memory. Page sizes typically range from 512 bytes to 4K bytes but whatever the page size, it is fixed throughout system execution.

The primary mechanisms used for implementing logical memory are the **page table base register** (abbr. PTBR) and the **page table**. The key issue here is logical address translation, how to convert a logical address into a physical address, and this is the responsibility of the MMU. A logical address is just string of bits (e.g. 32 in the case of a 32-bit machine architecture) that can be logically viewed as consisting of two parts: a page number and a byte offset into the page. The number of bits taken up by the first part will depend on the page size: 9 for a page size of 512 bytes, 10 for a page size of 1K bytes, etc. The remainder of the address bits are interpreted as the byte offset into the logical page being addressed.

Every process has a page table of its own and when a thread is dispatched on the CPU, the address of the page table of the process to which the thread belongs is placed in the PTBR. The MMU uses the PTBR to find the location of the page table and uses the page table to supply the mapping between the logical memory of processes and the main memory of the computer, represented by the physical page frames. The overall schema is depicted in Figure [5.1.](#page-85-0)

Figure 5.1 Logical/Virtual address translation using page tables.

Virtual memory. The simple memory-addressing mechanism just described works well as long as the frames corresponding to the pages of a process are all in main memory. However, as seen in Figure [5.1,](#page-85-0) some entries in a page table do not necessarily have to have frames assigned to them. The key insight behind virtual memory is that a page table can have more entries than the number of physical page frames, so a one-to-one assignment of frames to pages might not be possible. In other words, the size of virtual memory can and normally does exceed that of physical memory. Note that we use the term virtual memory now instead of logical memory to emphasize the fact that larger-thanphysical-memory address spaces are supported by this scheme.

Pagefaults. The key mechanism for implementing virtual memory is that each page table entry has a **validity bit**, which indicates whether the page has a main-memory frame assigned to it. This bit is checked by the MMU hardware and whenever a running thread makes a reference to a page whose validity bit is zero, a **pagefault** occurs: a special kind of interrupt that is used to notify the operating system of references to frame-less pages. The intended response from the OS is to assign a suitable frame to the page. The module responsible for this action is called the **pagefault handler**. A page whose validity bit is one (i.e. has a page frame assigned to it) is said to be *valid*.

Before examing the steps involved in handling a pagefault, let us first look more carefully at frame-less pages and their relationship to other resources owned by processes. If no frame is assigned to a page, where is the program code or data that the running thread is supposedly referencing? The answer is that a copy of the entire process space is kept in secondary storage on a **swap device**. In high-performance systems, a swap device can be a separate disk, but typically it is just a partition occupying part of a physical disk. Nevertheless, the operating system assigns a **logical device** to each such partition and at that level the swap device can be viewed as a separate device with its own characteristics and device number. In particular, in *OSP ²*, a swap device is viewed as a real device with a special device number, SwapDeviceID. Thus, every process (i.e., OSP task) has a corresponding **swap file** on the swap device, which contains an exact image of the process memory.

When a pagefault on page P of task T occurs, the pagefault handler has to do several things:

- 1. Suspend the thread that caused the interrupt until the situation that gave rise to the pagefault is rectified. This is done by creating a *new* event, pfEvent, of type SystemEvent and then executing suspend() on the thread using pfEvent as a parameter. A new system event is created using the constructor SystemEvent() of class SystemEvent. This event must be kept around until the end of pagefault processing, as it is needed to resume the thread before returning from the pagefault handler.
- 2. Find a suitable frame to assign to page P.
	- An obvious choice would be a free frame, i.e., a frame that is not assigned to any other page (of this or any other task). But there might not be such a frame at the moment (remember that there are fewer frames than pages!). In this case, **page replacement** must be performed, as described below. The result of a successful page-replacement action is that a free frame becomes available and is assigned to page P.
- 3. Perform a *swap-in*.

Once a frame is assigned to the faulty page, you need to make sure that it

contains the exact image of the page, which is available in the task's swap file. To do this, the pagefault handler must initiate a *swap-in*: a file read operation that would input the requisite page from the swap device and store it in the frame.

4. Suspend the pagefault handler.

An I/O operation takes time, so the pagefault handler must suspend itself until it is woken up by the disk interrupt coming from the swap device. Suspension of the pagefault handler actually happens as part of the file read operation that swaps the page in—you do not need to do this explicitly.

5. Finish up.

Once the image of the right page is copied into the frame, the pagefault handler should update the page table to make sure that the page entry is pointing to the right frame, and set the validity bit of the page appropriately. Next, the thread that caused the pagefault should be resumed and placed on the queue of the ready-to-run threads. This is done by executing the method notifyThreads() on the event pfEvent, which was created in Step \mathbb{I} Finally, as with any other interrupt handler, the dispatcher should be called to give control of the CPU to some ready-to-run thread.

Page replacement. In describing the actions of the pagefault handler, we deliberately omitted a saga of its own: What should you do if, in Step \mathbb{Z} , the pagefault handler cannot find a free frame? In this case, it becomes necessary to choose a frame F' occupied by some other page P' and use F' to satisfy the pagefault. The page P' is often called a **victim page** and it is said that the pagefault handler *evicts* this page from its frame.

The algorithm deployed by the pagefault handler for choosing such a frame is called the page-replacement algorithm, and the most well-known algorithm of this kind is LRU (Least Recently Used). LRU replaces the page in memory that has not been referenced for the longest time. Assuming that threads exhibit the principle of locality, meaning that they cluster memory references around a certain subset of their pages over a given window of time, then the LRU page should be the least likely page to be referenced in the near future and its replacement is a good bet.

The problem with the LRU policy is that it can be difficult to implement and for this reason other algorithms have been developed to approximate the performance of LRU while imposing little overhead. Many of these algorithms

¹ Handling disk interrupts is part of another project, module Devices. In the present project, one should assume that the disk interrupt handler functions according to the specifications given below.

are variants of a scheme known as the **clock policy**, which associates one or more **use bits** with each frame and organizes the frames as a circular buffer. Consider for simplicity the case of a single use bit added to each frame. A frame's use bit is set to 1 when a page is first loaded in the frame and whenever the page in the frame is referenced. When it comes time to replace a page, the clock algorithm scans the buffer looking for a frame with a use bit of zero; the page occupying the first such frame is chosen for replacement. Each time it encounters a frame with a use bit of 1, it resets that bit to zero and moves on to the next frame in the buffer. The use of multiple use bits per frame increases the algorithm's precision: the more use bits per frame deployed, the more closely the algorithm is able to approximate LRU.

From a performance perspective, a good page-replacement algorithm is characterized by a low pagefault rate. However, as far as the operating system is concerned, the only requirement of a page-replacement algorithm is that there should be no "undesirable side effects". One such side effect is due to the nature of the I/O subsystem. Suppose that a page-replacement algorithm chooses a frame F' that is involved in an active I/O operation. In some cases, a device that started an I/O cannot be stopped. So if you reuse the corresponding frame for some other purpose then the data in the frame may become corrupted (in case of a file-read operation) or, in case of a write operation, the data being written out might become corrupted if you change the content of the frame before the I/O is finished. Even if the device can be stopped immediately, it might still not be a good idea because stopping the device now might mean that the same I/O operation would have to be re-issued later.

Locking and unlocking of frames. How can an OS protect the frames associated with active I/O operations? A typical mechanism is to keep, for each frame, a count of the active or outstanding I/O operations that involve that frame. There are a variety of ways to maintain such a count. Here is an explanation of how it is done in \mathcal{OSP} *2*. When an I/O operation is to be performed on a certain I/O device, an I/O request block (abbr. IORB) is enqueued on the device's device queue. An IORB does not refer to frames directly. Instead, it references the *page* that is involved in the I/O. The thread that requested the I/O must perform a lock() operation (which is a method of class PageTable-Entry) on the page involved. If no frame is assigned to the page, a pagefault occurs, and the IORB will not be enqueued on the device until the pagefault processing is over. The lock() operation increments the **lock count** of the frame associated with the page and the unlock() operation decrements it. A page is considered to be locked in a frame if the lock count of the associated frame is a positive number.

Thus, by the time the IORB makes it to the device queue, the page involved

is locked and has an associated frame. The page-replacement mechanism is prohibited from taking frames that have positive lock counts.

Note that a page involved in an I/O is locked into a frame when the corresponding IORB is *enqueued* on the device queue of the device in question (a device might be busy and have a queue of outstanding $I/O's$, not when the IORB is selected for processing by the device. The reason should be obvious: To perform an I/O, the page referenced by the IORB must be in some frame in main memory. If not, it would have to be swapped in. But this requires another I/O and takes time. So, the selected IORB cannot be processed and the device would remain idle. In contrast, if pages are locked just before the IORB is enqueued, the corresponding frames would remain protected for the entire period while the IORB remains on the device queue (and until the device finishes the corresponding I/O). If the page being locked is frame-less, a pagefault occurs and the page is brought in *before* the IORB is selected for processing.

Dirty frames. Locking is not the only constraint that a page-replacement mechanism must abide by. Another issue has to do with so-called **dirty frames**. A dirty frame is one whose contents has been changed since the last time a page was swapped into the frame. If such a frame is chosen for replacement, the current contents of the frame must be saved in the swap file of the task that owns the page that currently occupies the frame. Otherwise, all changes made to the page will be lost. Thus, each frame needs another bit, the **dirty bit**, which indicates whether the contents of the frame has been changed. The actions that change the contents of a frame are the memory operation (MemoryWrite) and the I/O operation read(), which transfers data from a file to main memory.

Thus, we see that finding a victim page and evicting it is no simple matter: It may require an extra I/O operation to *swap-out* the victim page and synchronize its contents with the contents of that page in the swap file.

Frame table. Information about physical, main-memory frames is kept in the **frame table**: an array that has one entry per frame. Each entry is an object of the class FrameTableEntry. In fact, an *OSP ²* frame table contains more information than that. For instance, each frame entry contains a back reference to the page that occupies that frame (or null). Every frame entry also has a so-called **reference bit**, which indicates whether the frame has been *referenced* (as the result of executing refer() or due to I/O into or out of the frame). The reference bit often plays a role (as a use bit) in page-replacement algorithms.

In real computers, the reference and dirty bits are set in hardware but they are unset by software using special instructions. In contrast the lock count and the page reference in the frame table are manipulated entirely in software. In *OSP ²* you have to set and unset all of these items in software. In this sense, part of what you will do to implement the refer() method is really a simulation of various hardware functions. This includes setting the dirty and the reference bits, and also causing the pagefault interrupt itself. We describe these issues in more detail in Section [5.6.](#page-99-0)

Reserved frames. In *OSP ²*, frames have yet another bit, the **reserved bit**. Like the lock count, a reserved bit protects frames from the pagereplacement mechanism, but it is used for a different reason. Suppose a thread Th causes a pagefault on page P and control is transferred to the pagefault handler after blocking $Th.$ The pagefault handler may go through several distinct phases:

- 1. Finding a suitable frame F . Suppose F is dirty and is currently occupied by page P' .
- 2. Evicting P' by issuing an I/O operation that swaps P' out.
- 3. Waiting for the I/O to finish.
- 4. Initiating an I/O to swap page P into frame F .
- 5. Waiting for the I/O to finish.
- 6. Putting Th on the ready queue and quitting.

The problem is that while locking will prevent F from being grabbed by other threads *during* phases \mathbb{Z} and \mathbb{Z} nothing prevents it from being grabbed to satisfy other pagefaults between phases \Box and \Box , between phases \Box and \Box , and after phase $5.$ Thus, it might well happen that after trying so hard to assign a suitable frame to page P , the pagefault handler will find the frame stolen from under its nose before it gets a chance to assign F to P . To prevent this kind of unproductive behavior, the pagefault handler must *reserve* frame F in phase \Box and *un-reserve* it in phase [6.](#page-90-4)

Prepaging. Some pagefault handling algorithms perform **prepaging**, i.e., the swapping in of invalid pages that *did not* cause the pagefault. These algorithms are trying to guess which pages might be referenced by the thread in the near future and swap them in proactively. To implement prepaging, the pagefault handler can issue additional read() operations, which might require write() operations to swap some other pages out.

Prepaging a page is similar to bringing a page in as part of regular pagefault processing. However, selecting a frame for prepaging should be done with caution. In particular, make sure that it is not the frame that was selected for the original faulty page. Otherwise, you will end up evicting the page that the pagefault handler was supposed to make valid!

Since prepaging involves I/O , it is possible that the thread that initiated the pagefault will be killed by the time prepaging is finished. When this happens, prepaging should stop. One special case arises when prepaging is done from within the pagefault handler. The question then is what should be the return code for do handlePageFault(): SUCCESS or FAILURE? *OSP ²* expects FAILURE in this case. In particular, if the page that caused the pagefault became valid before the thread was killed, the page should be made invalid again prior to returning from the pagefault handler. However, you should realize that a more optimized operating system might make a different decision and keep such a page valid, because it might be used by other threads of the same task.

Proactive page cleaning. Some memory-management algorithms perform proactive page cleaning by periodically swapping them out on disk (but not invalidating them). The idea is to utilize the times when the swap device is idle and reduce the time needed to handle pagefaults by increasing the supply of clean pages.

Technically, this is done by setting up **daemons**: special system threads that are set to wake up periodically, perform the job assigned to them, and go back to sleep. We discussed the *OSP* 2 support for daemons in Section [1.7.](#page-29-0)

In order to set up a cleaning daemon, one creates a class that implements DaemonInterface (see Section $\boxed{1.7}$). The required method unleash() can then be made to execute the proactive cleaning algorithm. An essential part of this algorithm is a series of write() operations that write dirty frames out to the swap device (but keeps these pages valid). This daemon must be registered with the system at startup, as explained in Section \Box .

Having surveyed the major issues involved in pagefault handling, we are now ready to discuss the actual *OSP ²* classes and methods that constitute the MEMORY module. The class diagrams of Figure [5.2](#page-92-0) and Figure [5.3](#page-93-0) place these classes in a larger context.

5.3 Class FrameTableEntry

This class implements the entries in the frame table, the main repository of information about the status of the main-memory frames. It is defined as follows:

 \diamond public class FrameTableEntry extends IflFrameTableEntry

Figure 5.2 Overview of the package MEMORY, I.

The class constructor is the only method of this class that needs to be implemented as part of the project:

```
-
 public FrameTableEntry(int frameID)
```
Calls super(frameID) and might perform other initializations if the student implementation defines additional fields in this class.

Memory

Figure 5.3 Overview of the package MEMORY, II.

However, this class inherits a number of methods from its superclasses, and these methods are used by other classes in this project:

- public final int getLockCount() Returns the lock count of the frame.
- final public void incrementLockCount() Increments the lock count of the frame by 1.

 \diamond final public void decrementLockCount() Decrements the lock count of the frame by 1.

Summary of Class FrameTableEntry

The following table summarizes the attributes of the class FrameTableEntry and the methods for setting and querying them. These attributes and methods are all inherited from class IflFrameTableEntry and are described in more detail in Section [5.8.](#page-108-0)

- Reserved flag: Indicates if a thread has reserved this frame. The corresponding methods are isReserved(), getReserved(), setReserved(), and setUnreserved().
- Dirty flag: The methods for manipulating the dirtiness of a frame are isDirty() and setDirty().
- Reference flag: Indicates if the frame has been referenced. The methods that handle this attribute are getreferenced() and setreferenced().
- Lock count: This attribute represents the number of times the frame has been locked minus the number of unlock operations performed on the frame, and is accessed using the methods getLockCount(), incrementLockCount(), and decrementLockCount().
- Identity: The identity of a frame is its sequence number in the system-wide array of all main-memory frames. It can be queried using the method getID().
- Page: This is the page that occupies the frame (null, if the frame is free). This attribute can be set using setPage() and retrieved using getPage().

It should be noted that some information (such as page information and identity) in the *OSP ²* frame table entries is redundant and is not present in the frame table of a typical operating system. In fact, the *OSP ²* frame table can be seen as a cross between a normal frame table and what is known as an **inverted page table**.

5.4 Class PageTableEntry

This class implements the data structure that describes each entry in the page table. It is defined as follows:

\diamond public class <code>PageTableEntry</code> extends <code>IflPageTableEntry</code>

For this project, the student must implement the following methods of this class:

- public int do lock(IORB iorb)

The ultimate goal of this method is to increment the lock count of the frame associated with the page. However, the details are not as simple as one might think, because the page might be invalid at the time the lock operation is performed.

Thus, this method must first check if the page is in main memory by testing the validity bit of the page (using the method isValid()). If the page is invalid, a pagefault must be initiated.

To initiate a pagefault, the do lock() method calls the static method handlePageFault() of class PageFaultHandler, i.e., it calls the pagefault handler directly, without initiating an interrupt. Note that page locking is performed as part of an I/O request, when the CPU is already in kernel mode, so there is no need to cause an interrupt.

We have already seen that page locking involves considerably more than simply incrementing the lock count. Yet, there is still much more to do. Consider the following situation. Suppose thread Th_1 of task T makes a reference to page P either via the **refer()** operation or through locking. If the page is invalid, a pagefault is initiated. Suppose now that thread Th_2 of the same task comes along and also wants to lock the same page P. Should this cause a pagefault as well? The answer, of course, is no. The pagefault handler must already have found a suitable frame for P and the corresponding I/O requests must already be in the pipeline. Another pagefault would only confuse the system.

To help identify the pages that are involved in a pagefault, *OSP ²* provides the method getValidatingThread(). When applied to a page, this method returns the thread that caused a pagefault on that page (or null, if the page is not involved in a pagefault). In our case, this method would return Th_1 .

The proper action for Th_2 depends on whether $Th_2 = Th_1$. If $Th_2 = Th_1$, then the proper action is to return right after incrementing the lock count.

² You might be wondering how a thread that caused a pagefault can come back and request a lock on the page. The answer is simple: The lock can be requested by the swap-in I/O operation that must be performed as part of pagefault handling. This swap-in operation is performed on behalf of the same thread that caused the pagefault, so the locking thread and the validating thread would be one and the same.

If $Th_2 \neq Th_1$, then the proper action is to wait until P becomes valid. This is easy to accomplish because the class PageTableEntry happens to be a subclass of Event (see Section $\overline{4.3}$ for the description of this class). Thus, we can execute the suspend() method on Th_2 and pass page P as a parameter.

When the page becomes valid (or if the pagefault handler fails to make the page valid, say, because the original thread, $Th₁$, that caused the pagefault was killed during the wait), the threads waiting on the page will be unblocked by the pagefault handler (which is another class in this project) and will be able to continue. When such threads become unblocked inside the $do_lock()$ method, control falls through the call to suspend() and the do lock() method must exit and return the appropriate value: SUCCESS if the page became valid as a result of the pagefault and FAILURE otherwise.

In general, $do_lock()$ returns SUCCESS if the page was locked successfully (which does not necessarily involve a pagefault) or FAILURE if the page was not locked. The latter can happen if either the pagefault (which might occur due to locking) fails or if the thread that created iorb was killed while waiting for the lock operation to complete.

Finally, in the case of a successful return, you should remember to increment the lock count of the frame associated with the page, i.e., to do the actual locking. (Note that the focus of the previous discussion was on ensuring that the page is associated with a frame.) Incrementing the lock count of a frame is accomplished using method incrementLockCount() of class FrameTable-Entry.

 \diamond public void do_unlock()

Unlocking is, fortunately, much simpler than locking. All that is needed is to decrement the lock count via a call to decrementLockCount() of class FrameTableEntry. Make sure that the lock count does not become negative, which is a sign of a problem.

Relevant methods defined in other classes. The following is a list of methods from other classes that can be useful in implementing the methods of class PageTableEntry:

 \diamond final public ThreadCB getValidatingThread() PageTableEntry Returns the validating thread of the page, i.e., the thread that caused the pagefault on this page. If the page is not in pagefault or its validating thread was killed before the page became valid, then this method returns null. This method is inherited from a superclasses of PageTableEntry. \diamond final public void suspend(Event event) ThreadCB Suspends the thread on which this method is called and puts the thread on the waiting queue of event. \diamond final public int getStatus() $\qquad \qquad$ TaskCB Returns the task's status. - final public int getStatus() ThreadCB Returns the status of this thread. \diamond public final boolean isValid() $\qquad \qquad$ PageTableEntry Tells if the page is valid by checking the validity bit. \diamond public final boolean isReserved() $\qquad \qquad$ FrameTableEntry Tests if the frame is reserved. \diamond public final ThreadCB getThread() $10RB$ Returns the thread that requested the I/O. \diamond final public int getDeviceID() $10RB$ Returns the device involved in the I/O operation. \diamond final public int getIOType() $10RB$ Returns the I/O type represented by the IORB. *OSP ²* supports two types:

FileRead and FileWrite.

Summary of Class PageTableEntry

The following is a summary of the main attributes of class PageTableEntry and the methods for manipulating them. See Section [5.8](#page-108-0) for a description of these methods.

Validity flag: The validity flag is handled by the methods isValid() and setValid().

Frame: If the page is valid, there must be a frame associated with it, which is described by this attribute. The corresponding methods are getFrame() and setFrame().

- Identity: The identity of a page is its sequence number in the corresponding page table. It is set automatically by the system and can be queried using getID().
- Owner task: Points to the task that owns the page and is queried using method getTask() of PageTableEntry. This attribute is not really stored with the page; it is rather an attribute of the table to which the page belongs. Thus, this method simply queries the corresponding attribute of the page table.
- Validating thread: If the page is currently in pagefault processing, this is the thread that caused the pagefault. This thread can be obtained using the method getValidatingThread() and is set using setValidatingThread().

5.5 Class PageTable

The class PageTable represents page tables and is defined as follows:

```
\diamond public class <code>PageTable</code> extends <code>IflPageTable</code>
```
The only mandatory method to be implemented here is the class constructor:

```
-
 public PageTable(TaskCB ownerTask)
```
This constructor gets as a parameter the task for which the table is to be created. It first calls super(ownerTask), as all *OSP ²* constructors must do, and then constructs the page table. The page table is assumed to be an array of size equal to the maximum number of pages allowed, and is accessible through the variable pages inherited from the superclass Ifl-PageTable. The maximal number of pages allowed is calculated using the method MMU.getPageAddressBits(), which represents the number of bits dedicated to representing a page number out of the total number of bits in an address.

After calling super(), the variable pages must be initialized to a new array of PageTableEntry whose size is determined as described above. Then each page must be initialized with a suitable PageTableEntry object using the constructor of that class. Make sure that you use correct page id numbers and the correct page table in the PageTableEntry constructor when creating these page objects.

\diamond public void do_deallocateMemory()

This method is typically invoked by a terminating task on its page table object to unset the various flags for the frames allocated to the task. Specifically, it uses setPage() to nullify the page field that points to the page that occupies the frame (thereby freeing the frame), setDirty() to clean the page, and setReferenced() to unset the reference bit. It also un-reserves each frame that was reserved by that task. To find out which task has reserved a given frame, use the method getReserved() of class FrameTableEntry.

Note that this method does not need to (and should not) set the frame attribute of the deallocated pages to null. It is possible that some of these pages are being used by ongoing I/O operations that pump data into or out of the frames that are currently allocated to the killed task. The disk interrupt handler (which will be called each time an I/O is finished) needs to know both the frame and the page objects involved in the finished operation, and it gets the former from the latter.

Note that if a page of a killed task is locked, it can be unlocked only by the device interrupt handler. Unlocking inside the memory-management module can lead to inconsistencies. Try to analyze what might happen in this case in order to understand why this is dangerous.

Summary of Class PageTable

Here is a summary of the attributes and methods of class PageTable. All of these attributes are provided by class IflPageTable and are inherited from there.

- Page table: This is an array referenced by the variable pages. This array is created in the PageTable() constructor.
- Owner task: Describes the task to which the page table belongs, which can be obtained via the method getTask().

5.6 Class MMU

This class represents the memory-management unit of the simulated computer, and defines three methods: the initialization method that exist in every student module and $\text{do_refer}()$, which represents memory references made by the CPU while executing computer instructions. A detailed explanation is given below.

```
\diamond public static void init()
```
This method is called once, at the beginning, to initialize the data structures. Typically, it is used to initialize the frame table.

Since the total number of frames is known (MMU.getFrameTableSize()), each frame in the frame table can be initialized in a for-loop. Initially, all entries in the frame table are just null-objects and must be set to real frame table objects using the FrameTableEntry() constructor. To set a frame entry, use the method setFrame() in class MMU.

Another use of the $init()$ method is for the initialization of private static variables defined in other classes of the Memory package. For example, one can define an init() method in class PageFaultHandler which would be able to access any variable defined in that class. Then MMU.init() can call PageFaultHandler.init(). Since MMU.init() is called at the very beginning of the simulation, PageFaultHandler.init() is also going to be called at the beginning of the simulation.

\diamond public PageTableEntry do_refer(int memoryAddress, int referenceType,ThreadCB thread)

This method takes an address of a byte in the logical memory of the thread, a type of the memory reference (MemoryRead, MemoryWrite, or MemoryLock) and a thread that made the reference. The method then needs to determine the page of the thread's logical memory to which the reference was made. The methods getVirtualAddressBits() and getPageAddressBits(), both inherited from the superclass IflMMU, can be used to determine the number of bits allocated to represent the offset within the page. This number can then be used to compute the page size and then the page to which memoryAddress belongs.

Next, the method must check if the page is valid (the method isValid()). If so, you only need to appropriately set the referenced and the dirty bits of the page, and quit.

If the page is invalid, things are more interesting. There are two possibilities:

- 1. Some other thread of the same task has already caused a pagefault and the page is already on its way to main memory.
- 2. No other thread caused a pagefault on this invalid page.

As before, you can tell one case from the other with the help of the method getValidatingThread().

In the first case, the thread (that was passed as a parameter to $do_refer()$) should simply suspend itself on the page and wait until the page becomes valid. When the page eventually becomes valid, the method should set the referenced and dirty bits appropriately and quit. A thread is suspended by an invocation of the method suspend() in class ThreadCB. When the page becomes valid, execution continues past the suspend() statement. Keep in mind that since a long time may pass between the initial pagefault and the time the faulty page becomes valid, the simulator might decide to destroy the waiting thread. In this case, the dirty and referenced bit settings must not be changed. Thus, always use the getStatus() method to verify that the thread does not have status ThreadKill.

In the second case, the method must initiate a pagefault. Unlike in the do lock() method, a pagefault interrupt must be caused. It is not enough to just invoke the method handlePagefault() because at the time when the thread executes refer(), the machine is in the user mode executing a user thread. In contrast, when pagefault is caused by the lock() operation, the machine must already be in kernel mode, since lock() is called by the operating system itself.

To cause an interrupt, one must suitably set the various static fields of the class InterruptVector. This is done using the static methods setPage(), setReferenceType(), and setThread(). Then one must call the interrupt() method of class CPU and pass it the the type of the interrupt (i.e., PageFault). Eventually, this will invoke the method do handlePageFault() in class PageFaultHandler. Thus, when the interrupt() method returns, the page will be in the main memory and the thread will be in the ready queue.

Before exiting, $dofer()$ must set the reference and the dirty bits.

In both cases, it must be kept in mind that any thread might get killed while waiting for completion of I/O. Such is the wicked nature of the simulator. If a thread is killed, neither the dirty nor the reference bits should be changed. $\mathcal{O}S\mathcal{P}2$ is checking these conditions vigilantly. The method getStatus() should be used to determine the status of a thread.

On exit, do_refer() must return the referenced page.

Relevant methods defined in other classes. Here is a summary of the methods defined in other classes, which might be used in the implementation of the methods of class MMU:

```
\diamond final static public void setInterruptType(int inter)
                                                         InterruptVector
  Sets the type of the interrupt in the interrupt vector. The valid values
  are PageFault, DiskInterrupt, and TimerInterrupt.
```
- final static public int getInterruptType() InterruptVector Extracts the interrupt type from the interrupt vector.
- \diamond final static public void setThread(ThreadCB thread)

```
InterruptVector
```
Sets the thread field in the interrupt vector so that pagefault handlers can find out who has caused the interrupt.

```
\diamond final static public ThreadCB getThread() \hspace{1cm} InterruptVector
 Tells which thread has caused the interrupt.
\diamond final static public void setReferenceType(int ref)
                                                      InterruptVector
   Sets the memory reference type in the interrupt vector. The valid types
   are MemoryRead, MemoryWrite, and MemoryLock. Applicable to page-
   faults only.
-
 final static public int getReferenceType() InterruptVector
 Tells what the reference type was that caused the interrupt. Applicable
 to pagefaults only.
\diamond final public void suspend(Event event) \hfill ThreadCB
 Suspends the thread on which this method is called and puts the thread
 on the waiting queue of event.
-
 final static public FrameTableEntry getFrame(int frameNumber)
                                                                   MMU
  Returns the frame entry with the given frame number. This method is
  defined in the superclass of MMU, and is inherited.
\diamond final static public void setFrame(int index,
 FrameTableEntry entry) MMU
  Sets the frame with the given index to a non-null FrameTableEntry-
  object. This method is defined in the superclass of MMU, and is inherited.
\diamond final static public int getFrameTableSize() $\tt MMUReturns the number of frames in the simulated machine. This method
  is defined in the superclass of MMU, and is inherited.
\diamond final public ThreadCB getValidatingThread() PageTableEntry
  Returns the validating thread of the page.
\diamond final public void setValidatingThread(ThreadCB thread)
                                                       PageTableEntry
```
Sets the validating thread of the page.

Summary of Class MMU

The memory-management unit defines the hardware characteristics of the simulated computer. These characteristics and their access methods are described below.

Frame table: The table whose entries describe the individual main memory frames in $\mathcal{OSP}2$. The methods provided for accessing this table are: getFrame(), which returns a frame object at a given index in the frame

table; setFrame(), which sets a frame table entry with the given index; getFrameTableSize(), which returns the number of entries in the frame table (i.e., the number of main-memory frames in the system). These methods can be used to traverse the frame table in a for-loop.

- Number of bits in a virtual address: The number of bits determines the maximum addressable space in the simulated computer. For instance, 16 bits yield 2^{16} bytes of addressable space (64Kb). The method to find out this value is getVirtualAddressBits().
- Number of bits used to represent the offset within pages: This property directly affects the size of the pages (and frames) in the computer. For instance, 10 bits lead to 1Kb pages, while 12 bits mean that the pages are 4Kb large. The method to find out this value is getPageAddressBits().
- Page table base register: This register points to the page table of the running task. It is available through the methods getPTBR() and setPTBR().

5.7 Class PageFaultHandler

This class contains only one method that you are required to implement as part of the project. However, you might want to define additional methods to make the implementation more modular.

```
\diamond public static int do_handlePageFault(ThreadCB thread,
```
int referenceType, PageTableEntry page)

This is the actual pagefault handler. The thread and the page arguments are the thread and the page that caused the pagefault. The referenceType argument can be MemoryRead, MemoryWrite, or MemoryLock; it represents the type of memory reference that caused the pagefault. Knowing the type of memory reference is needed to set the dirty bit correctly. If the pagefault was caused by locking (in method do lock() of PageTableEntry), the reference type must be MemoryLock. Note that locking does not modify the contents of a page, so the page should *not* be marked dirty due to this type of memory reference.

The implementation of this method follows the general outline of pagefault processing described earlier. However, it is also necessary to check several exception conditions. First, the pagefault handler might be called incorrectly by the other methods in this project. So, always check if the page that is passed as a parameter is valid (already has a page frame assigned to it) and return FAILURE if it is. Second, it is possible that all frames are either locked or reserved and so it is not possible to find a victim page to evict and free up a frame. Return NotEnoughMemory if this is the case. Third, the thread that caused the pagefault can be killed by the simulator at any moment after the thread goes to sleep waiting for the swap-out or swap-in to complete. FAILURE should be returned in these cases.

The first two exceptional conditions must be checked at the beginning of pagefault processing, and the tests for destroyed threads must be done right after each swap-out and swap-in. In any case, before exiting, all threads that might be waiting on the page (see the explanations for $lock()$ and $refer()$) must be notified using the notifyThreads() method of class Event. Finally, dispatch() must be called.

In case of an exception, you should always think of the appropriate ways to handle the various bits associated with pages and frames. For instance, if the thread that caused the pagefault was killed while waiting for a swap-out, we cannot be sure whether the frame has become clean or not. So, the dirty bit should not be changed in such a case.

The normal processing of a pagefault goes as follows. First, the thread must be suspended on a SystemEvent object created with the help of the SystemEvent() constructor. This event object must be saved in a variable, because when pagefault handling is finished you must resume the thread by executing notifyThreads() on that event.

Next, a suitable frame must be found *and reserved* to protect it from theft by other invocations of the pagefault handler (on behalf of other threads). If the frame is free, the page's frame attribute can be updated and a swap-in operation can be performed right away. If the frame contains a clean page, the frame should be freed (explained below) and then a swap-in operation should be performed. If the frame contains a dirty page, then swap-out must be performed, followed by freeing the frame, followed by a swap-in. If all is well and the thread was not killed while waiting for the two I/O operations, you update the page table (explained below) to indicate that page is now valid and the frame table to indicate that the newly freed frame is now occupied by page. Finally, the following actions must be performed:

- **–** the frame used to satisfy the pagefault should be un-reserved
- **–** the threads that might be waiting on page should be notified using notifyThreads()
- **–** the thread that caused the pagefault must be resumed by executing notifyThreads() on the system event that you used to suspend the thread just after the entry into the pagefault handler

– dispatch() must be called

– SUCCESS should be returned.

Freeing frames: To free a frame, one should indicate that the frame does not hold any page (i.e., it holds the null page) using the setPage() method. The dirty and the reference bits should be set to false.

Updating a page table: To indicate that a page P is no longer valid, one must set its frame to null (using the setFrame() method) and the validity bit to false (using the setValid() method). To indicate that the page P has become valid and is now occupying a main memory frame F , you do the following:

- **–** use setFrame() to set the frame of P to F
- **–** use setPage() to set F's page to P
- **–** set the P's validity flag correctly
- **–** set the dirty and reference flags in F appropriately.

Performing a swap-in: This is done by issuing a read command on the swap file of the task that owns the page.

Performing a swap-out: This is done with the write command on the swap file of the task that owns the page.^{[3](#page-105-0)}

read() is a method of class OpenFile that is invoked on an OpenFile-object (which in our case is an open-file handle of a swap file) and takes three arguments: the *block number* in the file that is to be read, the *page* into which the file block is to be placed, and the *thread* that initiated the I/O. All these parameters can be obtained using the methods listed below. The only peculiarity is that a swap file contains an exact image of the task's memory, so there is a one-to-one correspondence between the pages and the blocks in the swap file. In other words, the block number should be equal to the page id.

write() is also a method in class OpenFile that is invoked on an open-file handle and takes the same arguments as $read()$.

Both read() and write() are blocking operations, i.e., they block the execution of the current thread until the I/O is finished.

Earlier we mentioned the method getValidatingThread(), which can be used to find out if a particular page is in the middle of a pagefault. It should

Note: It must be the task of the page, not of the thread. Indeed, in case of a swap out, the thread and the page might belong to different tasks. Think why.

be emphasized, however, that it is the responsibility of the pagefault handler (i.e., your implementation) to maintain the validating threads correctly. In particular, when a pagefault occurs you must set the validating thread to be the thread that caused the pagefault and set it to null when the pagefault is over. All this is done with the help of the method setValidatingThread() of the class PageTableEntry. It should also be mentioned that *OSP ²* monitors the validating thread field in every page and issues error messages when it is incorrect. In particular, if a pagefault must occur and the validating thread of a page stays null, it might complain that your implementation missed the interrupt.

Relevant methods defined in other classes. In addition to the relevant methods listed earlier, the following methods are used in handling pagefaults:

- \diamond public final boolean is $\texttt{Reserved}()$. FrameTableEntry Tests if the frame is reserved.
- \diamond public final boolean isDirty() $\qquad \qquad$ FrameTableEntry Tells if the frame is dirty by checking the "dirty" bit of the frame.
- \diamond public final void is $\texttt{Reference}()$ FrameTableEntry Checks the reference bit and tells if the frame has been referenced.
- \diamond public final OpenFile getSwapFile() \hfill TaskCB Returns the open swap file of the task. This swap file is then used in the read() and write() statements to perform the swap-in and swap-out operations. The swap file is represented by the OpenFile class, which is a handle that contains information about the disk blocks used by the file and some runtime information about the current status of the file. This operation blocks the current thread until the I/O operation is finished.
- \diamond final public void read(int blockNumber, PageTableEntry memoryPage,ThreadCB thread) 0penFile This method is invoked on an open-file handle (which is an instance of class OpenFile). It reads block blockNumber from the file (specified by an open-file handle) into page memoryPage on behalf of thread. The open-file handle mentioned above is an object of class OpenFile. In our concrete case, it would be a handle of a swap file. Since here read() is used for swapping pages into the memory, blocks in the swap file must directly correspond to pages in the main memory. Therefore blockNumber is determined by the ID of memoryPage. This operation blocks the current thread until the I/O operation is finished.
- \diamond final public void write(int blockNumber, PageTableEntry memoryPage,ThreadCB thread) 0penFile

This method is invoked on an open-file handle (which is an instance of class OpenFile). It writes page memoryPage to block blockNumber of the file on behalf of thread. As in the case of read(), blockNumber is determined by the ID of memoryPage.

- \diamond final public void suspend(Event event) \hfill ThreadCB Suspends the thread that calls this method, placing it on the waiting queue of event.
- \diamond final static public void dispatch() \hfill ThreadCB Dispatches a thread.
- \diamond final public ThreadCB getValidatingThread() PageTableEntry Returns the validating thread of the page.

- final public void setValidatingThread(ThreadCB thread)

```
PageTableEntry
```
Sets the validating thread of the page. Note that you have to make sure that the validating thread of a page is set correctly by the pagefault handler. In other words, you must set the page's validating thread using setValidatingThread() when a pagefault happens and you must set it back to null when the pagefault is over.

 \diamond final public static int handlePageFault (ThreadCB thread, int referenceType, PageTableEntry page) PageFaultHandler Invokes the pagefault handler. Returns SUCCESS if the pagefault has been handled successfully. Otherwise (for instance, it there is not enough memory) returns FAILURE.

- ◇ public SystemEvent(String name) SystemEvent Constructor for system events. Used to create an event on which to suspend a thread at the beginning of pagefault processing. The argument, name, is a string that will appear in the system log and can help distinguish this event from other types of SystemEvent.
- \diamond static public void create (String name, DaemonInterface work, int interval) Daemon Used to register a daemon with the system. See Section [1.7](#page-29-0) for details.

In addition most of the methods in class FrameTableEntry (such as getPage(), setReserved(), etc.) are required for the implementation of the *OSP ²* pagefault handler.
Summary of Class PageFaultHandler

This class does not maintain important data structures of its own. However, it plays a central role in memory management by initiating the I/O operations that swap pages in and out of the system and by maintaining the page tables of the running processes and the frame table of the entire system.

5.8 Methods Exported by Package Memory

The following public methods are defined in the classes of the Memory package. They are useful for implementing other student modules and are also used to implement the methods that are part of the current project. To the right of each method we list the class of the objects to which the method applies.

Sets the frame of the page to frame. If the page is being evicted, then frame is null.

setFrame() must be called before swapping in a page and after the page becomes invalid. In the former case, you need to set the frame of the page to tell the I/O subsystem where to put the page. The validity bit of the page should be set only after the page is loaded.

6 Devices*: Scheduling of Disk Requests*

6.1 Chapter Objective

The objective of project Devices is to teach students about device I/O and, relatedly, certain aspects of device drivers. One main focus will be the scheduling of disk I/O requests. To meet these objectives, students will be asked to implement the three public classes of the Devices package: Device, IORB, and DiskInterruptHandler. The class Device deals with the scheduling of I/O requests, IORB implements the I/O Request Block data structure, and Disk-InterruptHandler constitutes the interrupt handler for I/O devices.

6.2 Overview of I/O Handling

I/O supervisor and I/O Request Block. When the user thread issues a read() or write() system call, the OS assembles an **input/output request block** (or **IORB**) and passes the request to the basic I/O supervisor: the portion of the operating system responsible for managing the various I/O devices of the system. The IORB includes information about the thread that issued the call; the buffer page in main memory that contains the data to be written out or into which the data is to be copied from the secondary storage; the disk block to which the buffer data is to be written out or which contains the data to be read in; and the I/O device that is the target of the requested I/O operation.

The I/O supervisor examines the IORB and places it on the **device queue** of the targeted device. A device queue is nothing more than a queue of waitingto-be-serviced IORBs, one such queue per I/O device in the system.

Disk interrupt handler. When the device finishes servicing an I/O request, a device interrupt occurs, which is the way by which external devices notify the CPU about completion of an I/O operation. The eventual result of an I/O interrupt is that the appropriate device interrupt handler is called. In *OSP ²* the only external devices are disks, so the only device interrupt handler is the disk interrupt handler.

A disk interrupt handler performs a variety of functions, which we will describe in detail in Section $\overline{6.5}$. One of these is to invoke the I/O scheduler, which chooses the IORB to be serviced next, assuming the device queue is non-empty; i.e. contains at least one IORB. Once an IORB has been selected, it is dequeued from the device queue and the device is instructed to process the request. If the device queue is empty, the device simply idles.

Disk-scheduling algorithms. A variety of disk-scheduling policies have been proposed for use by the I/O scheduler. Many of these policies are concerned with performance and QoS (Quality of Service) issues related to the physical characteristics of a disk device. Such a device is typically configured as a number of platters, each of which has an upper and lower surface on which data can be magnetically encoded. A surface consists of a number of concentric tracks each of which is divided into storage regions known as sectors. For most disk drives, a fixed sector size of 512 bytes is used. The block size of a disk is the number of bytes transferred in a single I/O operation, and is usually a multiple of the sector size. The preceding discussion therefore tells us that a disk address consists of a surface number, track number, and sector number.

Each surface has its own disk arm, at the end of which is a read/write head that must be positioned over the appropriate track for an I/O operation to occur. The arms are attached to the disk-drive boom, which moves the arms in unison back and forth over the tracks of the various surfaces. This gives rise to the concept of the disk cylinder: the collection of tracks carved out of 3-space by virtue of having all read/write heads positioned over the same-numbered track on all surfaces.

Disk I/O can be slow compared with say the time it takes the CPU to access main memory due to the electromechanical aspects of disk operation. In particular, having to position the disk arm over the correct track before an I/O can take place is the biggest culprit. The time taken by this movement is called

the **seek time** and many proposed disk-scheduling strategies seek to minimize this delay. **Rotational delay**, the time spent waiting for the proper sector to circle under the read/write head, is another overhead of disk I/O but of much less concern to us since it is about an order of magnitude smaller than the seek time.

Some of the most well-known disk-scheduling algorithms are:

- Shortest Seek Time First (SSTF) Services the IORB that requires the least movement of the disk arm from its current position.
- SCAN The arm is moved in one direction only, satisfying all outstanding requests en route until it reaches the last track in that direction. The service direction is then reversed and the scan proceeds in the opposite direction.
- LOOK A variant of SCAN where the service direction is reversed when there are no more requests in the current service direction (rather than proceeding to the last track).
- C-SCAN A variant of SCAN which restricts scanning to one direction only. When the last track has been visited in that direction, the arm is returned to the opposite end of the disk and the scan begins again.
- C-LOOK The variant of LOOK in which scanning is restricted to one direction, just as in C-SCAN.
- Priority Unlike the above algorithms, this approach is not intended to optimize disk utilization but rather to meet other system objectives. For example, it may give priority to IORBs coming from interactive processes rather than those from computationally intensive batch jobs, with the goal of providing good interactive response time.

It is important to note that *OSP ²* disks do not support the command that moves the read/write head to a specified cylinder without starting an I/O. The head moves only when the startIO() command is issued. It is therefore not possible to implement strategies such as SCAN and LOOK which require the head to be moved to the first and last cylinders even when there are no outstanding I/O requests to these cylinders.

Synchronous versus asynchronous I/O. To conclude our discussion of disk-scheduling strategies, let us consider a relatively new disk-scheduling algorithm that has exhibited superior performance on web-server and file-system benchmarks. *Anticipatory scheduling* is useful in the context of synchronous I/O, where a thread that has issued an I/O operation is blocked until the I/O completes. In contrast, with asynchronous I/O , a thread initiates an I/O operation and then can continue processing while the I/O request is fulfilled.

 I/O in $OSP2$ is of the synchronous variety, although it is possible to simulate asynchronous I/O in $OSP 2$; see Section [7.7.](#page-137-0)

Seek-optimizing algorithms can get confused by synchronous I/O since in this case threads issue one I/O request at a time (after the previous request has finished). Thus the scheduler may incorrectly assume that the thread issuing the last I/O request has momentarily no further I/O requests and therefore selects a request from another thread. This is a bad decision on the part of the scheduler if the current thread is requesting data sequentially positioned on the disk which is often the case in practice. Anticipatory scheduling seeks to mitigate this problem by issuing a short, controlled delay period before selecting the next IORB to be serviced. This allows the thread that issued the last request to issue additional requests before the next scheduling decision is made.

In the rest of this section we provide a detailed description of the classes that comprise the package Devices. Figure [6.1](#page-114-0) places these classes in the overall context of *OSP ²*.

6.3 Class IORB

Before discussing the workings of the I/O supervisor, we need to look more closely at the structure of an IORB. The class for this data structure is defined as follows:

```
\diamond public class IORB extends If1IORB
```
and its only mandatory method has a six-argument constructor:

```
\diamond public IORB(ThreadCB thread, PageTableEntry page, int blockNumber,
int deviceID, int ioType, OpenFile openFile)
As usual for OSP 2 class constructors, the first thing this class does is call
super() with the same set of arguments. The rest depends on your imple-
mentation. For instance, if you define additional fields in this class, you can
initialize them in the constructor.
```
As follows from the argument list, an IORB keeps information about the thread which issued the request, the buffer page involved, the device and the device's block that contains the data to be read in or on which the page is to be written out, the type of I/O operation (which can be either MemoryRead or MemoryWrite, two predefined constants in *OSP ²*), and the open-file handle. The last of these arguments will be defined in more detail in Chapter \mathbb{Z} . For now it suffices to know that an open-file handle contains runtime information, such as the file size and the list of blocks allocated to the file, which the OS

Figure 6.1 An overview of the package DEVICES.

needs in order to process I/O operations on that file. This handle comes from one of the parameters of the read() or write() system call that created the IORB in question.

It is important to keep in mind that IORB is also a subclass of Event so threads can wait on it and be notified. See Section **1.6** to refresh your memory about *OSP ²* events.

Relevant methods defined in other classes. Typically, implementation of this class does not use methods provided by other *OSP ²* classes, since the only mandatory method in this class is the constructor and the components of an IORB can be queried via the built-ins provided by *OSP ²* itself (see below).

Summary of Class IORB

This class defines the IORB data structure that is used to maintain the information about all the active I/O operations. The following API can be used to query an IORB. All these methods are built-ins that apply to an IORB object and they return the components of that IORB as described below.

```
-
final public int getID()
```
Provides the Id of the IORB.

```
\diamond final public <code>OpenFile</code> get<code>OpenFile()</code>
```
Returns the open-file handle associated with the IORB.

```
\diamond final public <code>PageTableEntry</code> <code>getPage()</code>
```
Returns the buffer page in main memory, which is the source (in the case of $write()$ or the target (in the case of $read()$) of the I/O operation in question.

 \diamond final public int getDeviceID() Returns the device involved in the I/O operation.

```
\diamond final public int getIOType()
```
Returns the I/O type represented by the IORB. *OSP ²* supports two types: FileRead and FileWrite.

```
\diamond final public ThreadCB getThread()
 Returns the thread that requested the I/O.
```

```
\diamond final public int getBlockNumber()
```
Returns the block number of the device, which is the source (in the case of read()) or the target (in the case of $write()$) of the I/O.

```
\diamond public final void setCylinder(int cylinder)
```
Sets the target disk cylinder for this IORB to cylinder. This is done in do enqueueIORB() in Device. This method is used by *OSP ²* to make sure that both it and the student module calculate the cylinders associated with IORBs the same way.

```
\diamond public final int getCylinder()
```
Returns the target cylinder associated with this IORB. Since the IORB

cylinder is set in do enqueueIORB(), getCylinder() can be used only in do dequeueIORB().

6.4 Class Device

This class implements the I/O scheduler and performs other functions, such as starting I/O operations on devices. The following methods are part of the project and must be implemented by the student.

```
\diamond public static void init()
```
This method is called at the very beginning of the simulation and can be used to initialize static variables that might exist in the student program.

```
\diamond public Device(int id, int number0f{\tt Blocks})
```
This is the class constructor. It must call super(id,numberOfBlocks) and then initialize the device object. One thing that requires initialization is the variable iorbQueue described later in this section.

```
-
public int do enqueueIORB(IORB iorb)
```
This method is executed on a device object and puts iorb on the waiting queue of that device. When programming this method, however, you must first perform several tasks before the enqueueing. First, you must lock the page associated with the iorb using the lock() method of class PageTable-Entry. This is done in order to ensure that the page will not be swapped out from now till the end of the I/O operation. (If this page is not currently in main memory, lock() will cause a pagefault, which will eventually bring the page into main memory.)

Second, you must increment the IORB count of the open-file handle associated with iorb. This is accomplished using method incrementIORBCount() of class OpenFile. Because different threads can issue I/O operations concurrently on the same file, \mathcal{OSP} *2* needs to maintain a count of IORBs that are active for each open-file handle. Knowing the count allows it to ensure that files cannot be closed before all the outstanding I/O operations have finished. (Closing a file deallocates its file handle, which can cause havoc since outstanding IORBs for this file reference the handle.)

Third, you must set the iorb's cylinder, using method setCylinder(), to the cylinder that contains the disk block mentioned in the IORB.

You are now ready to enqueue the IORB but not before you check that the thread that requested the I/O is still alive (using the getStatus() method of class ThreadCB), i.e., its status is not ThreadKill. If the thread has died, method do enqueueIORB() should return FAILURE.

If the thread is alive and the device is idle (you can check for idleness by executing the method isBusy() on the device), you can start the I/O operation immediately using the method startIO() on the device object and passing it the iorb as a parameter. The method do enqueueIORB() should then return SUCCESS and exit.

If the device is busy, then put the iorb on the device queue and exit by returning SUCCESS. The device queue is represented by the variable iorbQueue that can take any object that implements the type GenericQueueInterface (Section $[1.5]$), as described later in this section.

Disk I/O scheduling is typically implemented as part of this method as the different scheduling strategies work best with differently structured device queues. For instance, for the C-SCAN strategy, the IORBs in the queue might need to be ordered according to the cylinder numbers that contain the requested disk blocks. In this case, sorting would be best done when IORBs are enqueued.

\diamond public IORB do_dequeueIORB()

This method selects an IORB from the device queue according to some scheduling strategy, deletes it from the queue, and returns the selected IORB. If the queue is empty, null is returned.

The I/O scheduling strategy (or parts of it) can also be implemented in this method, because ultimately it is this method that chooses the requests to be serviced. *OSP ²* does not mandate any particular way of implementing scheduling.

Note that you should *not* unlock the page used by the dequeued IORB. This is because the device has not finished servicing the IORB, so the page must stay locked. It will eventually be unlocked when the device finishes servicing the request and the device interrupt occurs.

\diamond public void do_cancelPendingIO(ThreadCB thread)

The purpose of this method is to iterate over the device queue removing all IORBs initiated by thread. The need to do this arises when a thread is killed. This prevents the device from servicing requests that nobody wants any more.

For each IORB associated with thread found in the queue, you must unlock the buffer page used by that IORB. Indeed, when the IORB was enqueued, the corresponding page was locked. Normally it would be unlocked in the device interrupt handler after the request is serviced. However, since you are removing the IORB from the device queue, this request will never be serviced, so you must unlock the page here.

In addition, you must decrement the IORB count of the open-file handle associated with the IORB. Again, normally this is done in the device interrupt handler, but because the IORB in question will never be serviced, you must decrement the count here.

Finally, you should *try* to close the open-file handle associated with the IORB. To understand why, let us consider what happens when a thread is trying to issue a close() system call on a file handle. If the handle does not have associated IORBs, the file is closed and the handle is deleted. However, if there are outstanding IORBs for the handle, the system sets the closePending flag for that handle, but does not close the file in order to allow the outstanding I/O requests to execute.^{[1](#page-118-0)} When all such I/O requests have finished, the file is closed. One of the places where the closePending flag should be checked is in the do cancelPendingIO() method. Indeed, if the file was not closed due to outstanding I/O requests and now you are canceling all the outstanding IORBs belonging to thread, it is possible that the file handle has no remaining IORBs, so it can be closed. In other words, when removing an IORB associated with thread you must check the closePending flag of the open-file handle of the IORB. If it is set to *true* and the count of IORBs for this handle has become 0, the file handle must be closed with the close() method of OpenFile. To check the current count of pending IORBs for a file handle use the method getIORBCount() of class OpenFile.

How to compute a cylinder from a block. Many scheduling strategies require you to compute a cylinder from a given block number. To do this, you first need to compute the number of blocks in a track.

A track consists of a number of blocks, which in turn consists of a number of sectors. To find the block size, you can use the functions getVirtualAddress-Bits() and getPageAddressBits(), since the size of a disk block equals the size of a main-memory page. The block size together with the sector size (getBytesPerSector()) gives the number of sectors in a block.

The number of blocks per track can be used to compute the track that holds the given block. To compute the cylinder number corresponding to the block you need to know the number of tracks per cylinder. In *OSP ²* we assume

You may have faced this issue while implementing the kill() method of TaskCB, which destroys a task. One job that this method is tasked with is closing all open files owned by the task. You may have experienced the unexpected effect of the close() system call where some open-file handles stayed around after being closed. The reason for this was the presence of outstanding IORBs.

that each disk platter is one sided, so the number of tracks in a cylinder equals the number of platters in the disk. The latter is obtained using the method getPlatters().

Relevant methods defined in other classes. The following methods defined in other modules are used by the methods in class Device.

In addition, the following methods, implemented in class Disk, are available. These methods can be useful in order to implement certain I/O scheduling strategies. Note that Disk is a subclass of Device. Since the devices we are dealing with in this project are disks, all these methods are applicable to the Device objects that occur in this project.

- \diamond final public int getHeadPosition() Returns the head position (the cylinder number where the read/write head is parked). Cylinders are counted from 0.
- final public int getPlatters() Returns the number of platters in the disk.
- \diamond final public int getTracksPerPlatter() Tells how many tracks a platter has (or, equivalently, the number of cylinders on the disk).
- \diamond final public int getSectorsPerTrack() Tells the number of sectors per track.
- final public int getBytesPerSector() Returns the number of bytes per sector.
- \diamond final public int getRevsPerTick() Returns the number of revolutions of the disk per tick.
- \diamond final public int getSeekTimePerCylinder() Tells how long it takes to seek to the next cylinder.

Summary of Class Device

The following API provided by class Device (implemented in its superclasses) can be used to obtain information about *OSP ²* devices. All the methods and variables listed apply to Device objects.

 \diamond protected GenericQueueInterface iorbQueue

This variable holds the device queue. It is manipulated by the methods do enqueueIORB() and do dequeueIORB(). The implementation of the device queue is *up to the student* module. The only requirement is that the class of the queue object must implement the interface GenericQueue-Interface. This interface mandates the methods length(), isEmpty(), and contains(), as described at the end of Section $\overline{1.5}$. Note that the interface defines only the methods *OSP ²* itself uses internally. For your purposes, your queue class would need additional methods, such as insertion and deletion of members of the queue. Note that since these methods are not defined in GenericQueueInterface you would need to use the *cast* operator to invoke them on iorbQueue.

```
\diamond final public boolean isBusy()
  Tests if the device is busy.
```
- \diamond final public void setBusy(boolean flag) Sets the device busy or idle depending on the value of flag.
- \diamond final static public Device get(int deviceID) Returns the device object with the given device Id.
- \diamond final public int getID() Returns the Id of the device.
- final public void startIO(IORB iorb) Starts the device and instructs it to perform the I/O operation specified in iorb. As part of this operation the device becomes busy, so you do not need to set it to busy explicitly.
- \diamond final public String ospDeviceQueue() This method returns a string that contains the OSP version of the waiting queue to the device. You can print it out and use it for debugging.
- \diamond final public int getTableSize() Returns the size of the device table.

6.5 Class DiskInterruptHandler

This class is declared as follows:

```
public class DiskInterruptHandler extends IflDiskInterruptHandler
```
It has only one method, do handleInterrupt(), which implements the device interrupt handler. The method has the following signature:

public void do_handleInterrupt()

The following actions need to be performed as part of the handler:

1. Obtain information about the interrupt from the interrupt vector, class InterruptVector, described in Section [1.4.](#page-19-0) The main piece of information is the IORB that caused the interrupt. It is obtained using the method getEvent() of class InterruptVector (since the IORB is the event that "caused" the interrupt). The other necessary pieces of information, the thread, page, open-file handle, etc., are obtained using the API described in Section [6.3.](#page-113-0)

- 2. The IORB count of the open-file handle associated with the IORB must be decremented using decrementIORBCount() as described earlier.
- 3. If the open file has the closePending flag set and the IORB count is 0, the file might need to be closed. The IORB count of a file handle can be obtained via the method getIORBCount(). See the relevant part of the description of the method do cancelPendingIO().
- 4. The page associated with the IORB must be unlocked, because the I/O operation (due to which the page was locked) is over.
- 5. If the I/O operation is *not* a page swap-in or swap-out, then, unless the thread that created the IORB is dead, you need to set the frame associated with the IORB's page as referenced using the method setReferenced() of FrameTableEntry. In addition if it was a read operation $(I/O$ type FileRead) then the frame must be set dirty (using the method setDirty() of FrameTableEntry). Of course, this can only be done if the task associated with the thread is still alive, as otherwise the memory of the task will be deallocated anyway. The thread's task is obtained using the method getTask() and its status is checked using the method getStatus(). A live task has status TaskLive; otherwise, the status is TaskTerm.

To find out whether an I/O is a swap-in or swap-out from/to the swap device, one should compare the device Id of the IORB (getDeviceID()) with SwapDeviceID, a constant defined in *OSP ²*.

- 6. If the I/O was directed to the swap device and the task that owns the thread and the IORB is alive, you should mark the frame as clean (setDirty(false)).
- 7. If the task that owns the IORB is dead (status TaskTerm) and the frame associated with the IORB was reserved by that task (verified using getReserved()), you must unreserve the frame using setUnreserved().
- 8. The threads that are waiting on the IORB must be woken up by a call to notifyThreads().
- 9. The device must be set to idle using the method setBusy() with the appropriate flag.
- 10. The device must be told to service a new I/O request. This IORB is picked up using the method dequeueIORB(). If it returns a non-null object, the device should be restarted with that IORB using the method startIO().
- 11. Finally, a new thread must be dispatched using method dispatch() of ThreadCB.

Relevant methods defined in other classes. The following methods defined in other modules can be used to implement the disk interrupt handler.

Summary of Class DiskInterruptHandler

This class typically does not maintain data structures of its own. However, since it is intended to process device interrupts, it indirectly manipulates other data structures, such as IORB's, threads, and page tables, through the methods provided by these classes.

6.6 Methods Exported by Package Devices

The package Devices exports the following methods that are used by other classes in *OSP ²*. To the right of each method we indicate the class where the method is defined.

7 FileSys*: The File System*

7.1 Chapter Objective

The objective of the FileSys project is to teach students about file-system design and organization and about the management of logical, file-based I/O in a modern operating system. To this end, students will be asked to implement the five public classes of the FileSys package: MountTable, which maps files to physical devices; INode, which keeps track of space allocation to files; DirectoryEntry, which defines the directory structures; OpenFile, which provides methods for manipulating open files via open-file handles (including the read() and write() operations); and FileSys, which provides a set of operations, such as create() and delete(), on non-open files.

7.2 File System Design Objectives

We briefly consider some of the main design issues in modern file systems, particularly those pertinent to the FileSys project, and then discuss how these are addressed in *OSP ²*.

Naming. In a modern file system, users are able to refer to a file by a symbolic file name. Typically such a name is in the form of a **pathname**, a sequence of directory names ending in a target file, which can also be a directory. For example, consider the pathname /home/fac/sas/osp/filesystem.tex. This pathname starts at the root of the hierarchical file system directory structure (see discussion of directories below) indicated by the / character. The **directory separator character** / is also used to delimit names in the sequence. The target file in this case is filesystem.tex. *OSP ²* supports a hierarchical directory structure and pathnames for symbolic file naming. Pathnames can also commence from the working directory such as in osp/filesystem.tex, assuming the working directory is /home/fac/sas. The working directory can be manipulated interactively within the command shell.

The process of following the sequence of directory entries along a pathname to reach the target file is known as **pathname dereferencing**. Pathname dereferencing becomes more complicated by the presence of mountable file systems, discussed below.

Directory structures. Early MS-DOS file systems supported *flat* file directory structures where all files resided at the same, single level. Today's directory structures are multi-level and hierarchical where directories may contain subdirectories and so on. Such hierarchies start at the *root* directory /. This does not necessarily impose a tree structure on directories as files can be *linked* to from any directory, as discussed below.

Links. Modern file systems, Unix-style ones in particular, provide a link() system call that allows one to create a new link (directory entry) for an existing file and increment its **link count** by one. The pathname of the existing file is given as the argument to link(). If successful, link() returns the pathname of the new directory entry.

Such a directory entry is a **hard link** to the existing file, and requires that both files reside on the same file system (see discussion of mountable file systems below). Both the old and the new link share equal access and rights to the underlying object. A hard link can thus be viewed as a pointer to a file and is indistinguishable from the original directory entry. Any changes to a file are effective independent of the name used to reference the file. A hard link may not refer to directories.

A **symbolic link** is an indirect pointer to a file; its directory entry contains the name of the file to which it is linked. Symbolic links may span file systems and may refer to directories.

Mountable file systems. Another feature of modern file systems is the mount() system call, which requests that a removable file system be **mounted** on a specified directory. Subsequent references to this directory will access the root directory (by default) of the mounted file system. The file system keeps track of mounted file systems and the directories on which they are mounted via a **mount table**. For example, suppose the root directory of a disk volume is mounted on /home/fac/sas. Then the pathname /home/fac/sas/osp/filesystem.tex ultimately references the target file named filesystem.tex on that mounted volume. Pathname dereferencing in the presence of mount tables is discussed more extensively in Section [7.4.](#page-129-0)

File storage allocation methods. How does the file system keep track of the disk blocks allocated to a particular file? Possibilities include *contiguous allocation*, where a single contiguous set of blocks is allocated to the file at the time of file creation; *chained allocation*, where each block allocated to the file contains a pointer to the next block in the chain; and *indexed allocation*, which associates a (multi-level) index structure with the file indicating the blocks that have been allocated to the file. Indexed allocation addresses many of the problems of contiguous and chained allocation, and is used in modern operating systems such as Unix, Windows, and *OSP ²*.

Free space management. How does the file system keep track of the free space on a disk, that is those disk blocks that can be allocated to a file whenever the need arises? Possibilities include *bit tables* which use a bit vector containing one bit for each block on the disk. An entry of 0 corresponds to a free block and an entry of 1 corresponds to a block in use. In the *chaining* method, each free portion of disk space contains a length field and a pointer to the next free portion in the chain. The *indexing* approach treats free space as a file and uses an index table as described under file allocation. The *free block list* method numbers each block sequentially and a list of all free blocks is maintained in a reserved portion of the disk.

7.3 Overview of the *OSP 2* **File System**

The *OSP ²* file system is a node-labeled tree, with support for hard links. The nodes of the tree represent files. The root node of the tree is labeled with the 1-character constant string, FileSys.DirSeparator, which can be "/" or "\". In the ensuing discussion, we shall use "/", but this should not be assumed in the student programs. The rest of the labels are strings of arbitrary characters except FileSys.DirSeparator. The labels are called **names** of files. A **full name** or the **pathname** of a file (or directory) associated with the current node is obtained by concatenating all the labels on the path from the root to that node while separating the different names with FileSys.DirSeparator.

A file can be a **plain file** or a **directory**. A directory is a special file that contains information about other files. These other files are **members** of the directory; they correspond to the nodes that are children of the directory node in the tree. Thus, internal nodes of the file tree can only be directories. The leaves of the tree can be either plain files or directories. A directory that appears as a leaf is said to be **empty**.

Note that directory names that differ only in DirSeparator at the end are considered the same; i.e., if DirSeparator is "/" and /foo is a directory then /foo/ is considered to be the same directory. Also, multiple occurrences of the separator character can be replaced by just one occurrence. For instance, /foo/bar and ///foo//bar refer to the same file.

A file (or a directory) can be created and deleted. To work with a file, a thread must first **open** it and obtain an **open-file handle**. This handle contains run-time information about the file. The read and write operations are performed on the *open-file handle* rather than on the name of a file. When a thread is done working with a file, it can **close** the file handle and thus destroy it. An open-file handle is a locus of run-time information about the file. In a typical operating system it includes (among other things) the inode of the file, the task, and the current position in the file. *OSP ²* does not keep the current position, but it does maintain the rest of this information.

A pathname identifies a unique file, but a file can have any number of names. In fact, a file is uniquely represented by its **inode** (index node), which contains information about the blocks allocated to the file. Pathnames are associated with inodes through **directory entries**, but a file's inode itself contains no information about the names associated with the file. To associate another name with a file, a thread can create a **hard link** to the file, which creates another association between a pathname and the file's inode.

Deleting a file does not necessarily destroy the file's inode. Instead, it destroys the directory entry that associates the inode with a particular pathname that was used as a parameter to the delete() operation. Each inode has an associated **hard-link count**: the number of hard links to the inode, which is also the number of distinct names associated with the file. When a delete operation is executed on a pathname associated with a particular inode, the hard-link count is decremented by one. The inode is deleted only when *both* the hard-link count and the open count (described below) become zero.

A file's inode not only keeps track of the number of hard links to the file, but also of the file's **open count**, the number of times the file has been opened. The same inode can be open multiple times because the open() operation can be executed on different names associated with the file (and, in fact, even on the same pathname). When this happens, a new open-file handle is allocated, and the same file can be accessed through different handles. Threads of the same task share the open-file handles, so typically they do not need to open the same file multiple times. However, different tasks might want to access the same file concurrently in which case they need separate file handles. When a file is opened through one of its pathnames, its open count is incremented by one. Closing a file (with the close() operation) decrements the open count by one.

We will now discuss each of the classes that belong to the package FILESYS. Figures [7.1](#page-130-0) and [7.2](#page-131-0) place them in the larger context of the *OSP ²* system.

7.4 Class MountTable

Mount tables associate files with devices. For example, in Windows, a file named $C:\text{foo}$ bar is said to be residing on device C and a file named $D:\abc\cde$ is on device D. A mount table will then associate the letters C and D with particular physical devices. $\frac{1}{2}$ $\frac{1}{2}$ $\frac{1}{2}$

In Unix systems the association between devices and files is more flexible, but also more complex. First, Unix does not use letters to represent devices. Instead, devices are associated with directories. A mount table then is a relation that consists of a list of pairs of the form \langle pathname, deviceID \rangle . The pathname part of such a pair is called a **mountpoint**.

OSP ² uses Unix-like mount tables. An example mount table is given in Figure $\sqrt{7.3}$ In that figure, we see four directories associated with four physical devices. The first question is: How does the system decide on which device any given file should reside? For example, consider the file /foo/bar/abc/cde. Since this file is a descendant of the root directory, /, and this directory is a mountpoint residing on device 0, one might think that this is where the file should live. However, this file is also in a subdirectory of mountpoint /foo, which lives on device 0. Looking more closely, we see that our file is also a descendant of mountpoint /foo/bar, which is on device 3. Which device is the correct one?

The actual mapping of files to devices works as follows. Given a full file name f , the system finds the longest name of a mountpoint d that matches f, where "matches" means that d is a prefix of f and f is a descendant of

¹ Typically a physical device is further subdivided into **partitions** and the drive letters (as well as directories in Unix—see below) are associated with partitions. In other words, partitions represent an intermediate layer between files and the actual devices they reside on. This intermediate layer does not exist in *OSP ²*, and we will ignore it here.

Figure 7.1 An overview of the package FILESYS, I.

d in the file-tree hierarchy. For example, the longest mountpoint in the table of Figure [7.3](#page-132-0) that matches /foo/bar/abc/cde is /foo/bar and thus the file /foo/bar/abc/cde resides on device 3. Note that if the mount table had a pair $\langle f \circ \rho \rangle$ bar/ab, 4) then the mountpoint **/foo/bar/ab** would *not* match /foo/bar/abc/cde because the latter file does *not* reside in a subdirectory of

Figure 7.2 An overview of the package FILESYS, II.

/foo/bar/ab (but rather in /foo/bar/abc).[2](#page-131-1)

The MountTable class in *OSP ²* is intended to provide the correct mapping

² Another way to describe the matching criterion is to *standardize* all file names. A **standardized file name** is a full file name such that multiple occurrences of DirSeparator are replaced with one occurrence and if the file is a directory then DirSeparator is added at the end of the name. Given a file name *f*, the matching mountpoint is the one whose standardized name is the longest prefix of *f*.

Directory name	Device ID
/foo	
/swap	
$/$ foo $/$ bar	3

Figure 7.3 A mount table.

of files to devices. The mount table itself is encapsulated in a superclass of MountTable. What is visible, however, is the static method getMountPoint(), which takes a device number and returns the corresponding mountpoint. Another method, getTableSize(), tells the number of available physical devices (which can be different for different parameter files). Device numbers range from 0 to getTableSize()-1. Thus, together these methods make it possible to access all mountpoints. To provide the file-to-device mapping, the student needs to implement the following methods of class MountTable:

- public static boolean do isMountPoint(String dirname)

This method tells if dirname is a mountpoint of one of the devices. It uses the method getMountPoint() internally.

- public static int do getDeviceID(String pathname)

This method checks the mount table and returns the Id of the device that hosts the file with the given pathname. The method for determining the device was described earlier.

As you can see, there are no methods for creating or deleting mountpoints. In *OSP* 2 all mountpoints are created by the system at startup and none gets destroyed during the execution of the system.

Built-ins and relevant methods from other classes. The implementation of these methods might need to use the following methods:

- ◇ public static String getMountPoint(int deviceID) MountTable Returns the mountpoint associated with device deviceID. This method is an *OSP ²* built-in.
- \diamond public static int getDeviceID(String pathname) MountTable Returns the device Id that hosts pathname. Note that this method eventually calls your method do getDeviceID() described above. You have to use getDeviceID() here instead of do getDeviceID() because of the convention explained in Section [1.9.2](#page-37-0) that prohibits student modules from calling the do_methods.

 \Diamond

the parameter file and can vary from one simulation run to another.

- final static public Device get(int deviceID) Device

Returns the device object with the given Id. In conjunction with getTableSize(), this method can be used in a loop to examine each device in turn, as device IDs range from 0 to getTableSize()-1. Note that all devices are mounted by *OSP ²* at the beginning of the simulation and no devices are added or removed during a simulation run. Therefore the number of devices remains constant and the device table has no "holes".

Summary of the class MountTable

This class maintains the mount table data structure, which maintains the correspondence between devices and directories through which these devices are accessed by the programs. Other modules of the file system layer access the mount table mainly using the methods getMountPoint() and getDeviceID().

7.5 Class INode

An *OSP* 2 inode represents a concrete file. An inode records information about the device where the file lives, and it keeps track of the blocks occupied by the file, the hard link count, and the open count.

The most important information here is the set of blocks occupied by the file. The actual data structure to be used to capture this information is up to the student implementation, although the course instructor may have specific requirements for this data structure.

The following methods of class INode are to be implemented as part of the FileSys project:

```
\diamond public INode(int deviceID)
```
The constructor. It should call super(deviceID) and then initialize the instance variables of the inode (if necessary).

 \diamond public static boolean do_isFreeBlock(int block,_int deviceID) Tells whether block on device with Id deviceID is free. 3

³ Note that from an object-oriented design perspective, this method better fits in class Device. However, space management is not a function of the basic I/O

 \diamond public int do_allocateFreeBlock()

When applied to an inode object, allocates a free block to that inode and returns the block number of that block. Marks the block as used. Make sure that the INode block count is set correctly (see the method setBlockCount()). Returns NONE if the device has no free blocks.

```
\diamond public void do releaseBlocks()
```
Releases all disk blocks occupied by the inode. Make sure that the INode block count is set correctly (setBlockCount()).

It is clear from the above that you have to keep track of the free space on the device. For some representations, such as bitmaps, it is useful to know the size of each device in blocks. The size can be obtained using the method getNumberOfBlocks() of the class Device.

Since you have to keep track of the valid inodes, you might also need to implement the **file allocation table** (or a **master file table**) thats hold these inodes.

Relevant methods defined in other classes.

supervisor that Device implements. This is an example of the tension between the layered architecture of an OS and the object-oriented design.

Summary of the class INode

The INode class has methods (implemented as built-ins) and variables which provide access to the various components of that class, as listed below:

- openCount: The count of active open-file handles associated with the inode, obtained using getOpenCount() and changed via incrementOpenCount() and decrementOpenCount().
- hardLinkCount: The number of pathnames associated with the inode. This count is obtained via getLinkCount() and changed using the methods incrementLinkCount() and decrementLinkCount().
- blockCount: The number of blocks allocated to the file (the file size). This item is obtained using getBlockCount() and set using setBlockCount().
- device ID: The device Id of the inode. It can be obtained using the method getDeviceID().

7.6 Class DirectoryEntry

If you were wondering how pathnames are associated with inodes, the suspense is over: this is done through directory entries defined by the class Directory-Entry. A directory entry includes a pathname, an inode, and a type (FileEntry or DirEntry). The type indicates whether the particular directory entry represents a plain file or a directory.

The methods of this class to be implemented as part of the FileSys project are listed below.

- public DirectoryEntry(String pathname, int type, INode inode) The class constructor. Calls super(), as usual, and initializes instance variables, if necessary.
- \diamond public static INode do_getINodeOf(String pathname) Given a pathname, returns the corresponding inode. In order to make this possible, the class DirectoryEntry must maintain the collection of all directory entries.

In addition, you need to implement a number of supporting methods that other classes in your package might need to use to insert directory entries into the directories, delete the entries, etc.

Relevant builtins and methods defined in other classes. This class does not use any standard methods defined in other classes of *OSP ²*. Some standard classes provided by Java itself might be useful. For instance, Hashtable and the associated methods can be used to maintain the Directory-Entry data structure. This would closely correspond to how directories are implemented in real operating systems.

Summary of Class DirectoryEntry

This class does not provide any methods, but there are several variables:

pathname: This property is accessible through the method

final public String getPathname()

This is the pathname represented by this directory entry.

INode: This property is accessible through the method

final public INode getINode()

It is the inode that this directory entry associates with the pathname of the directory entry. A related method in this class is getINodeOf(), which takes a pathname parameter and returns the corresponding INode:

final public static INode getINodeOf(String pathname)

Unlike getINode(), this method is static.

type: This property is accessible through the method

final public int getType()

It specifies the type of the directory entry, i.e., whether the entry represents a regular plain file (FileEntry) or a directory (DirEntry).

7.7 Class OpenFile

Class OpenFile provides methods for creating open-file handles, accessing the components of an open-file handle, and using open-file handles to perform I/O operations.

```
\diamond public \mathtt{OpenFile}(\mathtt{INode~inode,~TaskCB~task})}
```
This is a constructor for open-file handles. It must call super() with the same set of parameters and then, possibly, initialize the various variables that you might have added to the class.

```
\diamond static public OpenFile do_open(String filename, TaskCB task)
```
This method create an open-file handle. It receives a file name (which must correspond to a previously created file) and a task object, creates an openfile handle for the file, and adds the handle to the task's table of open files. (Recall from Chapter \mathbb{S} that the open-files table is one of the resources owned by a task.)

First, the file must already exist before it can be opened. Existence should be checked using a method that you implement in class FileSys. Note that this method will be unknown to the *OSP ²* IFL layer, i.e. it will not have a wrapper method in the IFL, and therefore its implementation and name are completely up to you. Second, opening a mountpoint is a violation, so you must check that the argument is not a mountpoint. (The method isMountPoint() of class MountTable can be used to check this.)

Once you pass these checks, a new open-file handle can be created. The OpenFile() constructor takes an inode and a task as parameters, so you must obtain the inode corresponding to filename (using the method getINodeOf() discussed earlier). After constructing the handle, you should add it to the task with the method addFile() of class TaskCB. Finally, the count of open files for the inode should be incremented (incrementOpenCount()) and the newly created file handle returned.

```
-
public int do close()
```
A file is closed when its open-file handle is no longer needed. However, closing a file is trickier than it might seem.

First, the file might still have outstanding (unprocessed) IORBs. As discussed in Chapter 6 , such a file cannot be closed immediately. Instead, you should *mark* the file as needing to be closed later and leave it alone. Marking is performed by setting the closePending flag to true, where closePending is a field of the context OpenFile object. The disk interrupt handler will close the file (by issuing another close operation) after the last outstanding IORB has been processed.

If the file *cannot* be closed due to outstanding IORBs, as described above, do close() should just exit and return FAILURE. If the file *can* be closed immediately, then you should do so, adjusting the relevant structures. One thing that needs to be done here is to decrement the open file count of the inode associated with the file handle. The inode is obtained using the getINode() method and the count is changed using decrementOpenCount() of class INode.

Next, you should check whether you can destroy the inode associated with the file handle and release the disk blocks owned by that inode. As discussed earlier, an inode can be deleted when both its open file count (getOpenCount()) and its hard-link count (getLinkCount()) are zero. The inode's disk blocks are released with the method releaseBlocks() of class INode. The method to remove an inode from the disk master file table should reside in class INode and its name (and, of course, its implementation) are left for you to decide.

Finally, the closePending field is reset to false, the file handle is removed from the open-files table of the task associated with that handle, and SUCCESS is returned.

```
-
public int do read(int fileBlockNumber,
PageTableEntry memoryPage, ThreadCB thread)
```
The do read() method is executed on a file-handle object. It creates a read request to the device associated with the file handle, enqueues the request to the device, and waits until the I/O is complete $- I/O$ operations in $\mathcal{OSP}2$ are synchronous at the thread level. That is, the thread that issues an I/O operation is eventually blocked until the operation is finished.^{[4](#page-138-0)}

It is recommended that you make sure that the parameters passed to open() are consistent. For example, the fileBlockNumber parameter must be within the appropriate range (non-negative and not exceed the file size). If it is not, FAILURE should be returned. Likewise, it is wise to check whether memoryPage and thread are not null.

In the next step, a new system event is created using the constructor SystemEvent() and the current thread is suspended on that event. At this point it is recommended that you refresh your memory about thread suspension and resumption by (re-)reading Section $\overline{4.3}$. A thread that is suspended on a system event is not really blocked, but instead can be thought of as

⁴ However, I/O is asynchronous at the task level: a thread that does not wish to wait for I/O can spawn another thread that performs the I/O. Meanwhile, the first thread can go about its business while the second thread would wait. When the I/O is done, the two threads can merge.

having changed status from user thread to system thread. When the read operation is complete, the event will "happen" and the thread will be resumed. To be able to resume the thread after the I/O is complete, you should save the SystemEvent object in a variable.

You are now ready to construct an IORB for the request. The inode and device Id can be extracted from the open-file handle using the appropriate methods. The I/O type (one of the parameters in the IORB constructor) is, naturally, FileRead. The only thing that requires care is the disk block number parameter to the constructor.

Note that the fileBlockNumber parameter to doread() is the number of the *logical* block within a file. It must be mapped to the *physical* block of the disk. Information about the disk blocks allocated to the file is stored in the inode, which is implemented in your INode class. It is recommended that you implement a method in INode that, when applied to an inode with a logical file block number as a parameter, returns the corresponding physical block.

After collecting all the needed components, you use the IORB() constructor to create an IORB for the read request.

Next, you must enqueue the request to the appropriate device using the method enqueueIORB() of class Device. Note that enqueueIORB() locks the target memory buffer page, which can cause some swapping activity, and the thread must wait until swapping is finished. As usual in *OSP ²* , a waiting thread might get killed, so it is necessary to ascertain that the thread is still alive after enqueueIORB() returns. If the thread was killed, do_read() should return FAILURE.

If enqueueIORB() finished successfully, thread must be suspended on iorb. When this I/O completes, thread will be notified and control will get past the suspend() operation. At this point, again, you must check if the thread is still alive. If it is dead, FAILURE is returned; if it is alive, you execute notifyThreads() on the previously created SystemEvent object and return SUCCESS.^{[5](#page-139-0)}

```
\diamond public int do_write(int fileBlockNumber,
PageTableEntry memoryPage, ThreadCB thread)
```
Writing is similar to reading in many respects. One important difference (in *OSP ²*, anyway) is that a file block is considered out of range only if it is

 5 Note that the logic of your implementation should be such that each suspend() is matched by a notifyThreads() system call.

negative. If fileBlockNumber is higher than the number of blocks in the file, the file is extended with the necessary number of blocks. For example, if the current size of the file is 2 blocks and fileBlockNumber is 5, then 4 new blocks must be allocated to the file. (Note that blocks are counted from 0, so 5 refers to the 6th block of the file.) Additional disk blocks are allocated to an inode as a result of the allocateFreeBlock() system call (*and not by any other means*!).

Another important difference is that the device might not have enough free space to accommodate the file expansion. In this case, FAILURE should be returned. Note that free disk space management is done in class INode and is the student's responsibility.

Relevant methods defined in other classes.

The constructor for system events. The type parameter is used to provide a tag with which the event will be displayed in the log file. This tag can be useful for debugging when you need to trace the execution of your project. When a thread is suspended on a SystemEvent, it can be thought of as having changed status from user thread to system thread. See Section $\overline{4.3}$ for more details on suspension and resumption of threads.

- \diamond public IORB(ThreadCB thread, PageTableEntry page, int blockNumber, int deviceID, int ioType, OpenFile openFile) Creates an IORB with the given parameters.
- final public int enqueueIORB(IORB iorb) Device Enqueues iorb to its associated device. This operation is blocking and can cause a pagefault (and the ensuing swapping) because enqueueIORB() needs to lock the target memory page in order to shield it from page replacement. See Chapters $\overline{5}$ and $\overline{6}$ for a more thorough explanation of page locking. This method returns SUCCESS if iorb has been successfully enqueued. A failure is returned when enqueuing fails (for example, if the original thread has died).
- final public int allocateFreeBlock() INode Allocates a free block to the inode. The block becomes occupied.

Summary of the class OpenFile

The class OpenFile maintains the following important variables, which are affected using the various methods of that class.

IORB count: The number of outstanding IORBs for the handle. Obtained using getIORBCount() and changed using incrementIORBCount() and decrementIORBCount().

- INode: The inode of the open-file handle. Obtained using getINode() and set using setINode().
- Task: The task that owns the open-file handle. Obtained using the getTask() method.
- closePending: This field is set to true by do close() if the OpenFile object has outstanding IORBs and cannot be closed immediately. When the last IORB for this OpenFile object is processed, do close() will close the file.

7.8 Class FileSys

You are to implement the following methods of class FileSys as part of this project.

 \diamond public static void init()

As usual in *OSP ²*, this method is called at the beginning of every simulation run. It can be used to initialize static variables that your implementation might use (for example, the variables used in the implementation of the mount table, in the open-files table, in the list of free blocks on the various devices, etc.).

 \diamond final static public int do_create(String pathname, int size) This method creates a file with a given pathname and size (in bytes). In one sentence, this means making the necessary checks and then creating the corresponding inode and the directory entry that relates pathname with that inode. The devil is in the details, however, and this is what we will be discussing next.

First, you have to check if the file with the same name already exists. If so, FAILURE is returned. If a file is a mountpoint (is listed in the mount table), then it is presumed to exist right from the start and, since mountpoints cannot be created or destroyed, FAILURE should be returned in this case as well. If the file does not exist, check if pathname refers to a directory or a plain file. A pathname refers to a directory if it ends with the filename separator, DirSeparator, but is not a mountpoint. It refers to a plain file otherwise.

Note, however, that the convention that a directory name must end with DirSeparator is used in the create() call only (just in order to avoid introducing yet another system call). In all other contexts, pathnames such as /foo/bar and /foo/bar/ refer to the same directory. Also, if a plain file by the name /foo/bar already exists and do create() is called with /foo/bar/ as a parameter, the call should fail and FAILURE returned, because there *cannot* be a file and a directory with the same name. Likewise, if $do_create('/foo/bar/",...)$ was earlier called to create a directory, then a subsequent call do_create("/foo/bar",...) should fail, because otherwise we would have a file and a directory with the same name.

In view of the above, it is generally a good idea to **normalize** file names before doing any file-name comparisons. A **normalized pathname** is a full pathname such that it does not have repeated occurrences of DirSeparator (pathnames /foo///bar// and /foo/bar/ are considered the same, but only the latter is normalized). It may be convenient to also remove the trailing DirSeparator in normalized directory names (except for the root of the file system, /), but this depends on the particular algorithms that you are using.

Next, you must check if the caller intended to create a file or a directory by checking the last character of pathname. The appropriate file-type indicator (FileEntry or DirEntry) will later go into the directory entry for the file. Also, for plain files, the size parameter indicates the size of the file in bytes. However, for directories this parameter is ignored, since directories are assumed to occupy *exactly one* disk block. The correct size parameter should be used when constructing the corresponding inode.

It is common in programming to attempt to create a file in a non-existent directory with the intent that the system would create all the intermediate subdirectories automatically. For instance, suppose that the directory /foo exists, but /foo/bar does not. In *OSP 2*, the call do_create("/foo/bar/moo/ abc.html",...) should then create the intermediate directories, /foo/bar and /foo/bar/moo, before creating /foo/bar/moo/abc.html. Note that this means that while creating the intermediate directories, do create() will call create() (its *OSP ²* wrapper), which in turn will call do create() *recursively*.

Next you should check the mount table to determine the device where the file is to be created. Recall from Section $\sqrt{7.4}$ that determining the device is the job of method getDeviceID() of class MountTable. You need to make sure that the device has enough free space. Recall that space management is the job of the INode class. You might want to implement a method in that class which returns the number of free blocks. If this number is less than the number of blocks needed to accommodate our file, FAILURE should be returned. It is therefore important to correctly calculate the number of blocks needed to accommodate a file-creation request. Recall that do create() gets the size of the file in bytes, and this has to be converted into disk blocks. The block size equals the size of a virtual memory page, which can be obtained using the two methods provided by the class MMU: getVirtualAddressBits() and
getPageAddressBits()<mark>!</mark>

Note, however, that *OSP ²* assumes that directories occupy exactly one block and the file-size parameter in do create() should be ignored in this case.

After all these checks, nothing (but a computer crash) can stop us from creating the file. You can use the constructor for the class INode to create a new inode. Next, you should use methods incrementLinkCount() and allocateFreeBlock() of INode to update the count of hard links to the inode and to allocate the right number of disk blocks to it. The inode should also be inserted into the device's file allocation table for safekeeping.

To complete the process, you must create a directory entry for pathname and insert it into the appropriate directory. This is accomplished using the constructor of DirectoryEntry and other methods that depend on your implementation of directories.

When all is done, SUCCESS is returned.

 \diamond final static public int do_link(String pathname, String linkname)

This method creates a new hard link, with name linkname, to the inode associated with pathname. The process is similar to creating a file: you need to check if a directory entry for linkname already exists and return FAILURE if it does. Otherwise (if there is no file named linkname), you must create an appropriate directory entry. However, there also are significant differences between linking and creating files.

First, no new inode need be created. Instead, the inode associated with pathname is used. Therefore, no additional space need be allocated. Second, hard links to directories are not allowed (as in Unix). Third, unlike the case of file creation, no intermediate directories are created. So, if the directory /foo exists but /foo/bar does not, then creation of a hard link /foo/bar/abc.html to another file should fail.

Other than that, creation of a new directory entry to associate linkname with the inode of pathname proceeds as in the case of do create(). In particular, do not forget to increment the hard-link count.

Note one interesting thing: after a hard link to an inode is created, linkname and pathname become virtually indistinguishable. That is, linkname is as much of a "file name" for the corresponding inode as pathname is. The inode

 6 Note that a file-creation request might specify size 0, in which case the request must succeed even if the device has no room.

itself does not contain any file-name information and all the naming takes place in directory entries.

\diamond final static public int do_delete(String pathname)

Destroying a file is not as simple as it might seem. First, you must check if a file with the name pathname exists. Note that you cannot always tell from the name whether it refers to a plain file or a directory, so you must use normalized names to do the checks. Also, non-empty directories cannot be deleted and, of course, deletion of mountpoints is not allowed. In all these cases, FAILURE should be returned.

Once you get past these checks, you must remember that pathname is just one of the several possible hard links to the inode associated with a file. If after deleting the directory entry for pathname and decrementing the hard-link count the number of hard links for the inode (obtained via getLinkCount()) is non-zero, do not delete the inode. Recall that inodes also have an open count, in addition to a hard-link count, which counts the number of openfile handles for the inode. If this count is positive, the inode must *not* be deleted. In both cases, however, the directory entry for pathname must still be deleted. If the hard-link count as well as the open count are zero, both the inode and the directory entry must be deleted. In case the inode is deleted, all its blocks must be freed up (using releaseBlocks()). Finally, SUCCESS should be returned.

```
-
final static public Vector do dir(String dirname)
```
This method returns a vector of *normalized* file names that reside in directory dirname. If dirname does not exist or is not a directory, null is returned.

Relevant methods from other classes. The following methods might be required to implement class FileSys.

```
\diamond public static boolean isMountPoint(String dir) MountTable
Tells if a given pathname is a mountpoint.
```

```
\diamond static final public int getVirtualAddressBits() \texttt{MMU}Tells how many bits are used to represent a virtual address. This method
 and the next method can be used to determine how many bits are needed
 to represent an address within a page, from which the page/block size
can be computed.
```
- \diamond static final public int getPageAddressBits() \texttt{MMU} Tells the number of bits used to represent a page address.
- public final int getLinkCount() INode Returns the number of hard links to the inode.

Summary of Class FileSys

In *OSP 2*, the class FileSys does not typically maintain important data structures of its own. Instead, it serves as a container for methods that do not logically belong to any other class in the package. For instance, the method do delete() for deleting files based on a string that represents the file name cannot be naturally attached to any other *OSP ²* class. Such methods do not normally maintain complex data of its own. Instead, they operate on the data structures defined in other classes, such as DirectoryEntry or MountTable, using the methods provided in those classes.

7.9 Methods Exported by the FileSys **Package**

The following is a summary of the public methods defined in the classes of the FileSys package or in the corresponding superclasses, which can be used to implement this and other student packages. To the right of each method we list the class of objects to which the method applies.

8 PORTS: Interprocess Communication

8.1 Chapter Objective

The objective of the Ports project is to teach students about interprocess communication and requires that the student implement two public classes: Message, which describes what *OSP ²* messages look like, and Port-CB, which implements the main communication primitives, such as send() and receive().

8.2 Interprocess Communication in *OSP 2*

Interprocess communication in *OSP ²* is based on the abstraction of a **port** and is modeled after the Mach micro-kernel. In Mach, a process can open a port, and other processes can then send messages to it which can be received by the owning process; a message is basically a block of bytes. Mach manages the ports, and provides guaranteed, in-order delivery, with large messages being handled efficiently by sharing pages between address spaces. There is a sophisticated permission mechanism which restricts the operations that processes can perform on ports.

Thus, a port is like your home mailbox. A task can create a port to serve as a mailbox to which threads from other tasks can send messages.^{[1](#page-148-0)4} Only threads

Note that threads of the same task do not need to communicate this way, since

of the owner task can read from the ports of that task; other threads only write to that port. In \mathcal{OSP} *2*, reading from a port is done using the **receive**() operation and writing is performed via the send() operation.

The *OSP ²* model of communication is based on *reliable* message delivery, i.e., correctly formed messages never get lost. When threads communicate, they exchange discrete entities, called **messages**. A message has length and Id. When a thread sends a message to a port, the message is delivered to the destination port and is placed in that port's **message buffer**. Port buffers are assumed to have finite byte size specified in a global constant PortBufferLength. If the message is bigger than this amount, the send() operation fails and the message is not delivered. If the message is smaller than PortBufferLength, it is considered well-formed and deliverable. However, the destination port might not have enough room due to other messages that might have been delivered to that port but not yet consumed. In this case, the send() operation suspends the sender thread until room becomes available.

When a thread wants to receive a message, it invokes the receive() method on a port. If a message is available, it is removed from the port message buffer and the operation succeeds. If, however, the port is empty, then the receiver thread is suspended until a message arrives.

It is thus clear that a mechanism is needed for threads to suspend themselves and to be notified. In \mathcal{OSP} *2*, this is accomplished through the familiar Event class. More precisely, PortCB is a subclass of Event, and threads can suspend themselves on a port when necessary. Likewise, when appropriate conditions arise (e.g., a port buffer gets more room or a message arrives at an empty port), threads that are waiting on the port can be notified. (Note that several threads can be waiting on the same port at the same time.)

The classes comprising the Ports package are described below. The class diagram of Figure [8.1](#page-150-0) places these classes in the overall context of the *OSP ²* system.

8.3 The Message **Class**

The Message class has only one required method, the class constructor, which takes a length argument and creates a message with a unique Id.

```
\diamond public Message(int length)
```
The message constructor. Must call super(length) as its first statement. Your implementation might also add other fields and methods to this class.

they share virtual address space and thus can communicate much more efficiently through shared variables.

Figure 8.1 A diagram summarizing the package PORTS.

In addition, your implementation of class PortCB can use a number of methods defined in class Message provided by *OSP ²*:

```
-
public int getID()
 Returns the Id of the message.
```

```
-
public int getLength()
 Returns the length of the message in bytes.
```
Built-ins and relevant methods defined in other classes. The method constructor for class Message does not use any methods provided by other *OSP ²* classes.

Summary of Class Message

A message in *OSP ²* is a simplified abstraction of messages used in real communication protocols, such as TCP/IP: it includes only these two parameters:

- ID: The ID of a message. The value of an ID can be retrieved using the method getID().
- length: The length of a message. This parameter can be queried using the method getLength().

8.4 The PortCB **Class**

The methods of PortCB to be implemented as part of the student project include the class constructor, the initialization method, the methods for creating/destroying ports and for sending/receiving messages.

A port has an Id, the owner task, a status (PortLive or PortDestroyed), and a message buffer. *OSP ²* provides methods for manipulating the message buffer of a port (appendMessage(), removeMessage(), isEmpty()), but the student implementation must keep track of the free space left in the buffer in order to be able to correctly decide when a message can be sent to the port.

```
\diamond public PortCB()
```
This is a class constructor whose only required statement is super(), the usual call to the corresponding constructor in the superclass.

```
\diamond public static void init()
```
This is the usual initialization method, which is called at the very beginning of the simulation run. It is a place where your implementation can initialize static variables.

```
-
public static PortCB do create()
```
This method creates and returns a new port. After a new PortCB object is created, it needs to be assigned to the current task, i.e., the task that owns the currently running thread. Recall from Chapter 5 that PTBR, the page table base register, always points to the page table of the current task. Thus, the current task can be retrieved using the following idiom: MMU.getPTBR().getTask().

To assign the port to the task, use the method addPort() of TaskCB. However, keep in mind that there is a limit of how many ports a task can have, which is defined by the global constant MaxPortsPerTask. If the task already has that many ports, addPort() will return FAILURE and do_create() should then return the null object.

If all is well, the owner task of the port should be set (using setTask()), and the status set to PortLive using the method setStatus() of class PortCB, which is provided by \mathcal{OSP} *2*. In addition, you have to initialize the variables that you might have introduced to keep track of the state of the message buffer. Finally, the newly created PortCB object is returned.

```
-
public void do destroy()
```
Ports are destroyed by the owner task when they are no longer needed for the task's operation or when the task itself is killed. To destroy a port, the port's status should be set to PortDestroyed, and the port should be removed from the task's table of active ports. The latter is accomplished using the method removePort() of TaskCB. Next, the port's owner task should be set to null using the method setTask() of PortCB.

You must also notify the threads that might be waiting for an event associated with this port. As usual, this is accomplished using the method notifyThreads() applied to the appropriate event.

```
-
public int do send(Message msg)
```
Prior to sending a message, you must first check that the message is wellformed. In *OSP ²*, this means that the parameter msg is not null and that the message length is not greater than the length of the port message buffer. If the message is not well-formed, FAILURE should be returned.

In the next step, a new system event must be created using the constructor SystemEvent() and the current thread must be suspended on that event. You already saw how to find the current task from the page table base register. The current thread is obtained using the method getCurrentThread() of that task.

At this point it is recommended that you refresh your memory about thread suspension and resumption as described in Section $\overline{4.3}$. A thread that is suspended on a system event is not really blocked, but instead can be thought of as having changed status from user thread to system thread. When the send operation is complete, the event will "happen" and the thread will be resumed. To be able to resume the thread before leaving do send(), you should save the SystemEvent object in a variable.

Now you are ready to attempt to send the message. Recall that if the destination port (i.e., the port on which the send() method is executed) does not have enough room in the message buffer, the sender thread must be suspended on that port. (Recall that you have saved the information about that thread before suspending it on a SystemEvent.) A thread *T* suspended on a port can be woken up when the port gets more room in its buffer. This happens when one of the threads that owns the port executes a receive() operation on that port. However, the sending thread *T* might discover that the port still does not have enough room for the message because either too little space was freed up or because some other thread managed to send a message to the port before *T* had a chance. In this case, *T* has to be suspended again (on the same port).

Another possibility is that the newly awakened thread was killed while waiting to send the message. FAILURE should be returned in this case. The third possibility is that the thread might have been awakened because the owner task decided to destroy the port on which the thread was suspended (or, maybe, the task itself was killed). Again, FAILURE should be returned. In addition, you should notify the threads that were suspended on the SystemEvent associated with the current send operation. (Recall that the current thread was suspended on this event at the beginning of the do_send() method.)

If none of the above problems are detected, you know that send should succeed. Thus, you should update the message buffer of the port (using $appendMessage()$ and, if the buffer was previously empty, notify the threads that may be waiting on that port in the receive mode. \mathbb{E} Finally, you should execute notifyThreads() on the previously created SystemEvent object and return SUCCESS.

\diamond public Message do_receive()

First, you must check that the receive operation is permitted, i.e., that the receiving thread's task owns the port on which **do_receive()** has been invoked. If this is not the case, null should be returned. Second, when a thread *T* executes a receive() operation on a port P, you must create a SystemEvent object and suspend *T* on that event. As explained earlier, this corresponds to *T* changing its status from user thread to system thread. Note that the receiving thread *T* is the currently executing thread, which can be obtained using the PTBR.

² Note that other threads may have been waiting to receive a message from this port *only* if its message buffer was empty.

Next, recall that the receiving thread must be suspended if the message buffer of the port contains no messages. This thread can be woken up when some other thread sends a message to that port. However, keep in mind that although a port can have several threads suspended in receive mode, only one of them will be awakened and thereby succeed in getting a message. All other threads would have to be suspended again.

There is a possibility that a woken-up thread was killed or that the port was destroyed. In both cases, do receive must return the null object. If none of the above bad things happen, the **do** receive() method succeeds. In this case, the method should "consume" a message from the port message buffer using removeMessage() and notify threads waiting on the port. (This is needed because consuming a message will probably free up space in the message buffer of the port and, as a result, some previously suspended send operation might be able to proceed.) Finally, the message consumed by this receive operation should be returned.

In all cases (whether the receive operation ended successfully or not), prior to exiting you must execute notifyThreads() on the previously created SystemEvent object for this receive operation.

Built-ins and relevant methods from other classes. A typical implementation of the methods in class PortCB uses the following methods defined in other classes or methods of PortCB provided by *OSP ²*:

Summary of the PortCB **class**

The PortCB class maintains information about the open ports attached to the various processes. The following list describes the main attributes of a port and the methods that are used to query these attributes.

- Port ID: $\mathcal{OSP2}$ assigns an ID to each port at creation time. This ID can be retrieved using the method getPortID() of the PortCB class.
- Owner: This is the task that owns the port. This attribute is manipulated using the methods getTask() and setTask().
- Status: PortLive or PortDestroyed. This attribute is manipulated using the methods getStatus() and setStatus().
- Message buffer: This buffer is manipulated using the methods appendMessage(), removeMessage(), and isEmpty() of class PortCB, and are provided by *OSP ²*. However, your implementation must keep track of the free space left in the message buffer.

8.5 Methods Exported by Package PORTS

The Ports package exports the following methods that are used by other packages in the system:

- \diamond final static public void create() Creates a new port.
- \diamond final public void destroy() Destroys an existing port.
- \diamond final public void send (Message msg) Sends a message, msg, to the port on which this method is invoked.
- \diamond final public Message receive() Receives a message from the port on which this method is invoked.

9 RESOURCES: Resource Management

9.1 Chapter Objective

The objective of the Resources project is to expose students to the concept of shared resources in a concurrent system, and to provide an environment in which they can implement various deadlock-handling techniques. *OSP* 2 simulation supports two approaches to handling deadlock in an operating system: **deadlock avoidance** and **deadlock detection**, discussed further below. To this end, students will be asked to implement the three public classes of the Resources package: ResourceCB, the resource control block; RRB, the resource request block; and ResourceTable.

9.2 Overview of Resource Management

The Resources project focuses on techniques for managing shared resources in a concurrent system. Examples of such resources include files, printer, disks, and interprocess-communication messaging buffer space. When processes compete for access to shared resources, especially when such access is exclusive, deadlock becomes an issue. Simply put, deadlock arises when there exists a closed chain of processes such that each process holds at least one resource needed by the next process in the chain. This phenomenon is known as **circular wait**.

For circular wait to exist it must be the case that processes require:

Mutual Exclusion. Mutually exclusive access to resources;

- Hold and Wait. A process may hold allocated resources while awaiting assignment of others; and
- No Preemption. No resource can be forcibly removed from a process holding it.

Clearly deadlock is an undesirable situation since if it is not dealt with properly the processes involved in the deadlock will wait forever, without furthering their execution. There are three main techniques for dealing with deadlock in an operating system:

- Deadlock Prevention. Design the system in such a way that the possibility of deadlock is excluded. This can be accomplished by constraining resource requests to prevent one of the four conditions of deadlock. For example, the hold-and-wait condition can be prevented by requiring that a process request all of its resources at one time and blocking the process until all requests can be granted simultaneously.
- Deadlock Avoidance. With this technique, a decision is made dynamically whether the current resource request will, if granted, potentially lead to a deadlock; if so, the request is denied. Deadlock avoidance thus requires knowledge of future process resource requests. A primary approach to deadlock avoidance utilizes the **Banker's algorithm**. The idea here is to determine if the current allocation of resources to processes represents a *safe state*: one in which there is at least one sequence of process resource requests that does not result in a deadlock; i.e. all of the processes can be run to completion.
- Deadlock Detection. Resource request are granted to processes whenever possible. Periodically, the operating system executes an algorithm that checks if deadlock (circular wait) exists. If so, a *recovery strategy* is undertaken, namely one of the following.
	- Abort all processes.
	- Back up each deadlocked process to some previously defined checkpoint and restart all processes.
	- Successively abort deadlocked processes until deadlock no longer exists.
	- Successively preempt resources until deadlock no longer exists.

9.3 Overview of Resource Management in *OSP 2*

OSP ² provides simulation support for deadlock avoidance and deadlock detection. This means that it understands the semantics of each of these two types of deadlock handling and provides appropriate error-checking facilities. For instance, in deadlock avoidance, a deadlock created after granting a resource allocation request to a process is considered an error, while in deadlock detection it is not.

The class ResourceCB does the bulk of the work. It represents the **resource control block**, where much of the information about the available resources is maintained. Resources are divided into **resource types**, where each resource type can have several **resource instances**. Each resource type is represented by a distinct resource control block.

A thread might issue a request to **acquire** a given number of instances of a particular resource type, but it does not care which particular resource instances are given to it as long as the instances are of the requested type. When such a request arrives, the operating system (which is part of the student code in class ResourceCB) must decide whether to grant the request, abort (kill) the requesting thread, or block the thread until its request is granted at some future time. This decision depends on the current state of resource allocation and on the deadlock-handling method (detection or avoidance) in use.

The class RRB represents **resource request blocks**. An RRB contains information about one outstanding request for one particular resource type issued by a particular thread. An RRB object is also an Event object (Section $\overline{1.6}$). When a thread issues a request that cannot be granted, the thread is suspended on the RRB associated with this request. Subsequently, when the needed resources become available, a notifyThreads() operation issued on that RRB will eventually wake up the thread.

The **resource table** is represented by the class ResourceTable; it is represented as an array of ResourceCB objects and lists all resource types available in the system. In *OSP ²* , all resource types are created at the beginning of simulation and no new resources are added or deleted afterwards. The total number of instances of each resource type remains constant as well. However, the number of *available* resource instances changes as processes acquire and release them.

Resource types are identified by a resource ID, a number between 0 and the resource table size, which is determined using the static method getSize() of class ResourceTable.

We will now describe the classes of package RESOURCES in detail. Figure \Box

depicts the relationship these classes have with the other classes in the *OSP ²* system.

9.4 Class ResourceTable

This class is the simplest of them all: only a constructor is required. You can add other methods and variables to support your implementation of the project, but these would be specific to your particular design.

```
\diamond public ResourceTable()
```
Calls super() and might do additional initialization, if the student implementation defines additional fields in this class.

OSP ² provides the following built-ins that you will use to implement other classes in this project:

 \diamond public static final ResourceCB getResourceCB(int resourceID) Since resource types are identified using their numeric IDs, this method lets you visit, in a loop, the resource control block of every resource type in the system.

```
-
public static final void getSize(int size)
```
Returns the size of the resource table, which is also the number of resource types available in the system.

Built-ins and relevant methods defined in other classes. Since this class has only its constructor, your implementation will not use any methods provided by other *OSP ²* classes.

Summary of Class ResourceTable

This class is intended to maintain the resource table of the system. A resource table is simply a fixed-size array of resource objects. This size can be queried using the method getSize(). In addition, resource objects can be retrieved from the table using the getResourceCB() method, as described earlier.

Resources

Figure 9.1 A diagram summarizing the package RESOURCES.

9.5 Class RRB

This class represents the resource request block, which threads use to specify their requests to the system. It is declared as follows:

```
\diamond public class RRB extends IflRRB
```
Note that IflRRB extends class Event, which makes it possible to treat RRB objects as events. In particular, threads can be suspended on an RRB object and later resumed.

An RRB object includes the following information:

- \Diamond The *ID*, which can be obtained with the help of the method $getID()$.
- The *thread* that issued the request; it can be obtained using the method getThread().
- The *resource type* involved in the request. Its control block can be obtained using the method getResource(). Only one resource type can be requested using an RRB.
- \Diamond The *quantity* of the requested resource. It is obtained by calling the method getQuantity().
- The *status* of the RRB. The status can be one of these constants defined by *OSP ²* : Denied, Suspended, Granted. The status is Denied when the system denies the request (because, for instance, the thread wants more resource instances than the total that the system has); it is Suspended if the system decides that the resource request cannot or should not be granted now, but can be in the future; when the request is granted, the status is set to Granted. Two methods are used to manipulate the status of an RRB: getStatus() and setStatus().

The class RRB contains only two methods that need to be implemented by the student:

- \diamond public RRB(ThreadCB thread, ResourceCB resource, int quantity) This is the class constructor. The first statement in this constructor must be super(thread, resource, quantity), but the rest depends on your program design.
- \diamond public void do_grant()

This method is used to grant the RRB on which it is invoked. Note that do grant() does not make any *decision* on whether to grant or not. This decision is made elsewhere, as described later in this chapter. Thus, this method does bookkeeping only. In particular, it decrements the number of available instances of the requested resource by the requested quantity and increments the number of allocated instances of this resource by that same quantity. The current number of available instances of a resource is given by the method getAvailable() and is set by the method setAvailable(). Similarly, the number of allocated resources is obtained and changed using the methods getAllocated() and setAllocated(), respectively.

To finish granting the request, the status of the RRB must be set to Granted and the thread that was waiting on this RRB should be resumed. The latter is done by invoking the method notifyThreads() of class Event (recall that a RRB is also an Event object).

Built-ins and relevant methods defined in other classes. The implementation of the methods in the RRB class relies on the following methods provided by other classes (or inherited from the superclasses of RRB):

Summary of Class RRB

The class RRB is intended to maintain the information about requests that were issued by the various threads for the non-shareable resources that are provided by the system. As mentioned earlier, an RRB object has the following attributes: *ID*, *thread*, *resource type*, the *quantity* of the requested resource type, and the *status* of the request. These attributes can be queried and manipulated using the methods described earlier in the section.

9.6 Class ResourceCB

This class does most of the work. In particular, this is where the deadlock detection and avoidance algorithms are implemented. The deadlock-avoidance algorithm is invoked by the do acquire() method, while deadlock detection is the responsibility of the method deadlockDetection(), which is invoked periodically by *OSP ²*. The ResourceCB class is declared as follows:

\diamond public class ResourceCB extends IflResourceCB

Most textbooks describe deadlock avoidance and detection algorithms in terms of the various resource allocation and resource request matrices, which are used for keeping track of the current state of system resources. This all looks simple enough, except for one important point: textbook algorithms all assume that all the threads and resource types are known in advance, so they represent the matrices as two-dimensional arrays. In a real system, neither resources, nor threads are static: they come and go and their total number cannot be assumed to be bounded by a known constant. Therefore, matrices used by the *real-life* deadlock-handling algorithms cannot be represented as two-dimensional arrays.

In *OSP ²*, the number of resource types is fixed, which simplifies things a bit. However, the number of threads that can potentially request resources is not known and cannot be estimated. Thus, using two-dimensional arrays for representing resource allocation and request matrices is also out of the question: you must come up with another suitable data structure. Since most operations in deadlock-detection and -avoidance algorithms reference the matrix elements via a specific resource and/or thread, your data structure must provide efficient access to the matrix elements using either of these keys. For instance, if you have to scan arrays and compare their entries to a particular thread ID or resource, it is a sure sign that you have chosen a bad data structure.

One good data structure in this case would be an array of hash tables, where each hash table represents all requests made by the various threads for a particular resource type. Since Java hash tables are dynamic, they provide exactly what the doctor ordered for this particular problem.

\diamond public ResourceCB(int qty)

This is the required class constructor. It must have $super(qty)$ as its first

statement, but the rest depends on your program design.

```
\diamond public static void init()
```
As in other student modules, this method is called by the simulator at the beginning of simulation. It can be used to initialize the static variables and structures that you might use in your implementation.

\diamond public RRB do acquire(int quantity)

This method is typically invoked by an *OSP ²* thread on a given resource type (represented by a ResourceCB object) in order to obtain quantity instances of that resource type. To determine which *OSP ²* thread has issued the request, the following method can be used. First, the current task can be found from the *page table base register*, or PTBR; see Section [5.2](#page-83-1) for more information on this subject. The value of the PTBR is the page table of the currently running task. In *OSP ²*, the value of the PTBR is obtained using the static method getPTBR() of class MMU, and the current task can be obtained from a page table via the method getTask().

Next, you have to create an RRB that describes the request. What follows depends on whether the simulator is in deadlock-avoidance or deadlockdetection mode (which is determined by an input simulation parameter that you might have spotted in the GUI window). To find out which mode is in effect, use the method getDeadlockMethod().

If the deadlock-handling method is Detection, there are three possibilities. If the system has enough available instances of the requested resource, the request is granted immediately by executing the method grant() on the RRB. If the requested number of instances cannot be granted under *any* circumstances (e.g., because the total number of instances of the requested resource type that are either held or requested by the given thread exceeds what the system has), then null is returned. If the requested number of instances cannot be granted immediately (but might be in the future, if all other threads release their resources) then the requesting thread must be suspended on the RRB and the RRB's status should be set to Suspended. The RRB status is set using the method setStatus(), while threads are suspended using the suspend() method of class ThreadCB. Recall that an RRB is an Event object as well, so in order to suspend a thread on an RRB, the RRB must be passed as a parameter to suspend(). Read more about thread suspension and resumption in Section [4.3.](#page-70-0)

If the deadlock-handling method is Avoidance, then you must use a deadlockavoidance algorithm, such as the Banker's algorithm. If this algorithm says that it is safe to grant the request, the RRB is granted. Otherwise, the thread is suspended and the RRB status is set to Suspended as well.

When a thread is suspended inside **do** acquire(), its execution is paused until the request is granted (possibly as a result of a release() operation on the same resource or of giveupResources() operation, which is invoked when a thread is killed), and the thread is resumed. Whether the RRB is granted immediately or the thread is suspended, do acquire() returns the RRB that was created earlier in order to represent the request.

- public void do release(int quantity)

This method might be invoked by an *OSP ²* thread on a given resource type (represented by a ResourceCB object) in order to release quantity instances of that resource type.

As with do acquire(), you first must find the thread that issued the release() request. Then the state of the resource allocation should be updated appropriately in order to reflect the new number of free resources and the new allocation of the given resource to the thread. Note that the thread might release some, but not all, instances held for this resource type. The exact details depend on your representation of the resource-allocation state, but this would typically involve the methods setAllocated(), setAvailable(), getAvailable(), etc.

This is not all, however. Since new resources became available after the release operation, it is possible that some of the previously suspended requests can now be granted. In order to be able to determine whether this is the case, one needs to keep track of the RRBs that were previously suspended in do acquire(). Once a grantable RRB is found, it should be granted (using the grant() method) and the thread waiting on that RRB is resumed (resumption is done by method grant()).

\diamond public static Vector do_deadlockDetection()

If the simulation method is Detection, this method will be periodically called by *OSP ²* in order to test your implementation of the deadlockdetection algorithm. This method should first check if a deadlock exists and, if so, remove it. Your instructor might have imposed specific requirements on your implementation of deadlock detection and recovery, and *OSP ²* adds its own.

First, there should be no deadlocks left after do deadlockDetection() returns. The result returned by this method should be a vector of ThreadCB objects that were found to be involved in a deadlock. *OSP ²* will compare this list with its own and will issue an error if the two lists differ. If no deadlock exists, null should be returned.

You can use any textbook deadlock-detection algorithm that can detect deadlocks in the presence of multiple instances per resource type. (For instance, cycle detection in a wait-for graph would *not* be a suitable algorithm for this purpose.)

Deadlock recovery is done by killing some or all of the threads involved in the deadlock. However, *OSP ²* insists that threads must not be killed unnecessarily. This means that no thread should be killed unless it is deadlocked and, in addition, if the deadlock is gone after killing of *some* deadlocked threads, then no further thread destruction should occur.^{[1](#page-167-0)}

Threads are killed using the kill() method of class ThreadCB. Note that when a thread is killed, it releases its resources by calling do_giveupResources() (described next). As in the case of the ϕ -release() method, this creates an opportunity for granting a previously suspended RRB and resuming the associated thread. See the description of do **release**() to learn how to do this.

 \diamond public static void do_giveupResources(ThreadCB thread)

This method is called in order to release all resources previously allocated to thread, and it happens when thread is terminated. You will never need to call this method in this project. Instead, your implementation of this method is made available to *other OSP ²* modules, which will call do giveupResources() when necessary. This method should go over the resources allocated to the given thread and update the number of the available instances of such resources accordingly. The number of resources allocated to the thread should also be adjusted (to 0).

Since the thread releases its resources, the system might have enough free resources to unblock some suspended RRBs. Therefore, as in the case of do release(), it is necessary to check the suspended RRBs and grant those that are grantable.

Built-ins and relevant methods defined in other classes. The following methods and fields, which are defined in other classes or are provided by the superclasses of ResourceCB, might be used in the implementation of the class ResourceCB.

- public final int getTotal() ResourceCB

Returns the total number of instances (free plus allocated) for this resource type.

¹ Note that if *^N* threads are involved in the deadlock, then killing any *^N [−]*1 of them will eliminate the deadlock. But often the deadlock can be eliminated by killing fewer than $N-1$ threads.

Resumes all threads that might be waiting on this event. In the case of package Resources, the event would be an RRB and the single resumed thread would be the thread that issued the corresponding request.

Summary of Class ResourceCB

Instances of this class are used to represent individual non-shareable resources in the system. An individual resource has the following attributes:

- ID: The identity of the resource. This parameter can be retrieved using the built-in getID().
- Total number of instances: This attribute describes the total number of instances of the resource that exist in the system. It can be obtained using the built-in method getTotal().
- Number of allocated instances: The number of instances of the resource that are currently allocated to a given thread. This parameter can be retrieved using the method getAllocated() and changed using the method setAllocated().

- Number of free instances: This parameter represents the number of free instances of the resource. It can be obtained by calling the built-in method getAvailable() and changed using the method setAvailable().
- Maximum number of claimable instances: This parameter represents the maximal number of instances of a resource that can possibly be acquired by a single thread.

9.7 Methods Exported by the Resources **Package**

Only one method defined in this package is used by other modules:

 \diamond public static void giveupResources(ThreadCB thread) $\;$ ResourceCB $\;$ Called by terminating threads in order to release the abstract shared resources held by that thread.
